Davidson's Principles and Practice of Medicine

23rd Edition

ELSEVIER

Davidson's
Principles and Practice of
Medicine

Sir Stanley Davidson (1894–1981)

This famous textbook was the brainchild of one of the great Professors of Medicine of the 20th century. Stanley Davidson was born in Sri Lanka and began his medical undergraduate training at Trinity College, Cambridge; this was interrupted by World War I and later resumed in Edinburgh. He was seriously wounded in battle, and the carnage and shocking waste of young life that he encountered at that time had a profound effect on his subsequent attitudes and values.

In 1930 Stanley Davidson was appointed Professor of Medicine at the University of Aberdeen, one of the first full-time Chairs of Medicine anywhere and the first in Scotland. In 1938 he took up the Chair of Medicine at Edinburgh and was to remain in this post until retirement in 1959. He was a renowned educator and a particularly gifted teacher at the bedside, where he taught that everything had to be questioned and explained. He himself gave most of the systematic lectures in Medicine, which were made available as typewritten notes that emphasised the essentials and far surpassed any textbook available at the time.

Principles and Practice of Medicine was conceived in the late 1940s with its origins in those lecture notes. The first edition, published in 1952, was a masterpiece of clarity and uniformity of style. It was of modest size and price, but sufficiently comprehensive and up to date to provide students with the main elements of sound medical practice. Although the format and presentation have seen many changes in 22 subsequent editions, Sir Stanley's original vision and objectives remain. More than half a century after its first publication, his book continues to inform and educate students, doctors and health professionals all over the world.

Preface

Well over two million copies of *Davidson's Principles and Practice of Medicine* have been sold since it was first published in 1952. Now in its 23rd Edition, *Davidson's* is regarded as a 'must-have' textbook for thousands of medical students, doctors and health professionals across the world, describing the pathophysiology and clinical features of the most important conditions encountered in the major specialties of adult medicine and explaining how to investigate, diagnose and manage them. The book is the winner of numerous prizes and awards and has been translated into many languages. Taking its origins from Sir Stanley Davidson's much-admired lecture notes, the book has endured because it continues to keep pace with how modern medicine is taught and to provide a wealth of information in an easy-to-read, concise and beautifully illustrated format.

Davidson's strives to ensure that readers can not only recognise the clinical features of a disease but also understand the underlying causes. To achieve this, each chapter begins with a summary of the relevant pre-clinical science, linking pathophysiology with clinical presentation and treatment so that students can use the book from the outset of their medical studies right through to their final examinations and beyond.

The regular introduction of new authors and editors is important for maintaining freshness. On this occasion, Professor Mark Strachan and Dr Richard Hobson have come on board as editors, and 26 new authors have joined our existing contributors to make up an outstanding team of authorities in their respective fields. As well as recruiting authors from around the globe, particularly for topics such as infectious diseases, HIV and envenomation, we welcome members from 17 countries on to our International Advisory Board. These leading experts provide detailed comments that are crucial to our revision of each new edition. A particularly important aspect in planning the revision is for the editors to meet students and faculty in medical schools in those countries where the book is most widely read, so that we can respond to the feedback of our global readership and their tutors. We use this feedback, along with the information we gather via detailed student reviews and surveys, to craft each edition. The authors, editors and publishing team aim to ensure that readers all over the world are best served by a book that integrates medical science with clinical medicine to convey key knowledge and practical advice in an accessible and readable format. The amount of detail is tailored to the needs of medical students working towards their final examinations, as well as candidates preparing for Membership of the Royal Colleges of Physicians (MRCP) or its equivalent.

With this new edition we have introduced several changes in both structure and content. The opening six chapters provide an account of the principles of genetics, immunology, infectious diseases and population health, along with a discussion of the core principles behind clinical decision-making and good prescribing. Subsequent chapters discuss medical emergencies in poisoning, envenomation and environmental medicine, while a new chapter explores common presentations in acute medicine, as well as the recognition and management of the critically ill. The disease-specific chapters that follow cover the major medical specialties, each one thoroughly revised and updated to ensure that readers have access to the 'cutting edge' of medical knowledge and practice. Two new chapters on maternal and adolescent/transition medicine now complement the one on ageing and disease, addressing particular problems encountered at key stages of patients' lives. Medical ophthalmology is also now included as a direct response to readers' requests.

The innovations introduced in recent editions have been maintained and, in many cases, developed. The highly popular 'Clinical Examination' overviews have been extended to the biochemistry, nutrition and dermatology chapters. The 'Presenting Problems' sections continue to provide an invaluable overview of the most common presentations in each disease area. The 'Emergency' and 'Practice Point' boxes have been retained along with the 'In Old Age', 'In Pregnancy' and 'In Adolescence' boxes, which emphasise key practical points in the presentation and management of the elderly, women with medical disorders who are pregnant or planning pregnancy, and teenagers transitioning between paediatric and adult services.

Education is achieved by assimilating information from many sources and readers of this book can enhance their learning experience by using several complementary resources. We are delighted to have a new self-testing companion book entitled *Davidson's Assessment in Medicine*, containing over 1250 multiple choice questions specifically tailored to the contents of *Davidson's*. The long-standing association of *Davidson's* with its sister books, *Macleod's Clinical Examination* (now in its 14th Edition) and *Principles and Practice of Surgery* (7th Edition), still holds good. Our 'family' has also expanded with the publication of *Davidson's Essentials of Medicine*, a long-requested pocket-sized version of the main text; *Davidson's 100 Clinical Cases*, which contains scenarios directly based on our 'Presenting Problems'; and *Macleod's Clinical Diagnosis*, which describes a systematic approach to the differential diagnosis of symptoms and signs. We congratulate the editors and authors of these books for continuing the tradition of easily digested and expertly illustrated texts.

We all take immense pride in continuing the great tradition first established by Sir Stanley Davidson and in producing an outstanding book for the next generation of doctors.

International Advisory Board

Acknowledgements

Following the publication of the 22nd edition of *Davidson's*, Professor Brian Walker and Dr Nicki Colledge retired as editors. We would like to express our gratitude for the immense contribution they both made to the continuing success of this textbook.

The current editors would like to acknowledge and offer grateful thanks for the input of all previous editions' contributors, without whom this new edition would not have been possible. In particular we are indebted to those former authors who step down with the arrival of this new edition. They include Assistant Professor Albiruni Ryan Abdul-Razak, Professor Andrew Bradbury, Dr Jenny Craig, Professor Allan Cumming, Dr Robert Dawe, Emeritus Professor Michael Field, Dr Jane Goddard, Professor Philip Hanlon, Dr Charlie Lees, Dr Helen Macdonald, Professor Iain McInnes, Dr Graham Nimmo, Dr Simon Noble, Dr David Oxenham, Professor Jonathan Seckl, Professor Michael Sharpe, Professor Neil Turner, Dr Simon Walker and Professor Timothy Walsh.

We are grateful to members of the International Advisory Board, all of whom provided detailed suggestions that have improved the book. Several members have now retired from the Board and we are grateful for their support during the preparation of previous editions. They include Professor OC Abraham, Professor Tofayel Ahmed, Professor Samar Banerjee, Professor Tapas Das, Professor Tsuguya Fukui, Professor Saman Gunatilake, Professor Wasim Jafri, Professor Saraladevi Naicker, Professor Nardeep Naithani, Professor Prem Pais, Professor A Ramachandran, the late Professor (Mrs) Harsha R Salkar and Professor Subhash Varma.

Detailed chapter reviews were commissioned to help plan this new edition and we are grateful to all those who assisted, including Professor Rustam Al-Shahi, Dr David Enoch, Dr Colin Forfar, Dr Richard Herriot and Dr Robert Lindsay.

The Editors and Publisher would like to thank all those who have provided valuable feedback on this textbook and whose comments have helped shape this new edition. We would particularly like to extend our thanks to the many readers who contact us with suggestions for improvements. This input has been invaluable and is much appreciated; we regret the names are too numerous to mention individually.

As part of the Publisher's review, 360 readers from over 200 universities and colleges around the world supplied many innovative ideas on how to enhance the book. We are deeply indebted to the following for their enthusiastic support and we trust we have listed all those who contributed; we apologise if any names have been accidentally omitted. Rabab Hasan Abbasi, Ayesha Abdul Aziz, Ahmed Al Abdullah, Osama Abuzagaia, Humaira Achakzai, Sajan Acharya, Anurag Adhikari, Esha Agarwal, Avin Aggarwal, Dorothy Agrapidis, Sakir Ahmed, Iman Akhtar, Muhammad Faizan Ali, Syeda A Rfa Ali, M Amogh, Ramprasath Anbazhagan, Anju George C, Vamseedhar Annam, Muhammad Ehtisham Ansar, David C Antoney, Hina Arif, Sriharsha Athota, Muhammed Ali Azher, Bilal Al Azzawi, Janak Bahirwani, Devyani Bahl, Mohammed Naseem Baig, Deepak Kumar Bandari, Sagnik Banerjee, Tapastanu Banerjee, Kieran Bannerman, Emily Bart, Suranjana Basak, Saravana Bavan, Mark Beeston, Andrew Beverstock, Jeetendra Bhandari, Navin Bhatt, Soumyadeep Bhaumik, Rajrsh Bhawani, Kriti Bhayana, Praveen Bhugra, Amit Bisht, Rahul Bisht, Rudradeep Biswas, Tamoghna Biswas, Moira Bradfield, S Charles Bronson, Rosie Jane Campbell, Anup Chalise, Subhankar Chatterjee, Chiranjivi Chaudhari, Lok Bandhu Chaudhary, Muhammad Hamid Chaudhary, Umar Iftikhar Chaudhry, Himshree Gaurang Chhaya, Smitha Chirayil, Alexandra Choa, Rahul Choudhary, Guy Conlon, Gabriel Metcalf-Cuenca, Jack Cuningham, Gopal Dabade, Saraswata Das, Rahul Dev, Muinul Islam Dewan, Sree Divya, Muhammad Dizayee, Lucy Drummond, Simon Dryden, Fiona Drysdale, Kaitlin Duell, Gemma Dwyer, Md Khader Faheem N, Mahedi Hasan Faisal, Ali Mokhtari Farivar, Mohammed Omar Farooq, Ten Fu Fatt, Muhammad Zubair Fazal, Rebecca Ferris, Rebecca Fisher, Kartik Nimish Gandhi, Vibhav Gandhi, James Gao, Ella Gardner, Ankit Kumar Garg, Vibhuti Garg, Vishal Garg, Rakesh Garlapati, Partha Sarathi Ghosh, Prattay Ghosh, Muhammad Umer Gill, Madelaine Gimzewska, Nikolaos D Giotis, Evan Goh, Iain Gow, Bharatiram Guduri, Aantriksha Gupta, Shiwam Kumar Gupta, Michael Hagarty, Md Rashid Haider, Iqra Haq, Abdalla A Hassan, Fatima Hemani, Bianca Honnekeri, Prerana Huddar, Sandip Hulke, Mohammed Laique Hussain, Syahir Ibrahim, Victor Ilubaera, Sushrut Ingawale, Aroobah Iqbal, Tooba Irshad, Nagib Ul-Islam, Sehra Jabeen, Jeevan Jacob, Samreen Jaffar, Ankita Jain, Anukriti Jain, Ghazfa Jamil, Karan Jatwani, Surani Dilhani Jayawickrema, Per-Kristian Jensen, Love Kapil, Ishwor Karki, Ewan D Kennedy, Amit Keshri, Haider Ali Khalid, Ali Khaliq, Hina Khan, Md Taha Ali Khan, Raazia Khan, Priya Khetarpal, Robert Kimmitt, Navneet Kishore, Narendranath Reddy Konda, Kirsten Kramers, Ajay Kumar, Gaurav Kumar, Karun Kumar, Mudit Kumar, Sathish Kumar A, Sonu Kumar, Ramasamy Shakthi Kumaran, Joachim Langhans, Keith Leung, Ang Li, Lai Nai Lim (Jeremiah), Marlene Da Vitoria Lobo, Bo Løfgren, Sham Kumar Lulla, Apurva Lunia, Arslan Luqman, Faizan Luqman, Mithilesh Chandra Malviya, Sudhir Mane, Sachin Mangal, G. The authors of Chapter 20 would like to thank Dr Drew Henderson, who reviewed the 'Diabetic nephropathy' section.

Two short sections in Chapter 3 on array comparative genomic hybridisation and single-molecule sequencing are adapted from Dr K Tatton-Brown's Massive Open Online Course for FutureLearn. We would like to thank the Open University and St George's, University of London, for permission to use this material.

We are especially grateful to all those working for Elsevier, in particular Laurence Hunter, Wendy Lee and Robert Britton, for their endless support and expertise in the shaping, collation and illustration of this edition.

SHR, IDP, MWJS, RPH
Edinburgh 2018

Introduction

The opening six chapters of the book, making up Part 1 on 'Fundamentals of Medicine', provide an account of the principles of genetics, immunology, infectious diseases and population health, along with a discussion of the core principles behind clinical decision-making and good prescribing. Subsequent chapters in Part 2, 'Emergency and Critical Care Medicine', discuss medical emergencies in poisoning, envenomation and environmental medicine, while a new chapter explores common presentations in acute medicine, as well as the recognition and management of the critically ill. The third part, 'Clinical Medicine', is devoted to the major medical specialties. Each chapter has been written by experts in the field to provide the level of detail expected of trainees in their discipline. To maintain the book's virtue of being concise, care has been taken to avoid unnecessary duplication between chapters.

The system-based chapters in Part 3 follow a standard format, beginning with an overview of the relevant aspects of clinical examination, followed by an account of functional anatomy, physiology and investigations, then the common presentations of disease, and details of the individual diseases and treatments relevant to that system. In chapters that describe the immunological, cellular and molecular basis of disease, this problem-based approach brings the close links between modern medical science and clinical practice into sharp focus.

The methods used to present information are described below.

Clinical examination overviews

The value of good clinical skills is highlighted by a two-page overview of the important elements of the clinical examination at the beginning of most chapters. The left-hand page includes a mannikin to illustrate key steps in examination of the relevant system, beginning with simple observations and progressing in a logical sequence around the body. The right-hand page expands on selected themes and includes tips on examination technique and interpretation of physical signs. These overviews are intended to act as an aide-mémoire and not as a replacement for a detailed text on clinical examination, as provided in our sister title, *Macleod's Clinical Examination.*

Presenting problems

Medical students and junior doctors must not only assimilate a great many facts about various disorders but also develop an analytical approach to formulating a differential diagnosis and a plan of investigation for patients who present with particular symptoms or signs. In *Davidson*'s this is addressed by incorporating a 'Presenting Problems' section into all relevant chapters. Nearly 250 presentations are included, which represent the most common reasons for referral to each medical specialty.

Boxes

Boxes are a popular way of presenting information and are particularly useful for revision. They are classified by the type of information they contain, using specific symbols.

General Information

These include causes, clinical features, investigations, treatments and other useful information.

Practice Point

There are many practical skills that students and doctors must master. These vary from inserting a nasogastric tube to reading an ECG or X-ray, or interpreting investigations such as arterial blood gases or thyroid function tests. 'Practice Point' boxes provide straightforward guidance on how these and many other skills can be acquired and applied.

Emergency

These boxes describe the management of many of the most common emergencies in medicine.

In Old Age

In many countries, older people comprise 20% of the population and are the chief users of health care. While they contract the same diseases as those who are younger, there are often important differences in the way they present and how they are best managed. Chapter 32, 'Ageing and disease', concentrates on the principles of managing the frailest group who suffer from multiple comorbidity and disability, and who tend to present with non-specific problems such as falls or delirium. Many older people, though, also suffer from specific single-organ pathology. 'In Old Age' boxes are thus included in each chapter and describe common presentations, implications of physiological changes of ageing, effects of age on investigations, problems of

treatment in old age, and the benefits and risks of intervention in older people.

In Pregnancy

Many conditions are different in the context of pregnancy, while some arise only during or shortly after pregnancy. Particular care must be taken with investigations (for example, to avoid radiation exposure to the fetus) and treatment (to avoid the use of drugs that harm the fetus). These issues are highlighted by 'In Pregnancy' boxes distributed throughout the book, which complement the new chapter on maternal medicine.

In Adolescence

Although paediatric medicine is not covered in *Davidson's*, many chronic disorders begin in childhood and adult physicians often contribute to multidisciplinary teams that manage young patients 'in transition' between paediatric and adult health-care services. This group of patients often presents a particular challenge, due to the physiological and psychological changes that occur in adolescence and which can have a major impact on the disease and its management. Adolescents can be encouraged to take over responsibility from their parents/carers in managing their disease, but are naturally rebellious and often struggle to adhere to the impositions of chronic treatment. To highlight these issues, we have introduced a new chapter on adolescent and transition medicine to accompany the 'In Adolescence' boxes that appear in relevant chapters.

Terminology

The recommended International Non-proprietary Names (INNs) are used for all drugs, with the exception of adrenaline and noradrenaline. British spellings have been retained for drug classes and groups (e.g. amphetamines not amfetamines).

Units of measurement

The International System of Units (SI units) is the recommended means of presentation for laboratory data and has been used throughout *Davidson's*. We recognise, though, that many laboratories around the world continue to provide data in non-SI units, so these have been included in the text for the commonly measured analytes. Both SI and non-SI units are also given in Chapter 35, which describes the reference ranges used in Edinburgh's laboratories. It is important to appreciate that these reference ranges may vary from those used in other laboratories.

Finding what you are looking for

A contents list is given on the opening page of each chapter. In addition, the book contains numerous cross-references to help readers find their way around, along with an extensive index. A list of up-to-date reviews and useful websites with links to management guidelines appears at the end of each chapter.

Giving us your feedback

The Editors and Publisher hope that you will find this edition of *Davidson's* informative and easy to use. We would be delighted to hear from you if you have any comments or suggestions to make for future editions of the book. Please contact us by e-mail at: davidson.feedback@elsevier.com. All comments received will be much appreciated and will be considered by the editorial team.

Clinical decision-making

Introduction

A great deal of knowledge and skill is required to practise as a doctor. Physicians in the 21st century need to have a comprehensive knowledge of basic and clinical sciences, have good communication skills, be able to perform procedures, work effectively in a team and demonstrate professional and ethical behaviour. But how doctors think, reason and make decisions is arguably their most critical skill. Knowledge is necessary, but not sufficient on its own for good performance and safe care. This chapter describes the principles of clinical decision-making, or clinical reasoning.

The problem of diagnostic error

It is estimated that diagnosis is wrong 10–15% of the time in specialties such as emergency medicine, internal medicine and general practice. Diagnostic error is associated with greater morbidity than other types of medical error, and the majority is considered to be preventable. For every diagnostic error there are a number of root causes. Studies of misdiagnosis assign three main categories, shown in Box 1.1; however, errors in clinical reasoning play a significant role in the majority of diagnostic adverse events.

1.1 Root causes of diagnostic error in studies

Error category	Examples
No fault	Unusual presentation of a disease Missing information
System error	Inadequate diagnostic support Results not available Error-prone processes Poor supervision of inexperienced staff Poor team communication
Human cognitive error	Inadequate data-gathering Errors in reasoning

Adapted from Graber M, Gordon R, Franklin N. Reducing diagnostic errors in medicine: what's the goal? Acad Med 2002; 77:981–992.

1.2 Reasons for errors in clinical reasoning

Source of error	Examples
Knowledge gaps	Telling a patient she cannot have biliary colic because she has had her gallbladder removed – gallstones can form in the bile ducts in patients who have had a cholecystectomy
Misinterpretation of diagnostic tests	Deciding a patient has not had a stroke because his brain scan is normal – computed tomography and even magnetic resonance imaging, especially when performed early, may not identify an infarct
Cognitive biases	Accepting a diagnosis handed over to you without question (the 'framing effect') instead of asking yourself 'What is the evidence that supports this diagnosis?'

Diagnostic error has been defined as 'a situation in which the clinician has all the information necessary to make the diagnosis but then makes the wrong diagnosis'. Why does this happen? Studies reveal three main reasons:

- knowledge gaps
- misinterpretation of diagnostic tests
- cognitive biases.

Examples of errors in these three categories are shown in Box 1.2.

Clearly, clinical knowledge is required for sound clinical reasoning, and an incomplete knowledge base or inadequate experience can lead to diagnostic error. However, this chapter focuses on other elements of clinical reasoning: namely, the interpretation of diagnostic tests, cognitive biases and human factors.

Clinical reasoning: definitions

'Clinical reasoning' describes the thinking and decision-making processes associated with clinical practice. It is a clinician's ability to make decisions (often with others) based on all the available clinical information, starting with the history and physical examination. Our understanding of clinical reasoning derives from the fields of education, cognitive psychology and studies of expertise.

Figure 1.1 shows the different elements involved in clinical reasoning. Good clinical skills are fundamental, followed by understanding how to use and interpret diagnostic tests. Other essential elements include an understanding of cognitive biases and human factors, and the ability to think about one's own thinking (which is explained in more detail later). Other key elements of clinical reasoning include patient-centred evidence-based medicine (EBM) and shared decision-making with patients and/or carers.

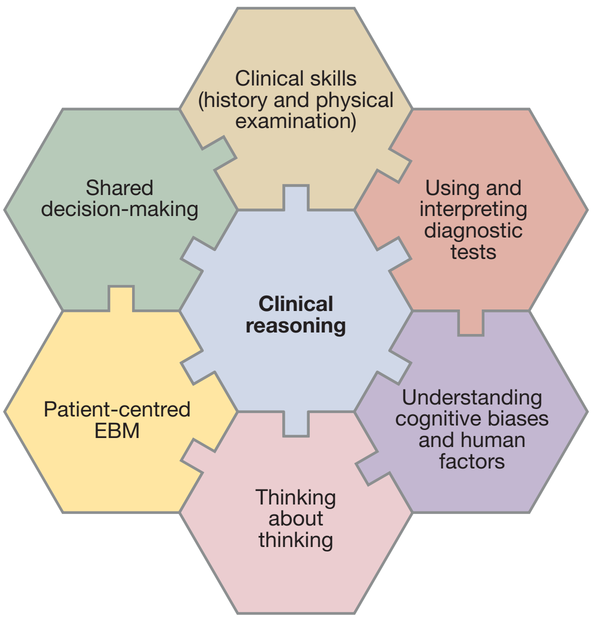

Fig. 1.1 Elements of clinical reasoning. (EBM = evidence-based medicine)

Clinical skills and decision-making

Even with major advances in medical technology, the history remains the most important part of the clinical decision-making process. Studies show that physicians make a diagnosis in 70–90% of cases from the history alone. It is important to remember that a good history is gathered not only from the patient but also, if necessary (and with consent if required), from all available sources: for example, paramedic and emergency department notes, eye-witnesses, relatives and/or carers.

Clinicians need to be aware of the diagnostic usefulness of clinical features in the history and examination. For example, students are taught that meningitis presents with the following features:

- headache
- fever
- meningism (photophobia, nuchal rigidity).

However, the frequency with which patients present with certain features and the diagnostic weight of each feature are important in clinical reasoning. For example, many patients with meningitis do not have classical signs of meningeal irritation (Kernig's sign, Brudzinski's sign and nuchal rigidity). In one prospective study, they had likelihood ratios of around 1, meaning they carried little diagnostic weight (Fig. 1.2).

Likelihood ratios (LR) are clinical diagnostic weights. An LR of greater than 1 increases the probability of disease (the higher the value, the greater the probability). Similarly, an LR of less than 1 decreases the probability of disease. LRs are developed against a diagnostic standard (e.g. in the case of meningitis, lumbar puncture results), so do not exist for all clinical findings. LRs illustrate how an individual clinical finding changes the probability of a disease. For example, in a person presenting with headache and fever, the clinical finding of nuchal rigidity (neck stiffness) may carry little weight in deciding whether to perform a lumbar puncture because LRs do not determine the prior probability of disease; they reflect only how a single clinical finding changes it. Clinicians have to take all the available information from the history and physical examination into account. If the overall clinical probability is high to begin with, a clinical finding with an LR of around 1 does not change this.

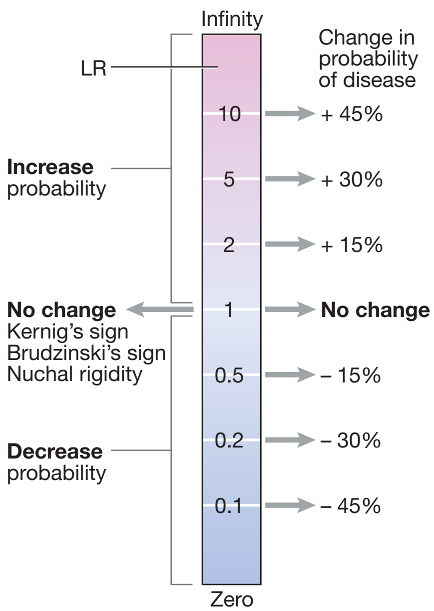

Fig. 1.2 Likelihood ratio (LR) of Kernig's sign, Brudzinski's sign and nuchal rigidity in the clinical diagnosis of meningitis.

$$\text{LR} = \frac{\text{probability of finding in patients } \textbf{with} \text{ disease}}{\text{probability of finding in patients } \textbf{without} \text{ disease}}$$

LRs are also used for diagnostic tests; here a physical examination finding can be considered a diagnostic test. *Data from Thomas KE, Hasbun R, Jekel J, Quagliarello VJ. The diagnostic accuracy of Kernig's sign, Brudzinski's sign, and nuchal rigidity in adults with suspected meningitis. Clin Infect Dis 2002; 35:46–52.*

'Evidence-based history and examination' is a term used to describe how clinicians incorporate knowledge about the prevalence and diagnostic weight of clinical findings into their history and physical examination. This is important because an estimate of clinical probability is vital in decision-making and the interpretation of diagnostic tests.

Use and interpretation of diagnostic tests

There is no such thing as a perfect diagnostic test. Test results give us test probabilities, not real probabilities. Test results have to be interpreted because they are affected by the following:

- how 'normal' is defined
- factors other than disease
- operating characteristics
- sensitivity and specificity
- prevalence of disease in the population.

Normal values

Most tests provide quantitative results (i.e. a value on a continuous numerical scale). In order to classify quantitative results as normal or abnormal, it is necessary to define a cut-off point. Many quantitative measurements in populations have a Gaussian or 'normal' distribution. By convention, the normal range is defined as those values that encompass 95% of the population, or 2 standard deviations above and below the mean. This means that 2.5% of the normal population will have values above, and 2.5% will have values below the normal range. For this reason, it is more appropriate to talk about the 'reference range' rather than the 'normal range' (Fig. 1.3).

Test results in abnormal populations also have a Gaussian distribution, with a different mean and standard deviation. In some diseases there is no overlap between results from the abnormal and normal population. However, in many diseases there is overlap; in these circumstances, the greater the difference between the test result and the limits of the reference range, the higher the chance that the person has a disease.

However, there are also situations in medicine when 'normal' is abnormal and 'abnormal' is normal. For example, a normal $PaCO_2$ in the context of a severe asthma attack is abnormal and means the patient has life-threatening asthma. A low ferritin in a young menstruating woman is not considered to be a disease at all. Normal, to some extent, is therefore arbitrary.

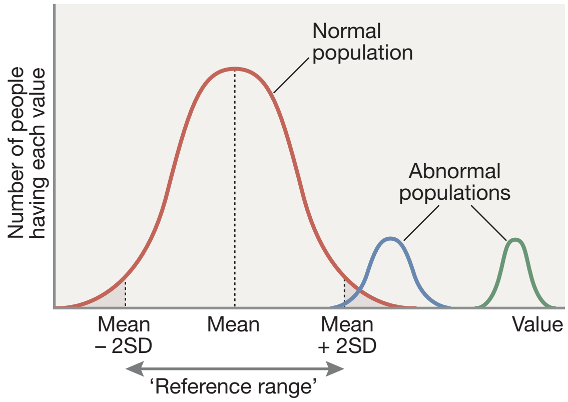

Fig. 1.3 Normal distribution and reference range. For many tests, the frequency distribution of results in the normal healthy population (red line) is a symmetrical bell-shaped curve. The mean ±2 standard deviations (SD) encompasses 95% of the normal population and usually defines the 'reference range'; 2.5% of the normal population have values above, and 2.5% below, this range (shaded areas). For some diseases (blue line), test results overlap with the normal population or even with the reference range. For other diseases (green line), tests may be more reliable because there is no overlap between the normal and abnormal population.

Factors other than disease that influence test results

A number of factors other than disease influence test results:

- age
- ethnicity
- pregnancy
- sex
- spurious (in vitro) results.

Box 1.3 gives some examples.

i 1.3 Examples of factors other than disease that influence test results

Factor	Examples
Age	Creatinine is lower in old age (due to relatively lower muscle mass) – an older person can have a significantly reduced eGFR rate with a 'normal' creatinine
Ethnicity	Healthy people of African ancestry have lower white cell counts
Pregnancy	Several tests are affected by late pregnancy, due to the effects of a growing fetus, including: Reduced urea and creatinine (haemodilution) Iron deficiency anaemia (increased demand) Increased alkaline phosphatase (produced by the placenta) Raised D-dimer (physiological changes in the coagulation system) Mild respiratory alkalosis (physiological maternal hyperventilation) ECG changes (tachycardia, left axis deviation)
Sex	Males and females have different reference ranges for many tests, e.g. haemoglobin
Spurious (in vitro) results	A spurious high potassium is seen in haemolysis and in thrombocytosis ('pseudohyperkalaemia')

(ECG = electrocardiogram; eGFR = estimated glomerular filtration rate, a better estimate of renal function than creatinine)

Operating characteristics

Tests are also subject to operating characteristics. This refers to the way the test is performed. Patients need to be able to comply fully with some tests, such as spirometry (p. 569), and if they cannot, then the test result will be affected. Some tests are very dependent on the skill of the operator and are also affected by the patient's body habitus and clinical state; ultrasound of the heart and abdomen are examples. A common mistake is when doctors refer to a test result as 'no abnormality detected' when, in fact, the report describes a technically difficult and incomplete scan that should more accurately be described as 'non-diagnostic'.

Some conditions are paroxysmal. For example, around half of patients with epilepsy have a normal standard electroencephalogram (EEG). A normal EEG therefore does not exclude epilepsy. On the other hand, around 10% of patients who do *not* have epilepsy have epileptiform discharges on their EEG. This is referred to as an 'incidental finding'. Incidental findings are common in medicine, and are increasing in incidence with the greater availability of more sensitive tests. Test results should always be interpreted in the light of the patient's history and physical examination.

Sensitivity and specificity

Diagnostic tests have characteristics termed 'sensitivity' and 'specificity'. Sensitivity is the ability to detect true positives; specificity is the ability to detect true negatives. Even a very good test, with 95% sensitivity, will miss 1 in 20 people with the disease. Every test therefore has 'false positives' and 'false negatives' (Box 1.4).

A very sensitive test will detect most disease but generate abnormal findings in healthy people. A negative result will therefore reliably exclude disease but a positive result does not mean the disease is present – it means further evaluation is required. On the other hand, a very specific test may miss significant pathology but is likely to establish the diagnosis beyond doubt when the result is positive. All tests differ in their sensitivity and specificity, and clinicians require a working knowledge of the tests they use in this respect.

In choosing how a test is used to guide decision-making there is a trade-off between sensitivity versus specificity. For example, defining an exercise electrocardiogram (p. 449) as abnormal if there is at least 0.5 mm of ST depression would ensure that very few cases of coronary artery disease are missed but would generate many false-positive results (high sensitivity, low specificity). On the other hand, a cut-off point of 2.0 mm of ST depression would detect most cases of important coronary artery disease with far fewer false positives. This trade-off is illustrated by the receiver operating characteristic curve of the test (Fig. 1.4).

An extremely important concept is this: the probability that a person has a disease depends on the pre-test probability, and the sensitivity and specificity of the test. For example, imagine that an elderly lady has fallen and hurt her left hip. On examination,

i 1.4 Sensitivity and specificity

	Disease	No disease
Positive test	A (True positive)	B (False positive)
Negative test	C (False negative)	D (True negative)

Sensitivity = A/(A+C) × 100
Specificity = D/(D+B) × 100

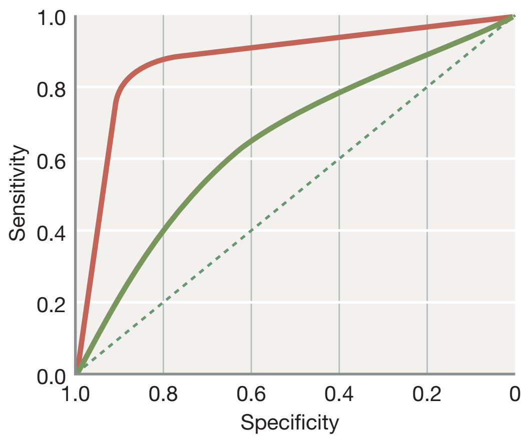

Fig. 1.4 Receiver operating characteristic graph illustrating the trade-off between sensitivity and specificity for a given test. The curve is generated by 'adjusting' the cut-off values defining normal and abnormal results, calculating the effect on sensitivity and specificity and then plotting these against each other. The closer the curve lies to the top left-hand corner, the more useful the test. The red line illustrates a test with useful discriminant value and the green line illustrates a less useful, poorly discriminant test.

the hip is extremely painful to move and she cannot stand. However, her hip X-rays are normal. Does she have a fracture?

The sensitivity of plain X-rays of the hip performed in the emergency department for suspected hip fracture is around 95%. A small percentage of fractures are therefore missed. If our patient has (or is at risk of) osteoporosis, has severe pain on hip movement and cannot bear weight on the affected side, then the clinical probability of hip fracture is high. If, on the other hand, she is unlikely to have osteoporosis, has no pain on hip movement and is able to bear weight, then the clinical probability of hip fracture is low.

Doctors are continually making judgements about whether something is true, given that something else is true. This is known as 'conditional probability'. Bayes' Theorem (named after English clergyman Thomas Bayes, 1702–1761) is a mathematical way to describe the post-test probability of a disease by combining pre-test probability, sensitivity and specificity. In clinical practice, doctors are not able to make complex mathematical calculations for every decision they make. In practical terms, the answer to the question of whether there is a fracture is that in a high-probability patient a normal test result does not exclude the condition, but in a low-probability patient it makes it very unlikely. This principle is illustrated in Figure 1.5.

Sox and colleagues (see 'Further information') state a fundamental assertion, which they describe as a profound and subtle principle of clinical medicine: the interpretation of new information depends on what you believed beforehand. In other words, the interpretation of a test result depends on the probability of disease before the test.

Prevalence of disease

Consider this problem that was posed to a group of Harvard doctors: if a test to detect a disease whose prevalence is 1 : 1000 has a false-positive rate of 5%, what is the chance that a person found to have a positive result actually has the disease, assuming you know nothing about the person's symptoms and signs? Take a moment to work this out. In this problem, we have removed clinical probability and are only considering prevalence. The answer is at the end of the chapter.

Predictive values combine sensitivity, specificity and prevalence. Sensitivity and specificity are characteristics of the test; the population does not change this. However, as doctors, we are interested in the question, 'What is the probability that a person with a positive test actually has the disease?' This is illustrated in Box 1.5.

Post-test probability and predictive values are different. Post-test probability is the probability of a disease after taking into account new information from a test result. Bayes' Theorem can be used to calculate post-test probability for a patient in any population. The pre-test probability of disease is decided by the doctor; it is a judgement based on information gathered prior to ordering the test. Predictive value is the proportion of patients with a test result who have the disease (or no disease) and is calculated from a table of results in a specific population (see Box 1.5). It is not possible to transfer this value to a different population. This is important to realise because published information about the performance of diagnostic tests may not apply to different populations.

In deciding the pre-test probability of disease, clinicians often neglect to take prevalence into account and this distorts their estimate of probability. To estimate the probability of disease in a patient more accurately, clinicians should anchor on the prevalence of disease in the subgroup to which the patient belongs and then adjust to take the individual factors into account.

i 1.5 Predictive values: 'What is the probability that a person with a positive test actually has the disease?'

	Disease	No disease
Positive test	A (True positive)	B (False positive)
Negative test	C (False negative)	D (True negative)

Positive predictive value = A/(A+B) × 100
Negative predictive value = D/(D+C) × 100

Dealing with uncertainty

Clinical findings are imperfect and diagnostic tests are imperfect. It is important to recognise that clinicians frequently deal with uncertainty. By expressing uncertainty as probability, new information from diagnostic tests can be incorporated more accurately. However, subjective estimates of probability can sometimes be unreliable. As the section on cognitive biases will demonstrate (see below), intuition can be a source of error.

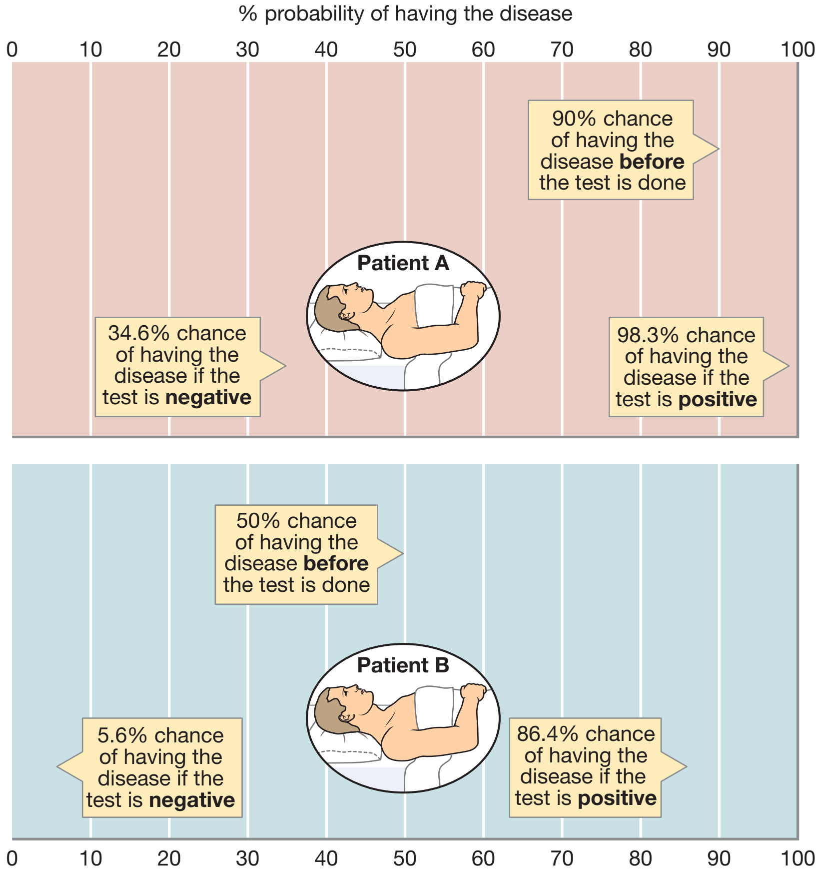

Fig. 1.5 The interpretation of a test result depends on the probability of the disease before the test is carried out. In the example shown, the test being carried out has a sensitivity of 95% and a specificity of 85%. Patient A has very characteristic clinical findings, which make the pre-test probability of the condition for which the test is being used very high – estimated as 90%. Patient B has more equivocal findings, such that the pre-test probability is estimated as only 50%. If the result in Patient A is negative, there is still a significant chance that he has the condition for which he is being tested; in Patient B, however, a negative result makes the diagnosis very unlikely.

Knowing the patient's true state is often unnecessary in clinical decision-making. Sox and colleagues (see 'Further information') argue that there is a difference between knowing that a disease is present and acting as if it were present. The requirement for diagnostic certainty depends on the penalty for being wrong. Different situations require different levels of certainty before starting treatment. How we communicate uncertainty to patients will be discussed later in this chapter (p. 10).

The treatment threshold combines factors such as the risks of the test, and the risks versus benefits of treatment. The point at which the factors are all evenly weighed is the threshold. If a test or treatment for a disease is effective and low-risk (e.g. giving antibiotics for a suspected urinary tract infection), then there is a lower threshold for going ahead. On the other hand, if a test or treatment is less effective or high-risk (e.g. starting chemotherapy for a malignant brain tumour), then greater confidence is required in the clinical diagnosis and potential benefits of treatment first. In principle, if a diagnostic test will not change the management of the patient, then careful consideration should be given to whether it is necessary to do the test at all.

In summary, test results shift our thinking, but rarely give a 'yes' or a 'no' answer in terms of a diagnosis. Sometimes tests shift the probability of disease by less than we realise. Pre-test probability is key, and this is derived from the history and physical examination, combined with a sound knowledge of medicine and an understanding of the prevalence of disease in the particular care setting or the population to which the patient belongs.

Cognitive biases

Advances in cognitive psychology in recent decades have demonstrated that human thinking and decision-making are prone to error. Cognitive biases are subconscious errors that lead to inaccurate judgement and illogical interpretation of information. They are prevalent in everyday life; as the famous saying goes, 'to err is human.'

Take a few moments to look at this simple puzzle. Do not try to solve it mathematically but listen to your intuition:

A bat and ball cost £1.10.
The bat costs £1 more than the ball.
How much does the ball cost?

The answer is at the end of the chapter. Most people get the answer to this puzzle wrong. Two things are going on: one is that humans have two distinct types of processes when it comes to thinking and decision-making – termed 'type 1' and 'type 2' thinking. The other is that the human brain is wired to jump to conclusions sometimes or to miss things that are obvious. British psychologist and patient safety pioneer James

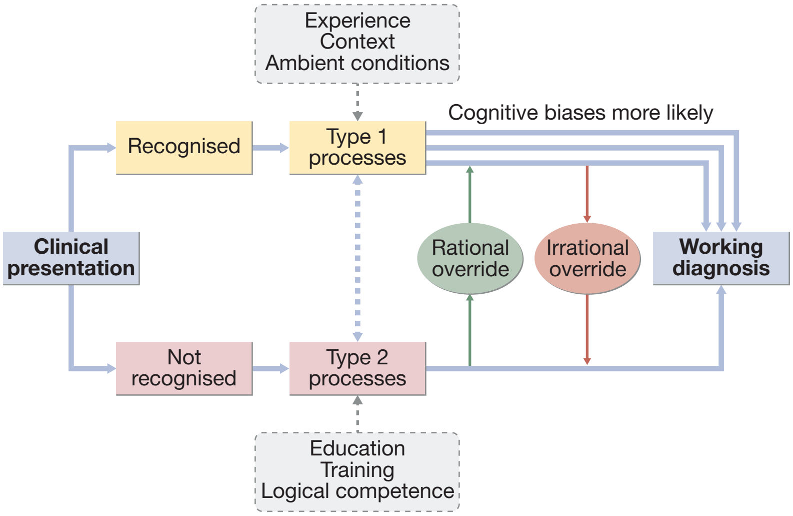

Fig. 1.6 The interplay between type 1 and type 2 thinking in the diagnostic process. *Adapted from Croskerry P. A universal model of diagnostic reasoning. Acad Med 2009; 84:1022–1028.*

Reason said that, 'Our propensity for certain types of error is the price we pay for the brain's remarkable ability to think and act intuitively – to sift quickly through the sensory information that constantly bombards us without wasting time trying to work through every situation anew.' This property of human thinking is highly relevant to clinical decision-making.

Type 1 and type 2 thinking

Studies of cognitive psychology and functional magnetic resonance imaging demonstrate two distinct types of processes when it comes to decision-making: intuitive (type 1) and analytical (type 2). This has been termed 'dual process theory'. Box 1.6 explains this in more detail.

Psychologists estimate that we spend 95% of our daily lives engaged in type 1 thinking – the intuitive, fast, subconscious mode of decision-making. Imagine driving a car, for example; it would be impossible to function efficiently if every decision and movement were as deliberate, conscious, slow and effortful as in our first driving lesson. With experience, complex procedures become automatic, fast and effortless. The same applies to medical practice. There is evidence that expert decision-making is well served by intuitive thinking. The problem is that although intuitive processing is highly efficient in many circumstances, in others it is prone to error.

Clinicians use both type 1 and type 2 thinking, and both types are important in clinical decision-making. When encountering a problem that is familiar, clinicians employ pattern recognition and reach a working diagnosis or differential diagnosis quickly (type 1 thinking). When encountering a problem that is more complicated, they use a slower, systematic approach (type 2 thinking). Both types of thinking interplay – they are not mutually exclusive in the diagnostic process. Figure 1.6 illustrates the interplay between type 1 and type 2 thinking in clinical practice.

Errors can occur in both type 1 and type 2 thinking; for example, people can apply the wrong rules or make errors in their application while using type 2 thinking. However, it has been argued that the common cognitive biases encountered in medicine tend to occur when clinicians are engaged in type 1 thinking.

For example, imagine being asked to see a young woman who is drowsy. She is handed over to you as a 'probable overdose' because she has a history of depression and a packet of painkillers was found beside her at home. Her observations show she has a Glasgow Coma Scale score of 10/15, heart rate 100 beats/min, blood pressure 100/60 mmHg, respiratory rate 14 breaths/min, oxygen saturations 98% on air and temperature 37.5°C. Already your mind has reached a working diagnosis. It fits a pattern (type 1 thinking). You think she has taken an overdose. At this point you can stop to think about your thinking (rational override in Fig. 1.6): 'What is the evidence for this diagnosis? What else could it be?'

On the other hand, imagine being asked to assess a patient who has been admitted with syncope. There are several different causes of syncope and a systematic approach is required to reach a diagnosis (type 2 thinking). However, you recently heard about a case of syncope due to a leaking abdominal aortic aneurysm. At the end of your assessment, following evidence-based guidelines, it is clear the patient can be discharged. Despite this, you decide to observe the patient overnight 'just in case' (irrational override in Fig. 1.6). In this example, your intuition is actually availability bias (when things are at the forefront of your mind), which has significantly distorted your estimate of probability.

i 1.6 Type 1 and type 2 thinking

Type 1	Type 2
Intuitive, heuristic (pattern recognition)	Analytical, systematic
Automatic, subconscious	Deliberate, conscious
Fast, effortless	Slow, effortful
Low/variable reliability	High/consistent reliability
Vulnerable to error	Less prone to error
Highly affected by context	Less affected by context
High emotional involvement	Low emotional involvement
Low scientific rigour	High scientific rigour

Common cognitive biases in medicine

Figure 1.7 illustrates the common cognitive biases prevalent in medical practice. Biases often work together; for example, in

Anchoring The common human tendency to rely too heavily on the first piece of information offered (the 'anchor') when making decisions	**Diagnostic momentum** Once a diagnostic label has been attached to a patient (by the patient or other health-care professionals), it can gather momentum with each review, leading others to exclude other possibilities in their thinking	**Premature closure** The tendency to close the decision-making process prematurely and accept a diagnosis before it, and other possibilities, have been fully explored
Ascertainment bias We sometimes see what we expect to see ('self-fulfilling prophecy'). For example, a frequent self-harmer attends the emergency department with drowsiness; everyone assumes he has taken another overdose and misses a brain injury	**Framing effect** How a case is presented – for example, in handover – can generate bias in the listener. This can be mitigated by always having 'healthy scepticism' about other people's diagnoses	**Psych-out error** Psychiatric patients who present with medical problems are under-assessed, under-examined and under-investigated because problems are presumed to be due to, or exacerbated by, their psychiatric condition
Availability bias Things may be at the forefront of your mind because you have seen several cases recently or have been studying that condition in particular. For example, when one of the authors worked in an epilepsy clinic, all blackouts were possible seizures	**Hindsight bias** Knowing the outcome may profoundly influence the perception of past events and decision-making, preventing a realistic appraisal of what actually occurred – a major problem in learning from diagnostic error	**Search satisficing** We may stop searching because we have found something that fits or is convenient, instead of systematically looking for the best alternative, which involves more effort
Base rate neglect The tendency to ignore the prevalence of a disease, which then distorts Bayesian reasoning. In some cases, clinicians do this deliberately in order to rule out an unlikely but worst-case scenario	**Omission bias** The tendency towards inaction, rooted in the principle of 'first do no harm.' Events that occur through natural progression of disease are more acceptable than those that may be attributed directly to the action of the health-care team	**Triage-cueing** Triage ensures patients are sent to the right department. However, this leads to 'geography is destiny'. For example, a diabetic ketoacidosis patient with abdominal pain and vomiting is sent to surgery. The wrong location (surgical ward) stops people thinking about medical causes of abdominal pain and vomiting
Commission bias The tendency towards action rather than inaction, on the assumption that good can come only from doing something (rather than 'watching and waiting')	**Overconfidence bias** The tendency to believe we know more than we actually do, placing too much faith in opinion instead of gathered evidence	**Unpacking principle** Failure to 'unpack' all the available information may mean things are missed. For example, if a thorough history is not obtained from either the patient or carers (a common problem in geriatric medicine), diagnostic possibilities may be discounted
Confirmation bias The tendency to look for confirming evidence to support a theory rather than looking for disconfirming evidence to refute it, even if the latter is clearly present. Confirmation bias is common when a patient has been seen first by another doctor	**Posterior probability** Our estimate of the likelihood of disease may be unduly influenced by what has gone on before for a particular patient. For example, a patient who has been extensively investigated for headaches presents with a severe headache, and serious causes are discounted	**Visceral bias** The influence of either negative or positive feelings towards patients, which can affect our decision-making

Fig. 1.7 Common cognitive biases in medicine. *Adapted from Croskerry P. Achieving quality in clinical decision-making: cognitive strategies and detection of bias. Acad Emerg Med 2002; 9:1184–1204.*

overconfidence bias (the tendency to believe we know more than we actually do), too much faith is placed in opinion instead of gathered evidence. This bias can be augmented by the availability bias and finally by commission bias (the tendency towards action rather than inaction) – sometimes with disastrous results.

The mark of a well-calibrated thinker is the ability to recognise what mode of thinking is being employed and to anticipate and recognise situations in which cognitive biases and errors are more likely to occur.

Human factors

'Human factors' is the science of the limitations of human performance, and how technology, the work environment and team communication can adapt for this to reduce diagnostic and other types of error. Analysis of serious adverse events in clinical practice shows that human factors and poor team communication play a significant role when things go wrong.

Research shows that many errors are beyond an individual's conscious control and are precipitated by many factors. The discipline of human factors seeks to understand interactions between:

- people and tasks or technology
- people and their work environment
- people in a team.

An understanding of these interactions makes it easier for health-care professionals, who are committed to 'first do no harm,' to work in the safest way possible. For example, performance is adversely affected by factors such as poorly designed processes and equipment, frequent interruptions and fatigue. The areas of the brain required for type 2 processing are most affected by things like fatigue and cognitive overload, and the brain reverts to type 1 processing to conserve cognitive energy. Figure 1.8 illustrates some of the internal and external factors that affect human judgement and decision-making.

Various experiments demonstrate that we focus our attention to filter out distractions. This is advantageous in many situations, but in focusing on what we are trying to see we may not notice the unexpected. In a team context, what is obvious to one person may be completely missed by someone else. Safe and effective team communication therefore requires us never to assume, and to verbalise things, even though they may seem obvious.

Reducing errors in clinical decision-making

Knowledge and experience do not eliminate errors. Instead, there are a number of ways in which we can act to reduce errors in clinical decision-making. Examples are:

- adopting 'cognitive debiasing strategies'
- using clinical prediction rules and other decision aids
- engaging in effective team communication.

Cognitive debiasing strategies

There are some simple and established techniques that can be used to avoid cognitive biases and errors in clinical decision-making.

History and physical examination

Taking a history and performing a physical examination may seem obvious, but these are sometimes carried out inadequately. This is the 'unpacking principle': failure to unpack all the available information means things can be missed and lead to error.

Problem lists and differential diagnosis

Once all the available data from history, physical examination and (sometimes) initial test results are available, these need to be synthesised into a problem list. The ability to identify key clinical data and create a problem list is a key step in clinical reasoning. Some problems (e.g. low serum potassium) require action but not necessarily a differential diagnosis. Other problems (e.g. vomiting) require a differential diagnosis. The process of generating a problem list ensures nothing is missed. The process of generating a differential diagnosis works against anchoring on a particular diagnosis too early, thereby avoiding search satisficing and premature closure (see Fig. 1.7).

Mnemonics and checklists

These are used frequently in medicine in order to reduce reliance on fallible human memory. ABCDE (airway, breathing, circulation, disability, exposure/examination) is probably the most successful checklist in medicine, used during the assessment and treatment of critically ill patients (ABCDE is sometimes prefixed with 'C' for 'control of any obvious problem'; see p. 188). Checklists ensure that important issues have been considered and completed, especially under conditions of complexity, stress or fatigue.

Red flags and ROWS ('rule out worst case scenario')

These are strategies that force doctors to consider serious diseases that can present with common symptoms. Red flags in back pain are listed in Box 24.19 (p. 996). Considering and investigating for possible pulmonary embolism in patients who

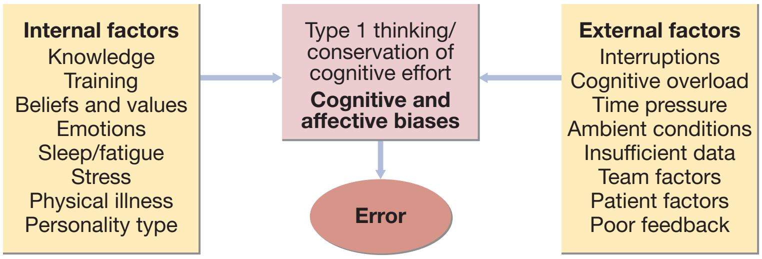

Fig. 1.8 Factors that affect our judgement and decision-making. Type 1 thinking = fast, intuitive, subconscious, low-effort.

present with pleuritic chest pain and breathlessness is a common example of ruling out a worst-case scenario, as pulmonary embolism can be fatal if missed. Red flags and ROWS help to avoid cognitive biases such as the 'framing effect' and 'premature closure'.

Newer strategies to avoid cognitive biases and errors in decision-making are emerging. These involve explicit training in clinical reasoning and human factors. In theory, if doctors are aware of the science of human thinking and decision-making, then they are more able to think about their thinking, understand situations in which their decision-making may be affected, and take steps to mitigate this.

Using clinical prediction rules and other decision aids

A clinical prediction rule is a statistical model of the diagnostic process. When clinical prediction rules are matched against the opinion of experts, the model usually outperforms the experts, because it is applied consistently in each case. However, it is important that clinical prediction rules are used correctly – that is, applied to the patient population that was used to create the rule. Clinical prediction rules force a scientific assessment of the patient's symptoms, signs and other data to develop a numerical probability of a disease or an outcome. They help clinicians to estimate probability more accurately.

A good example of a clinical prediction rule to estimate pre-test probability is the Wells score in suspected deep vein thrombosis (see Box 10.15, p. 187). Other commonly used clinical prediction rules predict outcomes and therefore guide the management plan. These include the GRACE score in acute coronary syndromes (see Fig. 16.62, p. 494) and the CURB-65 score in community-acquired pneumonia (see Fig. 17.32, p. 583).

Effective team communication

Effective team communication and proper handovers are vital for safe clinical care. The SBAR system of communication has been recommended by the UK's Patient Safety First campaign. It is a structured way to communicate about a patient with another health-care professional (e.g. during handover or when making a referral) and increases the amount of relevant information being communicated in a shorter time. It is illustrated in Box 1.7.

In increasingly complex health-care systems, patients are looked after by a wide variety of professionals, each of whom has access to important information required to make clinical decisions. Strict hierarchies are hazardous to patient safety if certain members of the team are not able to speak up.

1.7 The SBAR system of communicating

SBAR	Example (a telephone call to the Intensive Care team)
Situation	I am [name] calling from [place] about a patient with a NEWS of 10.
Background	[Patient's name], 30-year-old woman, no past medical history, was admitted last night with community-acquired pneumonia. Since then her oxygen requirements have been steadily increasing.
Assessment	Her vital signs are: blood pressure 115/60 mmHg, heart rate 120 beats/min, temperature 38°C, respiratory rate 32 breaths/min, oxygen saturations 89% on 15 L via reservoir bag mask. An arterial blood gas shows pH 7.3 (H^+ 50 nmol/L), $PaCO_2$ 4.0 kPa (30 mmHg), PaO_2 7 kPa (52.5 mmHg), standard bicarbonate 14 mmol/L. Chest X-ray shows extensive right lower zone consolidation.
Recommendation	Please can you come and see her as soon as possible? I think she needs admission to Intensive Care.

(NEWS = National Early Warning Score; a patient with normal vital signs scores 0)
From Royal College of Physicians of London. National Early Warning Score: standardising the assessment of illness severity in the NHS. Report of a working party. RCP, July 2012; www.rcplondon.ac.uk/projects/outputs/national-early-warning-score-news (accessed March 2016).

Patient-centred evidence-based medicine and shared decision-making

'Patient-centred evidence-based medicine' refers to the application of best-available research evidence while taking individual patient factors into account; these include both clinical and non-clinical factors (e.g. the patient's social circumstances, values and wishes). For example, a 95-year-old man with dementia and a recent gastrointestinal bleed is admitted with an inferior myocardial infarction. He is clinically well. Should he be treated with dual antiplatelet therapy and low-molecular-weight heparin as recommended in clinical guidelines?

As this chapter has described, clinicians frequently deal with uncertainty/probability. Clinicians need to be able to explain risks and benefits of treatment in an accurate and understandable way. Providing the relevant statistics is seldom sufficient to guide decision-making because a patient's perception of risk may be influenced by irrational factors as well as individual values.

Research evidence provides statistics but these can be confusing. Terms such as 'common' and 'rare' are nebulous. Whenever possible, clinicians should quote numerical information using consistent denominators (e.g. '90 out of 100 patients who have this operation feel much better, 1 will die during the operation and 2 will suffer a stroke'). Visual aids can be used to present complex statistical information (Fig. 1.9).

How uncertainty is conveyed to patients is important. Many studies demonstrate a correlation between effective clinician–patient communication and improved health outcomes. If patients feel they have been listened to and understand the problem and proposed treatment plan, they are more likely to follow the plan and less likely to re-attend.

Clinical decision-making: putting it all together

The following is a practical example that brings together many of the concepts outlined in this chapter:

A 25-year-old woman presents with right-sided pleuritic chest pain and breathlessness. She reports that she had an upper

Fig. 1.9 Visual portrayal of benefits and risks. The image refers to an operation that is expected to relieve symptoms in 90% of patients, but cause stroke in 2% and death in 1%. *From Edwards A, Elwyn G, Mulley A. Explaining risks: turning numerical data into meaningful pictures. BMJ 2002; 324:827–830, reproduced with permission from the BMJ Publishing Group.*

respiratory tract infection a week ago and was almost back to normal when the symptoms started. The patient has no past medical history and no family history, and her only medication is the combined oral contraceptive pill. On examination, her vital signs are normal (respiratory rate 19 breaths/min, oxygen saturations 98% on air, blood pressure 115/60 mmHg, heart rate 90 beats/min, temperature 37.5°C) and the physical examination is also normal. You have been asked to assess her for the possibility of a pulmonary embolism.

(More information on pulmonary embolism can be found on page 619.)

Evidence-based history and examination

Information from the history and physical examination is vital in deciding whether this could be a pulmonary embolism. Pleurisy and breathlessness are common presenting features of this disease but are also common presenting features in other diseases. There is nothing in the history to suggest an alternative diagnosis (e.g. high fever, productive cough, recent chest trauma). The patient's vital signs are normal, as is the physical examination. However, the only feature in the history and examination that has a negative likelihood ratio in the diagnosis of pulmonary embolism is a heart rate of less than 90 beats/min. In other words, the normal physical examination findings (including normal oxygen saturations) carry very little diagnostic weight.

Deciding pre-test probability

The prevalence of pulmonary embolism in 25-year-old women is low. We anchor on this prevalence and then adjust for individual patient factors. This patient has no major risk factors for pulmonary embolism. To assist our estimate of pre-test probability, we could use a clinical prediction rule: in this case, the modified Wells score for pulmonary embolism, which would give a score of 3 (low probability – answering yes only to the criterion 'PE is the number one diagnosis, an alternative is less likely').

Interpreting test results

Imagine the patient went on to have a normal chest X-ray and blood results, apart from a raised D-dimer of 900 (normal <500 ng/mL). A normal chest X-ray is a common finding in pulmonary embolism. Several studies have shown that the D-dimer assay has at least 95% sensitivity in acute pulmonary embolism but it has a low specificity. A very sensitive test will detect most disease but generate abnormal findings in healthy people. On the other hand, a negative result virtually, but not completely, excludes the disease. It is important at this point to realise that a raised D-dimer result does not mean this patient has a pulmonary embolism; it just means that we have not been able to exclude it. Since pulmonary embolism is a potentially fatal condition we need to rule out the worst-case scenario (ROWS), and the next step is therefore to arrange further imaging. What kind of imaging depends on individual patient characteristics and what is available.

Treatment threshold

The treatment threshold combines factors such as the risks of the test, and the risks versus benefits of treatment. A CT pulmonary angiogram (CTPA) could be requested for this patient, although in some circumstances ventilation–perfusion single-photon emission computed tomography ($\dot{V}/\dot{Q}$ SPECT, p. 620) may be a more suitable alternative. However, what if the scan cannot be performed until the next day? Because pulmonary embolism is potentially fatal and the risks of treatment in this case are low, the patient should be started on treatment while awaiting the scan.

Post-test probability

The patient's scan result is subsequently reported as 'no pulmonary embolism'. Combined with the low pre-test probability, this scan result reliably excludes pulmonary embolism.

Cognitive biases

Imagine during this case that the patient had been handed over to you as 'nothing wrong – probably a pulled muscle'. Cognitive biases (subconscious tendencies to respond in a certain way) would come into play, such as the 'framing effect', 'confirmation bias' and 'search satisficing'. The normal clinical examination might confirm the diagnosis of musculoskeletal pain in your mind, despite the examination being entirely consistent with pulmonary embolism and despite the lack of history and examination findings (e.g. chest wall tenderness) to support the diagnosis of musculoskeletal chest pain.

Human factors

Imagine that, after you have seen the patient, a nurse hands you some blood forms and asks you what tests you would like to request on 'this lady'. You request blood tests including a D-dimer on the wrong patient. Luckily, this error is intercepted.

Reducing cognitive error

The diagnosis of pulmonary embolism can be difficult. Clinical prediction rules (e.g. modified Wells score), guidelines (e.g. from the UK's National Institute for Health and Care Excellence, or NICE) and decision aids (e.g. simplified pulmonary embolism severity index, or PESI) are frequently used in combination with the doctor's opinion, derived from information gathered in the history and physical examination.

Person-centred EBM and information given to patient

The patient is treated according to evidence-based guidelines that apply to her particular situation. Tests alone do not make a diagnosis and at the end of this process the patient is told that the combination of history, examination and test results mean she is extremely unlikely to have a pulmonary embolism. Viral pleurisy is offered as an alternative diagnosis and she is reassured that her symptoms are expected to settle over the coming days with analgesia. She is advised to re-present to hospital if her symptoms suddenly get worse.

Answers to problems

Harvard problem (p. 5)

Almost half of doctors surveyed said 95%, but they neglected to take prevalence into account. If 1000 people are tested, there will be 51 positive results: 50 false positives and 1 true positive. The chance that a person found to have a positive result actually has the disease is 1/51 or 2%.

Bat and ball problem (p. 6)

This puzzle is from the book, *Thinking, Fast and Slow*, by Nobel laureate Daniel Kahneman (see 'Further information'). He writes, 'A number came to your mind. The number, of course, is 10p. The distinctive mark of this easy puzzle is that it evokes an answer that is intuitive, appealing – and wrong. Do the math, and you will see.' The correct answer is 5p.

Clinical therapeutics and good prescribing

Prescribing medicines is the major tool used by doctors to restore or preserve the health of patients. Medicines contain drugs (the specific chemical substances with pharmacological effects), either alone or in combination with additional drugs, in a formulation mixed with other ingredients. The beneficial effects of medicines must be weighed against their cost and potential adverse drug reactions and interactions. The latter two factors are sometimes caused by injudicious prescribing decisions and by prescribing errors. The modern prescriber must meet the challenges posed by the increasing number of drugs and formulations available and of indications for prescribing them, and the greater complexity of treatment regimens followed by individual patients ('polypharmacy', a particular challenge in the ageing population). The purpose of this chapter is to elaborate on the principles and practice that underpin good prescribing (Box 2.1).

i 2.1 Steps in good prescribing

- Make a diagnosis
- Consider factors that might influence the patient's response to therapy (age, concomitant drug therapy, renal and liver function etc.)
- Establish the therapeutic goal*
- Choose the therapeutic approach*
- Choose the drug and its formulation (the 'medicine')
- Choose the dose, route and frequency
- Choose the duration of therapy
- Write an unambiguous prescription (or 'medication order')
- Inform the patient about the treatment and its likely effects
- Monitor treatment effects, both beneficial and harmful
- Review/alter the prescription

*These steps in particular take the patient's views into consideration to establish a therapeutic partnership (shared decision-making to achieve 'concordance').

Principles of clinical pharmacology

Prescribers need to understand what the drug does to the body (pharmacodynamics) and what the body does to the drug (pharmacokinetics) (Fig. 2.1). Although this chapter is focused on the most common drugs, which are synthetic small molecules, the same principles apply to the increasingly numerous 'biological' therapies (sometimes abbreviated to 'biologics') now in use, which include peptides, proteins, enzymes and monoclonal antibodies (see Box 4.2, p. 65).

Pharmacodynamics

Drug targets and mechanisms of action

Modern drugs are usually discovered by screening compounds for activity either to stimulate or to block the function of a specific molecular target, which is predicted to have a beneficial effect in a particular disease (Box 2.2). Other drugs have useful but less selective chemical properties, such as chelators (e.g. for treatment of iron or copper overload), osmotic agents (used as diuretics in cerebral oedema) or general anaesthetics (that alter the biophysical properties of lipid membranes). The following characteristics of the interaction of drugs with receptors illustrate some of the important determinants of the effects of drugs:

- *Affinity* describes the propensity for a drug to bind to a receptor and is related to the 'molecular fit' and the strength of the chemical bond. Some drug–receptor interactions are *irreversible*, either because the affinity is so strong or because the drug modifies the structure of its molecular target.

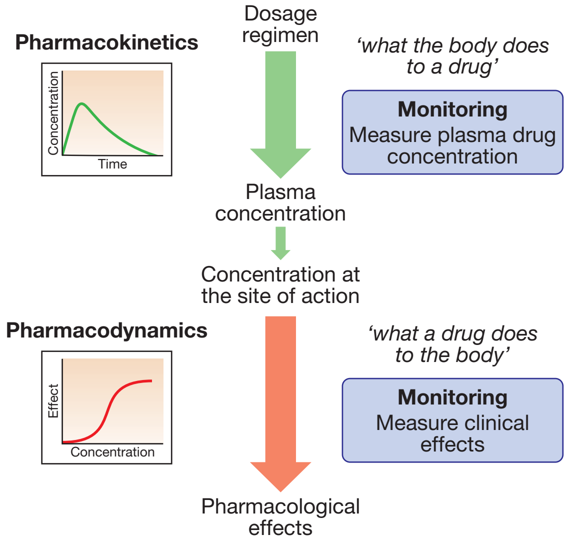

Fig. 2.1 Pharmacokinetics and pharmacodynamics.

- *Selectivity* describes the propensity for a drug to bind to one target rather than another. Selectivity is a relative term, not to be confused with absolute specificity. It is common for drugs targeted at a particular subtype of receptor to exhibit some effect at other subtypes. For example, β-adrenoceptors can be subtyped on the basis of their responsiveness to the endogenous agonist noradrenaline (norepinephrine): the concentration of noradrenaline required to cause bronchodilatation (via β_2-adrenoceptors) is ten times higher than that required to cause tachycardia (via β_1-adrenoceptors). 'Cardioselective' β-blockers have anti-anginal effects on the heart (β_1) but may still cause bronchospasm in the lung (β_2) and are contraindicated for asthmatic patients.
- *Agonists* bind to a receptor to produce a conformational change that is coupled to a biological response. As agonist concentration increases, so does the proportion of receptors occupied, and hence the biological effect. *Partial agonists* activate the receptor but cannot produce a maximal signalling effect equivalent to that of a full agonist, even when all available receptors are occupied.
- *Antagonists* bind to a receptor but do not produce the conformational change that initiates an intracellular signal. A *competitive antagonist* competes with endogenous ligands to occupy receptor-binding sites, with the resulting antagonism depending on the relative affinities and concentrations of drug and ligand. *Non-competitive antagonists* inhibit the effect of an agonist by mechanisms other than direct competition for receptor binding with the agonist (e.g. by affecting post-receptor signalling).

Dose–response relationships

Plotting the logarithm of drug dose against drug response typically produces a sigmoidal dose–response curve (Fig. 2.2). Progressive increases in drug dose (which, for most drugs, is proportional to the plasma drug concentration) produce increasing

2

2.2 Examples of target molecules for drugs

Drug target	Description	Examples
Receptors		
Channel-linked receptors	Ligand binding controls a linked ion channel, known as 'ligand-gated' (in contrast to 'voltage-gated' channels that respond to changes in membrane potential)	Nicotinic acetylcholine receptor GABA receptor Sulphonylurea receptor
G-protein-coupled receptors (GPCRs)	Ligand binding affects one of a family of 'G-proteins' that mediate signal transduction either by activating intracellular enzymes (such as adenylate or guanylate cyclase, producing cyclic AMP or GMP, respectively) or by controlling ion channels	Muscarinic acetylcholine receptor β-adrenoceptors Dopamine receptors 5-Hydroxytryptamine (5-HT, serotonin) receptors Opioid receptors
Kinase-linked receptors	Ligand binding activates an intracellular protein kinase that triggers a cascade of phosphorylation reactions	Insulin receptor Cytokine receptors
Transcription factor receptors	Intracellular and also known as 'nuclear receptors'; ligand binding promotes or inhibits gene transcription and hence synthesis of new proteins	Steroid receptors Thyroid hormone receptors Vitamin D receptors Retinoid receptors PPARγ and α receptors
Other targets		
Voltage-gated ion channels	Mediate electrical signalling in excitable tissues (muscle and nervous system)	Na^+ channels Ca^{2+} channels
Enzymes	Catalyse biochemical reactions. Drugs interfere with binding of substrate to the active site or of co-factors	Cyclo-oxygenase ACE Xanthine oxidase
Transporter proteins	Carry ions or molecules across cell membranes	5-HT re-uptake transporter Na^+/K^+ ATPase
Cytokines and other signalling molecules	Small proteins that are important in cell signalling (autocrine, paracrine and endocrine), especially affecting the immune response	Tumour necrosis factors Interleukins
Cell surface antigens	Block the recognition of cell surface molecules that modulate cellular responses	Cluster of differentiation molecules (e.g. CD20, CD80)

(ACE = angiotensin-converting enzyme; AMP = adenosine monophosphate; ATPase = adenosine triphosphatase; GABA = γ-aminobutyric acid; GMP = guanosine monophosphate; PPAR = peroxisome proliferator-activated receptor)

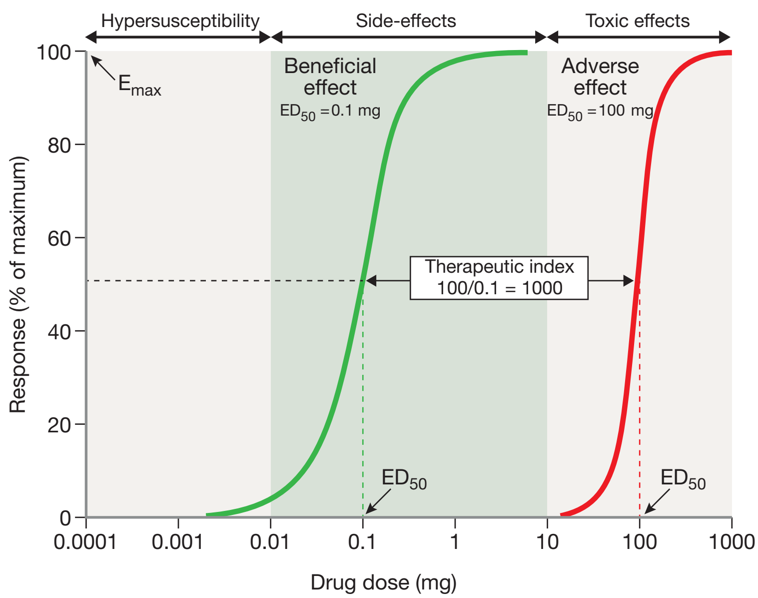

Fig. 2.2 Dose–response curve. The green curve represents the beneficial effect of the drug. The maximum response on the curve is the E_{max} and the dose (or concentration) producing half this value ($E_{max}/2$) is the ED_{50} (or EC_{50}). The red curve illustrates the dose–response relationship for the most important adverse effect of this drug. This occurs at much higher doses; the ratio between the ED_{50} for the adverse effect and that for the beneficial effect is the 'therapeutic index', which indicates how much margin there is for prescribers when choosing a dose that will provide beneficial effects without also causing this adverse effect. Adverse effects that occur at doses above the therapeutic range are normally called 'toxic effects', while those occurring within the therapeutic range are 'side-effects' and those below it are 'hyper-susceptibility effects'.

response but only within a relatively narrow range of dose; further increases in dose beyond this range produce little extra effect. The following characteristics of the drug response are useful in comparing different drugs:

- *Efficacy* describes the extent to which a drug can produce a target-specific response when all available receptors or binding sites are occupied (i.e. E_{max} on the dose–response curve). A full agonist can produce the maximum response of which the receptor is capable, while a partial agonist at the same receptor will have lower efficacy. *Therapeutic efficacy* describes the effect of the drug on a desired biological endpoint and can be used to compare drugs that act via different pharmacological mechanisms (e.g. loop diuretics induce a greater diuresis than thiazide diuretics and therefore have greater therapeutic efficacy).
- *Potency* describes the amount of drug required for a given response. More potent drugs produce biological effects at lower doses, so they have a lower ED_{50}. A less potent drug can still have an equivalent efficacy if it is given in higher doses.

The dose–response relationship varies between patients because of variations in the many determinants of pharmacokinetics and pharmacodynamics. In clinical practice, the prescriber is unable to construct a dose–response curve for each individual patient. Therefore, most drugs are licensed for use within a recommended range of doses that is expected to reach close to the top of the dose–response curve for most patients. However, it is sometimes possible to achieve the desired therapeutic efficacy at doses towards the lower end of, or even below, the recommended range.

Therapeutic index

The adverse effects of drugs are often dose-related in a similar way to the beneficial effects, although the dose–response curve for these adverse effects is normally shifted to the right (Fig. 2.2). The ratio of the ED_{50} for therapeutic efficacy and for a major adverse effect is known as the 'therapeutic index'. In reality, drugs have multiple potential adverse effects, but the concept of therapeutic index is usually based on adverse effects that might require dose reduction or discontinuation. For most drugs, the therapeutic index is greater than 100 but there are some notable exceptions with therapeutic indices of less than 10 (e.g. digoxin, warfarin, insulin, phenytoin, opioids). The doses of such drugs have to be titrated carefully for individual patients to maximise benefits but avoid adverse effects.

Desensitisation and withdrawal effects

Desensitisation refers to the common situation in which the biological response to a drug diminishes when it is given continuously or repeatedly. It may be possible to restore the response by increasing the dose of the drug but, in some cases, the tissues may become completely refractory to its effect.

- *Tachyphylaxis* describes desensitisation that occurs very rapidly, sometimes with the initial dose. This rapid loss of response implies depletion of chemicals that may be necessary for the pharmacological actions of the drug (e.g. a stored neurotransmitter released from a nerve terminal) or receptor phosphorylation.
- *Tolerance* describes a more gradual loss of response to a drug that occurs over days or weeks. This slower change implies changes in receptor numbers or the development of counter-regulatory physiological changes that offset the actions of the drug (e.g. accumulation of salt and water in response to vasodilator therapy).
- *Drug resistance* is a term normally reserved for describing the loss of effectiveness of an antimicrobial (p. 116) or cancer chemotherapy drug.
- In addition to these pharmacodynamic causes of desensitisation, reduced response may be the consequence of lower plasma and tissue drug concentrations as a result of altered *pharmacokinetics* (see below).

When drugs induce chemical, hormonal and physiological changes that offset their actions, discontinuation may allow these changes to cause 'rebound' withdrawal effects (Box 2.3).

2.3 Examples of drugs associated with withdrawal effects

Drug	Symptoms	Signs	Treatment
Alcohol	Anxiety, panic, paranoid delusions, visual and auditory hallucinations	Agitation, restlessness, delirium, tremor, tachycardia, ataxia, disorientation, seizures	Treat immediate withdrawal syndrome with benzodiazepines
Barbiturates, benzodiazepines	Similar to alcohol	Similar to alcohol	Transfer to long-acting benzodiazepine then gradually reduce dosage
Glucocorticoids	Weakness, fatigue, decreased appetite, weight loss, nausea, vomiting, diarrhoea, abdominal pain	Hypotension, hypoglycaemia	Prolonged therapy suppresses the hypothalamic–pituitary–adrenal axis and causes adrenal insufficiency requiring glucocorticoid replacement. Withdrawal should be gradual after prolonged therapy (p. 670)
Opioids	Rhinorrhoea, sneezing, yawning, lacrimation, abdominal and leg cramping, nausea, vomiting, diarrhoea	Dilated pupils	Transfer addicts to long-acting agonist methadone
Selective serotonin re-uptake inhibitors (SSRIs)	Dizziness, sweating, nausea, insomnia, tremor, delirium, nightmares	Tremor	Reduce SSRIs slowly to avoid withdrawal effects

Pharmacokinetics

Understanding 'what the body does to the drug' (Fig. 2.3) is extremely important for prescribers because this forms the basis on which the optimal route of administration and dose regimen are chosen and explains the majority of inter-individual variation in the response to drug therapy.

Drug absorption and routes of administration

Absorption is the process by which drug molecules gain access to the blood stream. The rate and extent of drug absorption depend on the route of administration (Fig. 2.3).

Enteral administration

These routes involve administration via the gastrointestinal tract:

- *Oral*. This is the most common route of administration because it is simple, convenient and readily used by patients to self-administer their medicines. Absorption after an oral dose is a complex process that depends on the drug being swallowed, surviving exposure to gastric acid, avoiding unacceptable food binding, being absorbed across the small bowel mucosa into the portal venous system, and surviving metabolism by gut wall or liver enzymes ('first-pass metabolism'). As a consequence, absorption is frequently incomplete following oral administration. The term 'bioavailability' describes the proportion of the dose that reaches the systemic circulation intact.
- *Buccal, intranasal and sublingual (SL)*. These routes have the advantage of enabling rapid absorption into the systemic circulation without the uncertainties associated with oral administration (e.g. organic nitrates for angina pectoris, triptans for migraine, opioid analgesics).
- *Rectal (PR)*. The rectal mucosa is occasionally used as a site of drug administration when the oral route is compromised because of nausea and vomiting or unconsciousness (e.g. diazepam in status epilepticus).

Parenteral administration

These routes avoid absorption via the gastrointestinal tract and first-pass metabolism in the liver:

- *Intravenous (IV)*. The IV route enables all of a dose to enter the systemic circulation reliably, without any concerns about absorption or first-pass metabolism (i.e. the dose is 100% bioavailable), and rapidly achieve a high plasma concentration. It is ideal for very ill patients when a rapid, certain effect is critical to outcome (e.g. benzathine benzylpenicillin for meningococcal meningitis).
- *Intramuscular (IM)*. IM administration is easier to achieve than the IV route (e.g. adrenaline (epinephrine) for acute anaphylaxis) but absorption is less predictable and depends on muscle blood flow.
- *Subcutaneous (SC)*. The SC route is ideal for drugs that have to be administered parenterally because of low oral bioavailability, are absorbed well from subcutaneous fat, and might ideally be injected by patients themselves (e.g. insulin, heparin).
- *Transdermal.* A transdermal patch can enable a drug to be absorbed through the skin and into the circulation (e.g. oestrogens, nicotine, nitrates).

Other routes of administration

- *Topical* application of a drug involves direct administration to the site of action (e.g. skin, eye, ear). This has the advantage of achieving sufficient concentration at this site while minimising systemic exposure and the risk of adverse effects elsewhere.
- *Inhaled (INH)* administration allows drugs to be delivered directly to a target in the respiratory tree, usually the small airways (e.g. salbutamol, beclometasone). However, a significant proportion of the inhaled dose may be absorbed from the lung or is swallowed and can reach the systemic circulation. The most common mode of delivery is the metered-dose inhaler but its success depends on some degree of manual dexterity and timing (see Fig. 17.23, p. 571). Patients who find these difficult may use a 'spacer' device to improve drug delivery. A special mode

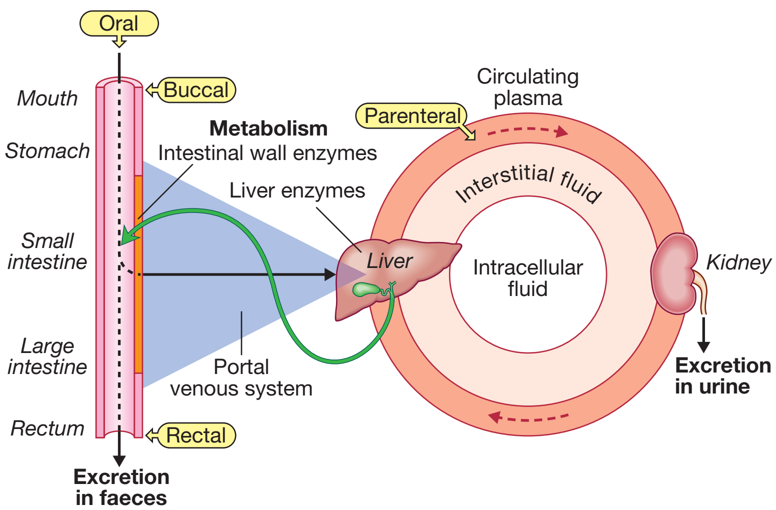

Fig. 2.3 Pharmacokinetics summary. Most drugs are taken orally, are absorbed from the intestinal lumen and enter the portal venous system to be conveyed to the liver, where they may be subject to first-pass metabolism and/or excretion in bile. Active drugs then enter the systemic circulation, from which they may diffuse (or sometimes be actively transported) in and out of the interstitial and intracellular fluid compartments. Drug that remains in circulating plasma is subject to liver metabolism and renal excretion. Drugs excreted in bile may be reabsorbed, creating an enterohepatic circulation. First-pass metabolism in the liver is avoided if drugs are administered via the buccal or rectal mucosa, or parenterally (e.g. by intravenous injection).

of inhaled delivery is via a nebulised solution created by using pressurised oxygen or air to break up solutions and suspensions into small aerosol droplets that can be directly inhaled from the mouthpiece of the device.

Drug distribution

Distribution is the process by which drug molecules transfer into and out of the blood stream. This is influenced by the drug's molecular size and lipid solubility, the extent to which it binds to proteins in plasma, its susceptibility to drug transporters expressed on cell surfaces, and its binding to its molecular target and to other cellular proteins (which can be irreversible). Most drugs diffuse passively across capillary walls down a concentration gradient into the interstitial fluid until the concentration of free drug molecules in the interstitial fluid is equal to that in the plasma. As drug molecules in the blood are removed by metabolism or excretion, the plasma concentration falls, drug molecules diffuse back from the tissue compartment into the blood and eventually all will be eliminated. Note that this reverse movement of drug away from the tissues will be prevented if further drug doses are administered and absorbed into the plasma.

Volume of distribution

The apparent volume of distribution (V_d) is the volume into which a drug appears to have distributed following intravenous injection. It is calculated from the equation

$$V_d = D/C_0$$

where D is the amount of drug given and C_0 is the initial plasma concentration (Fig. 2.4A). Drugs that are highly bound to plasma proteins may have a V_d below 10 L (e.g. warfarin, aspirin), while those that diffuse into the interstitial fluid but do not enter cells because they have low lipid solubility may have a V_d between 10 and 30 L (e.g. gentamicin, amoxicillin). It is an 'apparent' volume because those drugs that are lipid-soluble and highly tissue-bound may have a V_d of greater than 100 L (e.g. digoxin, amitriptyline). Drugs with a larger V_d have longer half-lives (see below), take longer to reach steady state on repeated administration and are eliminated more slowly from the body following discontinuation.

Drug elimination

Drug metabolism

Metabolism is the process by which drugs are chemically altered from a lipid-soluble form suitable for absorption and distribution to a more water-soluble form that is necessary for excretion. Some drugs, known as 'prodrugs', are inactive in the form in which they are administered but are converted to an active metabolite in vivo.

Phase I metabolism involves oxidation, reduction or hydrolysis to make drug molecules suitable for phase II reactions or for excretion. Oxidation is by far the most common form of phase I reaction and chiefly involves members of the cytochrome P450 family of membrane-bound enzymes in the endoplasmic reticulum of hepatocytes.

Phase II metabolism involves combining phase I metabolites with an endogenous substrate to form an inactive conjugate that is much more water-soluble. Reactions include glucuronidation, sulphation, acetylation, methylation and conjugation with glutathione. This is necessary to enable renal excretion, because lipid-soluble metabolites will simply diffuse back into the body after glomerular filtration (p. 349).

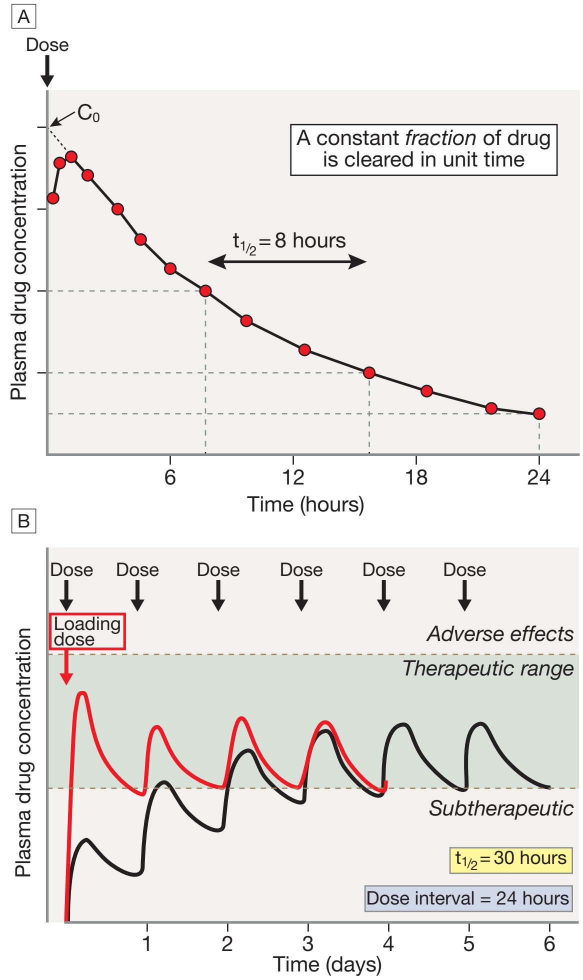

Fig. 2.4 Drug concentrations in plasma following single and multiple drug dosing. **A** In this example of first-order kinetics following a single intravenous dose, the time period required for the plasma drug concentration to halve (half-life, $t_{1/2}$) remains constant throughout the elimination process. **B** After multiple dosing, the plasma drug concentration rises if each dose is administered before the previous dose has been entirely cleared. In this example, the drug's half-life is 30 hours, so that with daily dosing the peak, average and trough concentrations steadily increase as drug accumulates in the body (black line). Steady state is reached after approximately 5 half-lives, when the rate of elimination (the product of concentration and clearance) is equal to the rate of drug absorption (the product of rate of administration and bioavailability). The long half-life in this example means that it takes 6 days for steady state to be achieved and, for most of the first 3 days of treatment, plasma drug concentrations are below the therapeutic range. This problem can be overcome if a larger loading dose (red line) is used to achieve steady-state drug concentrations more rapidly.

Drug excretion

Excretion is the process by which drugs and their metabolites are removed from the body.

Renal excretion is the usual route of elimination for drugs or their metabolites that are of low molecular weight and sufficiently water-soluble to avoid reabsorption from the renal tubule. Drugs bound to plasma proteins are not filtered by the glomeruli. The pH of the urine is more acidic than that of plasma, so that some drugs (e.g. salicylates) become un-ionised and tend to

be reabsorbed. Alkalination of the urine can hasten excretion (e.g. after a salicylate overdose; p. 138). For some drugs, active secretion into the proximal tubule lumen, rather than glomerular filtration, is the predominant mechanism of excretion (e.g. methotrexate, penicillin).

Faecal excretion is the predominant route of elimination for drugs with high molecular weight, including those that are excreted in the bile after conjugation with glucuronide in the liver, and any drugs that are not absorbed after enteral administration. Molecules of drug or metabolite that are excreted in the bile enter the small intestine, where they may, if they are sufficiently lipid-soluble, be reabsorbed through the gut wall and return to the liver via the portal vein (see Fig. 2.3). This recycling between the liver, bile, gut and portal vein is known as 'enterohepatic circulation' and can significantly prolong the residence of drugs in the body.

Elimination kinetics

The net removal of drug from the circulation results from a combination of drug metabolism and excretion, and is usually described as 'clearance', i.e. the volume of plasma that is completely cleared of drug per unit time.

For most drugs, elimination is a high-capacity process that does not become saturated, even at high dosage. The rate of elimination is therefore directly proportional to the drug concentration because of the 'law of mass action', whereby higher drug concentrations will drive faster metabolic reactions and support higher renal filtration rates. This results in 'first-order' kinetics, when a constant fraction of the drug remaining in the circulation is eliminated in a given time and the decline in concentration over time is exponential (Fig. 2.4A). This elimination can be described by the drug's half-life ($t_{1/2}$), i.e. the time taken for the plasma drug concentration to halve, which remains constant throughout the period of drug elimination. The significance of this phenomenon for prescribers is that the effect of increasing doses on plasma concentration is predictable – a doubled dose leads to a doubled concentration at all time points.

For a few drugs in common use (e.g. phenytoin, alcohol), elimination capacity is exceeded (saturated) within the usual dose range. This is called 'zero-order' kinetics. Its significance for prescribers is that, if the rate of administration exceeds the maximum rate of elimination, the drug will accumulate progressively, leading to serious toxicity.

Repeated dose regimens

The goal of therapy is usually to maintain drug concentrations within the therapeutic range (see Fig. 2.2) over several days (e.g. antibiotics) or even for months or years (e.g. antihypertensives, lipid-lowering drugs, thyroid hormone replacement therapy). This goal is rarely achieved with single doses, so prescribers have to plan a regimen of repeated doses. This involves choosing the size of each individual dose and the frequency of dose administration.

As illustrated in Figure 2.4B, the time taken to reach drug concentrations within the therapeutic range depends on the half-life of the drug. Typically, with doses administered regularly, it takes approximately 5 half-lives to reach a 'steady state' in which the rate of drug elimination is equal to the rate of drug administration. This applies when starting new drugs and when adjusting doses of current drugs. With appropriate dose selection, steady-state drug concentrations will be maintained within the therapeutic range. This is important for prescribers because it means that the effects of a new prescription, or dose titration, for a drug with a long half-life (e.g. digoxin – 36 hours) may not be known for a few days. In contrast, drugs with a very short half-life (e.g. dobutamine – 2 minutes) have to be given continuously by infusion but reach a new steady state within minutes.

For drugs with a long half-life, if it is unacceptable to wait for 5 half-lives until concentrations within the therapeutic range are achieved, then an initial 'loading dose' can be given that is much larger than the maintenance dose and equivalent to the amount of drug required in the body at steady state. This achieves a peak plasma concentration close to the plateau concentration, which can then be maintained by successive maintenance doses.

'Steady state' actually involves fluctuations in drug concentrations, with peaks just after administration followed by troughs just prior to the next administration. The manufacturers of medicines recommend dosing regimens that predict that, for most patients, these oscillations result in troughs within the therapeutic range and peaks that are not high enough to cause adverse effects. The optimal dose interval is a compromise between convenience for the patient and a constant level of drug exposure. More frequent administration (e.g. 25 mg 4 times daily) achieves a smoother plasma concentration profile than 100 mg once daily but is much more difficult for patients to sustain. A solution to this need for compromise in dosing frequency for drugs with half-lives of less than 24 hours is the use of 'modified-release' formulations. These allow drugs to be absorbed more slowly from the gastrointestinal tract and reduce the oscillation in plasma drug concentration profile, which is especially important for drugs with a low therapeutic index (e.g. levodopa).

Inter-individual variation in drug responses

Prescribers have numerous sources of guidance about how to use drugs appropriately (e.g. dose, route, frequency, duration) for many conditions. However, this advice is based on average dose–response data derived from observations in many individuals. When applying this information to an individual patient, prescribers must take account of inter-individual variability in response. Some of this variability is predictable and good prescribers are able to anticipate it and adjust their prescriptions accordingly to maximise the chances of benefit and minimise harm. Inter-individual variation in responses also mandates that effects of treatment should be monitored (p. 34).

Some inter-individual variation in drug response is accounted for by differences in pharmacodynamics. For example, the beneficial natriuresis produced by the loop diuretic furosemide is often significantly reduced at a given dose in patients with renal impairment, while delirium caused by opioid analgesics is more likely in the elderly. Differences in pharmacokinetics more commonly account for different drug responses, however. Examples of factors influencing the absorption, metabolism and excretion of drugs are shown in Box 2.4.

It is hoped that a significant proportion of the inter-individual variation in drug responses can be explained by studying genetic differences in single genes ('pharmacogenetics'; Box 2.5) or the effects of multiple gene variants ('pharmacogenomics'). The aim is to identify those patients most likely to benefit from specific treatments and those most susceptible to adverse effects. In this way, it may be possible to select drugs and dose regimens for individual patients to maximise the benefit-to-hazard ratio ('personalised medicine').

2.4 Patient-specific factors that influence pharmacokinetics

Age
- Drug metabolism is low in the fetus and newborn, may be enhanced in young children, and becomes less effective with age
- Drug excretion falls with the age-related decline in renal function

Sex
- Women have a greater proportion of body fat than men, increasing the volume of distribution and half-life of lipid-soluble drugs

Body weight
- Obesity increases volume of distribution and half-life of lipid-soluble drugs
- Patients with higher lean body mass have larger body compartments into which drugs are distributed and may require higher doses

Liver function
- Metabolism of most drugs depends on several cytochrome P450 enzymes that are impaired in patients with advanced liver disease
- Hypoalbuminaemia influences the distribution of drugs that are highly protein-bound

Kidney function
- Renal disease and the decline in renal function with ageing may lead to drug accumulation

Gastrointestinal function
- Small intestinal absorption of oral drugs may be delayed by reduced gastric motility
- Absorptive capacity of the intestinal mucosa may be reduced in disease (e.g. Crohn's or coeliac disease) or after surgical resection

Food
- Food in the stomach delays gastric emptying and reduces the rate (but not usually the extent) of drug absorption
- Some food constituents bind to certain drugs and prevent their absorption

Smoking
- Tar in tobacco smoke stimulates the oxidation of certain drugs

Alcohol
- Regular alcohol consumption stimulates liver enzyme synthesis, while binge drinking may temporarily inhibit drug metabolism

Drugs
- Drug–drug interactions cause marked variation in pharmacokinetics (see Box 2.11)

2.5 Examples of pharmacogenetic variations that influence drug response

Genetic variant	Drug affected	Clinical outcome
Pharmacokinetic		
Aldehyde dehydrogenase-2 deficiency	Ethanol	Elevated blood acetaldehyde causes facial flushing and increased heart rate in ~50% of Japanese, Chinese and other Asian populations
Acetylation	Isoniazid, hydralazine, procainamide	Increased responses in slow acetylators, up to 50% of some populations
Oxidation (CYP2D6)	Nortriptyline	Increased risk of toxicity in poor metabolisers
	Codeine	Reduced responses with slower conversion of codeine to more active morphine in poor metabolisers, 10% of European populations Increased risk of toxicity in ultra-fast metabolisers, 3% of Europeans but 40% of North Africans
Oxidation (CYP2C18)	Proguanil	Reduced efficacy with slower conversion to active cycloguanil in poor metabolisers
Oxidation (CYP2C9)	Warfarin	Polymorphisms known to influence dosages
Oxidation (CYP2C19)	Clopidogrel	Reduced enzymatic activation results in reduced antiplatelet effect
Sulphoxidation	Penicillamine	Increased risk of toxicity in poor metabolisers
Human leucocyte antigen (HLA)-B*1502	Carbamazepine	Increased risk of serious dermatological reactions (e.g. Stevens–Johnson syndrome) for 1 in 2000 in Caucasian populations (much higher in some Asian countries)
Pseudocholinesterase deficiency	Suxamethonium (succinylcholine)	Decreased drug inactivation leads to prolonged paralysis and sometimes persistent apnoea requiring mechanical ventilation until the drug can be eliminated by alternate pathways; occurs in 1 in 1500 people
Pharmacodynamic		
Glucose-6-phosphate dehydrogenase (G6PD) deficiency	Oxidant drugs, including antimalarials (e.g. chloroquine, primaquine)	Risk of haemolysis in G6PD deficiency
Acute intermittent porphyria	Enzyme-inducing drugs	Increased risk of an acute attack
SLC01B1 polymorphism	Statins	Increased risk of rhabdomyolysis
HLA-B*5701 polymorphism	Abacavir	Increased risk of skin hypersensitivity reactions
HLA-B*5801 polymorphism	Allopurinol	Increased risk of rashes in Han Chinese
HLA-B*1502 polymorphism	Carbamazepine	Increased risk of skin hypersensitivity reactions in Han Chinese
Hepatic nuclear factor 1 alpha (HNF1A) polymorphism	Sulphonylureas	Increased sensitivity to the blood glucose-lowering effects
Human epidermal growth factor receptor 2 (HER2)-positive breast cancer cells	Trastuzumab	Increased sensitivity to the inhibitory effects on growth and division of the target cancer cells

Adverse outcomes of drug therapy

The decision to prescribe a drug always involves a judgement of the balance between therapeutic benefits and risk of an adverse outcome. Both prescribers and patients tend to be more focused on the former but a truly informed decision requires consideration of both.

Adverse drug reactions

Some important definitions for the adverse effects of drugs are:

- *Adverse event.* A harmful event that occurs while a patient is taking a drug, irrespective of whether the drug is suspected of being the cause.
- *Adverse drug reaction (ADR).* An unwanted or harmful reaction that is experienced following the administration of a drug or combination of drugs under normal conditions of use and is suspected to be related to the drug. An ADR will usually require the drug to be discontinued or the dose reduced.
- *Side-effect.* Any effect caused by a drug other than the intended therapeutic effect, whether beneficial, neutral or harmful. The term 'side-effect' is often used interchangeably with 'ADR', although the former usually implies an ADR that occurs during exposure to normal therapeutic drug concentrations (e.g. vasodilator-induced ankle oedema).
- *Hypersensitivity reaction.* An ADR that occurs as a result of an immunological reaction and often at exposure to subtherapeutic drug concentrations. Some of these reactions are immediate and result from the interaction of drug antigens with immunoglobulin E (IgE) on mast cells and basophils, which causes a release of vasoactive biomolecules (e.g. penicillin-related anaphylaxis). 'Anaphylactoid' reactions present similarly but occur through a direct non-immune-mediated release of the same mediators or result from direct complement activation (p. 75). Hypersensitivity reactions may occur via other mechanisms such as antibody-dependent (IgM or IgG), immune complex-mediated or cell-mediated pathways.
- *Drug toxicity.* Adverse effects of a drug that occur because the dose or plasma concentration has risen above the therapeutic range, either unintentionally or intentionally (drug overdose; see Fig. 2.2 and p. 137).
- *Drug abuse.* The misuse of recreational or therapeutic drugs that may lead to addiction or dependence, serious physiological injury (such as liver damage), psychological harm (abnormal behaviour patterns, hallucinations, memory loss) or death (p. 1184).

Prevalence of ADRs

ADRs are a common cause of illness, accounting in the UK for approximately 3% of consultations in primary care and 7% of emergency admissions to hospital, and affecting around 15% of hospital inpatients. Many 'disease' presentations are eventually attributed to ADRs, emphasising the importance of always taking a careful drug history (Box 2.6). Factors accounting for the rising prevalence of ADRs are the increasing age of patients, polypharmacy (higher risk of drug interactions), increasing availability of over-the-counter medicines, increasing use of herbal or traditional medicines, and the increase in medicines available via the Internet that can be purchased without a prescription from a health-care professional. Risk factors for ADRs are shown in Box 2.7.

2.6 How to take a drug history

Information from the patient (or carer)

Use language that patients will understand (e.g. 'medicines' rather than 'drugs', which may be mistaken for drugs of abuse) while gathering the following information:

- Current prescribed drugs, including formulations (e.g. modified-release tablets), doses, routes of administration, frequency and timing, duration of treatment
- Other medications that are often forgotten (e.g. contraceptives, over-the-counter drugs, herbal remedies, vitamins)
- Drugs that have been taken in the recent past and reasons for stopping them
- Previous drug hypersensitivity reactions, their nature and time course (e.g. rash, anaphylaxis)
- Previous ADRs, their nature and time course (e.g. ankle oedema with amlodipine)
- Adherence to therapy (e.g. 'Are you taking your medication regularly?')

Information from GP medical records and/or pharmacist

- Up-to-date list of medications
- Previous ADRs
- Last order dates for each medication

Inspection of medicines

- Drugs and their containers (e.g. blister packs, bottles, vials) should be inspected for name, dosage, and the number of dosage forms taken since dispensed

(ADR = adverse drug reaction)

2.7 Risk factors for adverse drug reactions

Patient factors

- Elderly age (e.g. low physiological reserve)
- Gender (e.g. ACE inhibitor-induced cough in women)
- Polypharmacy (e.g. drug interactions)
- Genetic predisposition (see Box 2.5)
- Hypersensitivity/allergy (e.g. β-lactam antibiotics)
- Diseases altering pharmacokinetics (e.g. hepatic or renal impairment) or pharmacodynamic responses (e.g. bladder instability)
- Adherence problems (e.g. cognitive impairment)

Drug factors

- Steep dose–response curve (e.g. insulin)
- Low therapeutic index (e.g. digoxin, cytotoxic drugs)

Prescriber factors

- Inadequate understanding of principles of clinical pharmacology
- Inadequate knowledge of the patient
- Inadequate knowledge of the prescribed drug
- Inadequate instructions and warnings provided to patients
- Inadequate monitoring arrangements planned

(ACE = angiotensin-converting enzyme)

ADRs are important because they reduce quality of life for patients, reduce adherence to and therefore efficacy of beneficial treatments, cause diagnostic confusion, undermine the confidence of patients in their health-care professional(s) and consume health-care resources.

Retrospective analysis of ADRs has shown that more than half could have been avoided if the prescriber had taken more care in anticipating the potential hazards of drug therapy. For example, non-steroidal anti-inflammatory drug (NSAID) use accounts for many thousands of emergency admissions, gastrointestinal bleeding episodes and a significant number of deaths. In many cases, the patients are at increased risk due to their age, interacting drugs (e.g. aspirin, warfarin) or a past history of peptic ulcer disease. Drugs that commonly cause ADRs are listed in Box 2.8.

Prescribers and their patients ideally want to know the frequency with which ADRs occur for a specific drug. Although this may be well characterised for more common ADRs observed in clinical trials, it is less clear for rarely reported ADRs when the total numbers of reactions and patients exposed are not known. The words used to describe frequency can be misinterpreted by patients but widely accepted meanings include: very common (10% or more), common (1–10%), uncommon (0.1–1%), rare (0.01–0.1%) and very rare (0.01% or less).

Classification of ADRs

ADRs have traditionally been classified into two major groups:

- *Type A ('augmented') ADRs*. These are predictable from the known pharmacodynamic effects of the drug and are dose-dependent, common (detected early in drug development) and usually mild. Examples include constipation caused by opioids, hypotension caused by antihypertensives and dehydration caused by diuretics.
- *Type B ('bizarre') ADRs*. These are not predictable, are not obviously dose-dependent in the therapeutic range, are rare (remaining undiscovered until the drug is marketed) and often severe. Patients who experience type B reactions are generally 'hyper-susceptible' because of unpredictable immunological or genetic factors (e.g. anaphylaxis caused by penicillin, peripheral neuropathy caused by isoniazid in poor acetylators).

This simple classification has shortcomings, and a more detailed classification based on dose (see Fig. 2.2), timing and susceptibility (DoTS) is now used by those analysing ADRs in greater depth (Box 2.9). The AB classification can be extended as a reminder of some other types of ADR:

- *Type C ('chronic/continuous') ADRs*. These occur only after prolonged continuous exposure to a drug. Examples include osteoporosis caused by glucocorticoids, retinopathy caused by chloroquine, and tardive dyskinesia caused by phenothiazines.
- *Type D ('delayed') ADRs*. These are delayed until long after drug exposure, making diagnosis difficult. Examples include malignancies that may emerge after immunosuppressive treatment post-transplantation (e.g. azathioprine, tacrolimus) and vaginal cancer occurring many years after exposure to diethylstilboestrol.
- *Type E ('end-of-treatment') ADRs*. These occur after abrupt drug withdrawal (see Box 2.3).

A teratogen is a drug with the potential to affect the development of the fetus in the first 10 weeks of intrauterine life (e.g. phenytoin, warfarin). The thalidomide disaster in the early 1960s highlighted the risk of teratogenicity and led to mandatory testing of all new drugs. Congenital defects in a live infant or aborted fetus should

2.8 Drugs that are common causes of adverse drug reactions

Drug or drug class	Common adverse drug reactions
ACE inhibitors (e.g. lisinopril)	Renal impairment Hyperkalaemia
Antibiotics (e.g. amoxicillin)	Nausea Diarrhoea
Anticoagulants (e.g. warfarin, heparin)	Bleeding
Antipsychotics (e.g. haloperidol)	Falls Sedation Delirium
Aspirin	Gastrotoxicity (dyspepsia, gastrointestinal bleeding)
Benzodiazepines (e.g. diazepam)	Drowsiness Falls
β-blockers (e.g. atenolol)	Cold peripheries Bradycardia
Calcium channel blockers (e.g. amlodipine)	Ankle oedema
Digoxin	Nausea and anorexia Bradycardia
Diuretics (e.g. furosemide, bendroflumethiazide)	Dehydration Electrolyte disturbance (hypokalaemia, hyponatraemia) Hypotension Renal impairment
Insulin	Hypoglycaemia
NSAIDs (e.g. ibuprofen)	Gastrotoxicity (dyspepsia, gastrointestinal bleeding) Renal impairment
Opioid analgesics (e.g. morphine)	Nausea and vomiting Delirium Constipation

(ACE = angiotensin-converting enzyme; NSAID = non-steroidal anti-inflammatory drug)

2.9 DoTS classification of adverse drug reactions

Category	Example
Dose	
Below therapeutic dose	Anaphylaxis with penicillin
In the therapeutic dose range	Nausea with morphine
At high doses	Hepatotoxicity with paracetamol
Timing	
With the first dose	Anaphylaxis with penicillin
Early stages of treatment	Hyponatraemia with diuretics
On stopping treatment	Benzodiazepine withdrawal syndrome
Significantly delayed	Clear-cell cancer with diethylstilboestrol
Susceptibility	See patient factors in Box 2.7

(INR = international normalised ratio)

provoke suspicion of an ADR and a careful exploration of drug exposures (including self-medication and herbal remedies).

Detecting ADRs – pharmacovigilance

Type A ADRs become apparent early in the development of a new drug. By the time a new drug is licensed and launched on to a possible worldwide market, however, a relatively small number of patients (just several hundred) may have been exposed to it, meaning that rarer but potentially serious type B ADRs may remain undiscovered. Pharmacovigilance is the process of detecting ('signal generation') and evaluating ADRs in order to help prescribers and patients to be better informed about the risks of drug therapy. Drug regulatory agencies may respond to this information by placing restrictions on the licensed indications, reducing the recommended dose range, adding special warnings and precautions for prescribers in the product literature, writing to all health-care professionals or withdrawing the product from the market.

Voluntary reporting systems allow health-care professionals and patients to report suspected ADRs to the regulatory authorities. A good example is the 'Yellow Card' scheme that was set up in the UK in response to the thalidomide tragedy. Reports are analysed to assess the likelihood that they represent a true ADR (Box 2.10). Although voluntary reporting is a continuously operating and effective early-warning system for previously unrecognised rare ADRs, its weaknesses include low reporting rates (only 3% of all ADRs and 10% of serious ADRs are ever reported), an inability to quantify risk (because the ratio of ADRs to prescriptions is unknown), and the influence of prescriber awareness on likelihood of reporting (reporting rates rise rapidly following publicity about potential ADRs).

More systematic approaches to collecting information on ADRs include 'prescription event monitoring', in which a sample of prescribers of a particular drug are issued with questionnaires concerning the clinical outcome for their patients, and the collection of population statistics. Many health-care systems routinely collect patient-identifiable data on prescriptions (a surrogate marker of exposure to a drug), health-care events (e.g. hospitalisation, operations, new clinical diagnoses) and other clinical data (e.g. haematology, biochemistry). As these records are linked, with appropriate safeguards for confidentiality and data protection, they are providing a much more powerful mechanism for assessing both the harms and benefits of drugs.

All prescribers will inevitably see patients experiencing ADRs caused by prescriptions written by themselves or their colleagues. It is important that these are recognised early. In addition to the features in Box 2.10, features that should raise suspicion of an ADR and the need to respond (by drug withdrawal, dosage reduction or reporting to the regulatory authorities) include:

- concern expressed by a patient that a drug has harmed them
- abnormal clinical measurements (e.g. blood pressure, temperature, pulse, blood glucose and weight) or laboratory results (e.g. abnormal liver or renal function, low haemoglobin or white cell count) while on drug therapy
- new therapy started that could be in response to an ADR (e.g. omeprazole, allopurinol, naloxone)
- the presence of risk factors for ADRs (see Box 2.7).

i 2.10 TREND analysis of suspected adverse drug reactions

Factor	Key question	Comment
Temporal relationship	What is the time interval between the start of drug therapy and the reaction?	Most ADRs occur soon after starting treatment and within hours in the case of anaphylactic reactions
Re-challenge	What happens when the patient is re-challenged with the drug?	Re-challenge is rarely possible because of the need to avoid exposing patients to unnecessary risk
Exclusion	Have concomitant drugs and other non-drug causes been excluded?	ADR is a diagnosis of exclusion following clinical assessment and relevant investigations for non-drug causes
Novelty	Has the reaction been reported before?	The suspected ADR may already be recognised and mentioned in the SPC approved by the regulatory authorities
De-challenge	Does the reaction improve when the drug is withdrawn or the dose is reduced?	Most, but not all, ADRs improve on drug withdrawal, although recovery may be slow

(SPC = summary of product characteristics)

Drug interactions

A drug interaction has occurred when the administration of one drug increases or decreases the beneficial or adverse responses to another drug. Although the number of potential interacting drug combinations is very large, only a small number are common in clinical practice. Important drug interactions are most likely to occur when the affected drug has a low therapeutic index, steep dose–response curve, high first-pass or saturable metabolism, or a single mechanism of elimination.

Mechanisms of drug interactions

Pharmacodynamic interactions occur when two drugs produce additive, synergistic or antagonistic effects at the same drug target (e.g. receptor, enzyme) or physiological system (e.g. electrolyte excretion, heart rate). These are the most common interactions in clinical practice and some important examples are given in Box 2.11.

Pharmacokinetic interactions occur when the administration of a second drug alters the concentration of the first at its site of action. There are numerous potential mechanisms:

- *Absorption interactions.* Drugs that either delay (e.g. anticholinergic drugs) or enhance (e.g. prokinetic drugs) gastric emptying influence the rate of rise in plasma concentration of other drugs but not the total amount of drug absorbed. Drugs that bind to form insoluble complexes or chelates (e.g. aluminium-containing antacids binding with ciprofloxacin) can reduce drug absorption.
- *Distribution interactions*. Co-administration of drugs that compete for protein binding in plasma (e.g. phenytoin and diazepam) can increase the unbound drug concentration, but the effect is usually short-lived due to increased elimination and hence restoration of the pre-interaction equilibrium.

i 2.11 Common drug interactions

Mechanism	Object drug	Precipitant drug	Result
Pharmaceutical*			
Chemical reaction	Sodium bicarbonate	Calcium gluconate	Precipitation of insoluble calcium carbonate
Pharmacokinetic			
Reduced absorption	Tetracyclines	Calcium, aluminium, and magnesium salts	Reduced tetracycline absorption
Reduced protein binding	Phenytoin	Aspirin	Increased unbound and reduced total phenytoin plasma concentration
Reduced metabolism:			
CYP3A4	Amiodarone	Grapefruit juice	Cardiac arrhythmias because of prolonged QT interval (p. 476)
	Warfarin	Clarithromycin	Enhanced anticoagulation
CYP2C19	Phenytoin	Omeprazole	Phenytoin toxicity
CYP2D6	Clozapine	Paroxetine	Clozapine toxicity
Xanthine oxidase	Azathioprine	Allopurinol	Azathioprine toxicity
Monoamine oxidase	Catecholamines	Monoamine oxidase inhibitors	Hypertensive crisis due to monoamine toxicity
Increased metabolism (enzyme induction)	Ciclosporin	St John's wort	Loss of immunosuppression
Reduced renal elimination	Lithium	Diuretics	Lithium toxicity
	Methotrexate	NSAIDs	Methotrexate toxicity
Pharmacodynamic			
Direct antagonism at same receptor	Opioids	Naloxone	Reversal of opioid effects used therapeutically
	Salbutamol	Atenolol	Inhibits bronchodilator effect
Direct potentiation in same organ system	Benzodiazepines	Alcohol	Increased sedation
	ACE inhibitors	NSAIDs	Increased risk of renal impairment
Indirect potentiation by actions in different organ systems	Digoxin	Diuretics	Digoxin toxicity enhanced because of hypokalaemia
	Warfarin	Aspirin, NSAIDs	Increased risk of bleeding because of gastrotoxicity and antiplatelet effects
	Diuretics	ACE inhibitors	Blood pressure reduction (may be therapeutically advantageous) because of the increased activity of the renin–angiotensin system in response to diuresis

*Pharmaceutical interactions are related to the formulation of the drugs and occur before drug absorption.
(ACE = angiotensin-converting enzyme; NSAID = non-steroidal anti-inflammatory drug)

- *Metabolism interactions*. Many drugs rely on metabolism by different isoenzymes of cytochrome P450 (CYP) in the liver. CYP enzyme inducers (e.g. phenytoin, rifampicin) generally reduce plasma concentrations of other drugs, although they may enhance activation of prodrugs. CYP enzyme inhibitors (e.g. clarithromycin, cimetidine, grapefruit juice) have the opposite effect. Enzyme induction effects usually take a few days to manifest because of the need to synthesise new CYP enzyme, in contrast to the rapid effects of enzyme inhibition.
- *Excretion interactions*. These primarily affect renal excretion. For example, drug-induced reduction in glomerular filtration rate (e.g. diuretic-induced dehydration, angiotensin-converting enzyme (ACE) inhibitors, NSAIDs) can reduce the clearance and increase the plasma concentration of many drugs, including some with a low therapeutic index (e.g. digoxin, lithium, aminoglycoside antibiotics). Less commonly, interactions may be due to competition for a common tubular organic anion transporter (e.g. methotrexate excretion may be inhibited by competition with NSAIDs).

Avoiding drug interactions

Drug interactions are increasing as patients are prescribed more medicines (polypharmacy). Prescribers can avoid the adverse consequences of drug–drug interactions by taking a careful drug history (see Box 2.6) before prescribing additional drugs, only prescribing for clear indications, and taking special care when prescribing drugs with a narrow therapeutic index (e.g. warfarin). When prescribing an interacting drug is unavoidable, good prescribers will seek further information and anticipate the potential risk. This will allow them to provide special warnings for the patient and arrange for monitoring, either of the clinical effects (e.g. coagulation tests for warfarin) or of plasma concentration (e.g. digoxin).

Medication errors

A medication error is any *preventable* event that may lead to inappropriate medication use or patient harm while the medication is in the control of the health-care professional or patient. Errors may occur in prescribing, dispensing, preparing solutions, administration or monitoring. Many ADRs are considered in retrospect to have been 'avoidable' with more care or forethought; in other words, an adverse event considered by one prescriber to be an unfortunate ADR might be considered by another to be a prescribing error.

Medication errors are very common. Several thousand medication orders are dispensed and administered each day in a medium-sized hospital. Recent UK studies suggest that

2.12 Hospital prescribing errors

Error type	Approximate % of total
Omission on admission	30
Underdose	11
Overdose	8
Strength/dose missing	7
Omission on discharge	6
Administration times incorrect/missing	6
Duplication	6
Product or formulation not specified	4
Incorrect formulation	4
No maximum dose	4
Unintentional prescribing	3
No signature	2
Clinical contraindication	1
Incorrect route	1
No indication	1
Intravenous instructions incorrect/missing	1
Drug not prescribed but indicated	1
Drug continued for longer than needed	1
Route of administration missing	1
Start date incorrect/missing	1
Risk of drug interaction	<0.5
Controlled drug requirements incorrect/missing	<0.5
Daily dose divided incorrectly	<0.5
Significant allergy	<0.5
Drug continued in spite of adverse effects	<0.5
Premature discontinuation	<0.5
Failure to respond to out-of-range drug level	<0.5

7–9% of hospital prescriptions contain an error, and most are written by junior doctors. Common prescribing errors in hospitals include omission of medicines (especially failure to prescribe regular medicines at the point of admission or discharge, i.e. 'medicines reconciliation'), dosing errors, unintentional prescribing and poor use of documentation (Box 2.12).

Most prescription errors result from a combination of failures by the individual prescriber and the health-service systems in which they work (Box 2.13). Health-care organisations increasingly encourage reporting of errors within a 'no-blame culture' so that they can be subject to 'root cause analysis' using human error theory (Fig. 2.5). Prevention is targeted at the factors in Box 2.13, and can be supported by prescribers communicating and cross-checking with colleagues (e.g. when calculating doses adjusted for body weight, or planning appropriate monitoring after drug administration), and by health-care systems providing clinical pharmacist support (e.g. for checking the patient's previous medications and current prescriptions) and electronic prescribing (which avoids errors due to illegibility or serious dosing mistakes, and may be combined with a clinical decision support system to take account of patient characteristics and drug history, and provide warnings of potential contraindications and drug interactions).

2.13 Causes of prescribing errors

Systems factors

- Working hours of prescribers (and others)
- Patient throughput
- Professional support and supervision by colleagues
- Availability of information (medical records)
- Design of prescription forms
- Distractions
- Availability of decision support
- Checking routines (e.g. clinical pharmacy)
- Reporting and reviewing of incidents

Prescriber factors

Knowledge

- Clinical pharmacology principles
- Drugs in common use
- Therapeutic problems commonly encountered
- Knowledge of workplace systems

Skills

- Taking a good drug history
- Obtaining information to support prescribing
- Communicating with patients
- Numeracy and calculations
- Prescription writing

Attitudes

- Coping with risk and uncertainty
- Monitoring of prescribing
- Checking routines

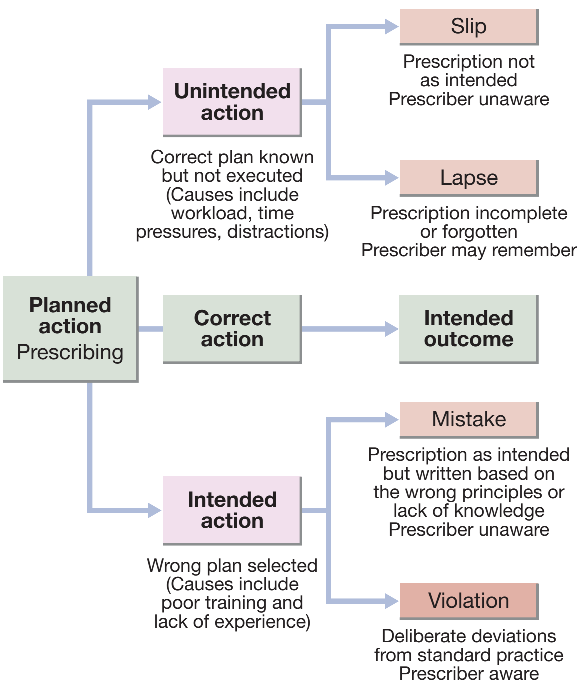

Fig. 2.5 Human error theory. Unintended errors may occur because the prescriber fails to complete the prescription correctly (a slip; e.g. writes the dose in 'mg' not 'micrograms') or forgets part of the action that is important for success (a lapse; e.g. forgets to co-prescribe folic acid with methotrexate); prevention requires the system to provide appropriate checking routines. Intended errors occur when the prescriber acts incorrectly due to lack of knowledge (a mistake; e.g. prescribes atenolol for a patient with known severe asthma because of ignorance about the contraindication); prevention must focus on training the prescriber.

Responding when an error is discovered

All prescribers will make errors. When they do, their first duty is to protect the patient's safety. This will involve a clinical review and the taking of any steps that will reduce harm (e.g. remedial treatment, monitoring, recording the event in the notes, informing colleagues). Patients should be informed if they have been exposed to potential harm. For errors that do not reach the patient, it is the prescriber's duty to report them, so that others can learn from the experience and take the opportunity to reflect on how a similar incident might be avoided in the future.

Drug regulation and management

Given the powerful beneficial and potentially adverse effects of drugs, the production and use of medicines are strictly regulated (e.g. by the Food and Drug Administration in the USA, Medicines and Healthcare Products Regulatory Agency in the UK, and Central Drugs Standard Control Organisation in India). Regulators are responsible for licensing medicines, monitoring their safety (pharmacovigilance; p. 23), approving clinical trials, and inspecting and maintaining standards of drug development and manufacture.

In addition, because of the high costs of drugs and their adverse effects, health-care services must prioritise their use in light of the evidence of their benefit and harm, a process referred to as 'medicines management'.

Drug development and marketing

Naturally occurring products have been used to treat illnesses for thousands of years and some remain in common use today. Examples include morphine from the opium poppy (*Papaver somniferum*), digitalis from the foxglove (*Digitalis purpurea*), curare from the bark of a variety of species of South American trees, and quinine from the bark of the *Cinchona* species. Although plants and animals remain a source of discovery, the majority of new drugs come from drug discovery programmes that aim to identify small-molecule compounds with specific interactions with a molecular target that will induce a predicted biological effect.

The usual pathway for development of these small molecules includes: identifying a plausible molecular target by investigating pathways in disease; screening a large library of compounds for those that interact with the molecular target in vitro; conducting extensive medicinal chemistry to optimise the properties of lead compounds; testing efficacy and toxicity of these compounds in vitro and in animals; and undertaking a clinical development programme (Box 2.14). This process typically takes longer than 10 years and may cost up to US$1 billion. Manufacturers have a defined period of exclusive marketing of the drug while it remains protected by an original patent, typically 10–15 years, during which time they must recoup the costs of developing the drug. Meanwhile, competitor companies will often produce similar 'me too' drugs of the same class. Once the drug's patent has expired, 'generic' manufacturers may step in to produce cheaper formulations of the drug. Paradoxically, if a generic drug is produced by only one manufacturer, the price may actually rise, sometimes substantially. Newer 'biological' products are based on large molecules (e.g. human recombinant antibodies) derived from complex manufacturing processes involving specific cell lines, molecular cloning and purification processes. After the patent for the originator product expires, other manufacturers may develop similar products ('biosimilars') that share similar pharmacological actions but are not completely identical. 'Biosimilars' are considered distinct from 'generic' medications, as complex biological molecules are more susceptible to differences in manufacturing processes than conventional small-molecule-type pharmaceuticals.

The number of new drugs produced by the pharmaceutical industry has declined in recent years. The traditional approach of targeting membrane-bound receptors and enzymes with small molecules (see Box 2.2) is now giving way to new targets, such as complex second-messenger systems, cytokines, nucleic acids and cellular networks. These require novel therapeutic agents, which present new challenges for 'translational medicine', the discipline of converting scientific discoveries into a useful medicine with a well-defined benefit–risk profile (Box 2.15).

2.14 Clinical development of new drugs

Phase I

- Healthy volunteers (20–80)
- These involve initial single-dose, 'first-into-man' studies, followed by repeated-dose studies. They aim to establish the basic pharmacokinetic and pharmacodynamic properties, and short-term safety
- Duration: 6–12 months

Phase II

- Patients (100–200)
- These investigate clinical effectiveness ('proof of concept'), safety and dose–response relationship, often with a surrogate clinical endpoint, in the target patient group to determine the optimal dosing regimen for larger confirmatory studies
- Duration: 1–2 years

Phase III

- Patients (100s–1000s)
- These are large, expensive clinical trials that confirm safety and efficacy in the target patient population, using relevant clinical endpoints. They may be placebo-controlled studies or comparisons with other active compounds
- Duration: 1–2 years

Phase IV

- Patients (100s–1000s)
- These are undertaken after the medicine has been marketed for its first indication to evaluate new indications, new doses or formulations, long-term safety or cost-effectiveness

Licensing new medicines

New drugs are given a 'market authorisation', based on the evidence of quality, safety and efficacy presented by the manufacturer. The regulator not only will approve the drug but also will take great care to ensure that the accompanying information reflects the evidence that has been presented. The summary of product characteristics (SPC), or 'label', provides detailed information about indications, dosage, adverse effects, warnings, monitoring and so on. If approved, drugs can be made available with different levels of restriction:

- *Controlled drug (CD)*. These drugs are subject to strict legal controls on supply and possession, usually due to their abuse potential (e.g. opioid analgesics).

i 2.15 Novel therapeutic alternatives to conventional small-molecule drugs

Approaches	Therapeutic indications	Challenges
Monoclonal antibodies		
Targeting of receptors or other molecules with relatively specific antibodies	Cancer Chronic inflammatory diseases (e.g. rheumatoid arthritis, inflammatory bowel disease)	Selectivity of action Complex manufacturing process
Small interfering RNA (siRNA)		
Inhibition of gene expression	Macular degeneration	Delivery to target
Gene therapy		
Delivery of modified genes that supplement or alter host DNA	Cystic fibrosis Cancer Cardiovascular disease	Delivery to target Adverse effects of delivery vector (e.g. virus)
Stem cell therapy		
Stem cells differentiate and replace damaged host cells	Parkinson's disease Spinal cord injury Ischaemic heart disease	Delivery to target Immunological compatibility Long-term effects unknown

- *Prescription-only medicine (PoM)*. These are available only from a pharmacist and can be supplied only if prescribed by an appropriate practitioner.
- *Pharmacy (P)*. These are available only from a pharmacist but can be supplied without a prescription.
- *General sales list (GSL)*. These medicines may be bought 'over the counter' (OTC) from any shop and without a prescription.

Although the regulators take great care to agree the exact indications for prescribing a medicine, based on the evidence provided by the manufacturer, there are some circumstances in which prescribers may direct its use outside the terms stated in the SPC ('off-label' prescribing). Common situations where this might occur include prescribing outside the approved age group (e.g. prescribing for children) or using an alternative formulation (e.g. administering a medicine provided in a solid form as an oral solution). Other important examples might include prescribing for an indication for which there are no approved medicines or where all of the approved medicines have caused unacceptable adverse effects. Occasionally, medicines may be prescribed when there is no marketing authorisation in the country of use. Examples include when a medicine licensed in another country is imported for use for an individual patient ('unlicensed import') or when a patient requires a specific preparation of a medicine to be manufactured ('unlicensed special'). When prescribing is 'off-label' or 'unlicensed', there is an increased requirement for prescribers to be able to justify their actions and to inform and agree the decision with the patient.

Drug marketing

The marketing activities of the pharmaceutical industry are well resourced and are important in the process of recouping the massive costs of drug development. In some countries, such as the USA, it is possible to promote a new drug by direct-to-consumer advertising, although this is illegal in the countries of the European Union. A major focus is on promotion to prescribers via educational events, sponsorship of meetings, advertisements in journals, involvement with opinion leaders, and direct contact by company representatives. Such largesse has the potential to cause significant conflicts of interest and might tempt prescribers to favour one drug over another, even in the face of evidence on effectiveness or cost-effectiveness.

Managing the use of medicines

Many medicines meet the three key regulatory requirements of quality, safety and efficacy. Although prescribers are legally entitled to prescribe any of them, it is desirable to limit the choice so that treatments for specific diseases can be focused on the most effective and cost-effective options, prescribers (and patients) gain familiarity with a smaller number of medicines, and pharmacies can concentrate stocks on them.

The process of ensuring optimal use of available medicines is known as 'medicines management' or 'quality use of medicines'. It involves careful evaluation of the evidence of benefit and harm from using the medicine, an assessment of cost-effectiveness, and support for processes to implement the resulting recommendations. These activities usually involve both national (e.g. National Institute for Health and Care Excellence (NICE) in the UK) and local organisations (e.g. drug and therapeutics committees).

Evaluating evidence

The principles of evidence-based medicine are described on page 10. Drugs are often evaluated in high-quality randomised controlled trials, the results of which can be considered by systematic review (Fig. 2.6). Ideally, data are available not only for comparison with placebo but also for 'head-to-head' comparison with alternative therapies. Trials are conducted in selected patient populations, however, and are not representative of every clinical scenario, so extrapolation to individual patients is not always straightforward. Other subtle bias may be introduced because of the sources of funding (e.g. pharmaceutical industry) and the interests of the investigators in being involved in research that has a 'positive' impact. These biases may be manifest in the way the trials are conducted or in how they are interpreted or reported. A common example of the latter is the difference between relative and absolute risk of clinical events reported in prevention trials. If a clinical event is encountered in the placebo arm at a rate of 1 in 50 patients (2%) but only 1 in 100 patients (1%) in the active treatment arm, then the impact of treatment can be described as either a 50% relative risk reduction or 1% absolute risk reduction. Although the former sounds more impressive, it is the latter that is of more importance to the

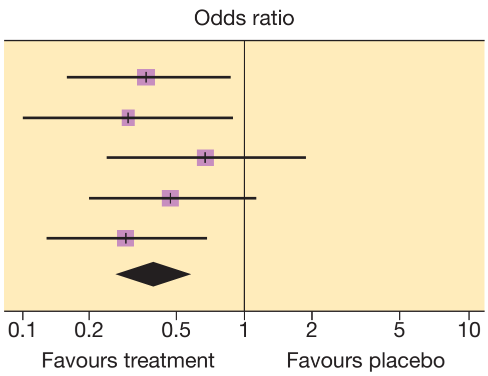

Fig. 2.6 Systematic review of the evidence from randomised controlled clinical trials. This forest plot shows the effect of warfarin compared with placebo on the likelihood of stroke in patients with atrial fibrillation in five randomised controlled trials that passed the quality criteria required for inclusion in a meta-analysis. For each trial, the purple box is proportionate to the number of participants. The tick marks show the mean odds ratio and the black lines indicate its 95% confidence intervals. Note that not all the trials showed statistically significant effects (i.e. the confidence intervals cross 1.0). However, the meta-analysis, represented by the black diamond, confirms a highly significant statistical benefit. The overall odds ratio is approximately 0.4, indicating a mean 60% risk reduction with warfarin treatment in patients with the characteristics of the participants in these trials.

individual patient. It means that the number of patients that needed to be treated (NNT) for 1 to benefit (compared to placebo) was 100. This illustrates how large clinical trials of new medicines can produce highly statistically significant and impressive relative risk reductions and still predict a very modest clinical impact.

Evaluating cost-effectiveness

New drugs often represent an incremental improvement over the current standard of care but are usually more expensive. Health-care budgets are limited in every country and so it is impossible to fund all new medicines. This means that very difficult financial decisions have to be taken with due regard to the principles of ethical justice. The main approach taken is cost-effectiveness analysis (CEA), where a comparison is made between the relative costs and outcomes of different courses of action. CEA is usually expressed as a ratio where the denominator is a gain in health and the numerator is the cost associated with the health gain. A major challenge is to compare the value of interventions for different clinical outcomes. One method is to calculate the quality-adjusted life years (QALYs) gained if the new drug is used rather than standard treatment. This analysis involves estimating the 'utility' of various health states between 1 (perfect health) and 0 (dead). If the additional costs and any savings are known, then it is possible to derive the incremental cost-effectiveness ratio (ICER) in terms of cost/QALY. These principles are exemplified in Box 2.16. There are, however, inherent weaknesses in this kind of analysis: it usually depends on modelling future outcomes well beyond the duration of the clinical trial data that are available; it assumes that QALYs gained at all ages are of equivalent value; and the appropriate standard care against which the new drug should be compared is often uncertain.

These pharmacoeconomic assessments are challenging and resource-intensive, and are undertaken at national level in most countries, e.g. in the UK by NICE.

i 2.16 Cost-effectiveness analysis

A clinical trial lasting 2 years compares two interventions for the treatment of colon cancer:

- Treatment A: standard treatment, cost £1000/year, oral therapy
- Treatment B: new treatment, cost £6000/year, monthly intravenous infusions, often followed by a week of nausea.

The new treatment (B) significantly increases the average time to progression (18 months versus 12 months) and reduces overall mortality (40% versus 60%). The health economist models the survival curves from the trial in order to undertake a cost–utility analysis and concludes that:

- Intervention A: allows an average patient to live for 2 extra years at a utility 0.7 = 1.4 QALYs (cost £2000)
- Intervention B: allows an average patient to live for 3 extra years at a utility 0.6 = 1.8 QALYs (cost £18 000).

The health economists conclude that treatment B provides an extra 0.4 QALYs at an extra cost of £16 000, meaning that the ICER = £40 000/QALY. They recommend that the new treatment should not be funded on the basis that their threshold for cost acceptability is £30 000/QALY.

(ICER = incremental cost-effectiveness ratio; QALY = quality-adjusted life year)

Implementing recommendations

Many recommendations about drug therapy are included in clinical guidelines written by an expert group after systematic review of the evidence. Guidelines provide recommendations rather than obligations for prescribers and are helpful in promoting more consistent and higher-quality prescribing. They are often written without concern for cost-effectiveness, however, and may be limited by the quality of available evidence. Guidelines cannot anticipate the extent of the variation between individual patients who may, for example, have unexpected contraindications to recommended drugs or choose different priorities for treatment. When deviating from respected national guidance, prescribers should be able to justify their practice.

Additional recommendations for prescribing are often implemented locally or imposed by bodies responsible for paying for health care. Most health-care units have a drug and therapeutics committee (or equivalent) comprised of senior and junior medical staff, pharmacists and nurses, as well as managers (because of the implications of the committee's work for governance and resources). This group typically develops local prescribing policy and guidelines, maintains a local drug formulary and evaluates requests to use new drugs. The local formulary contains a more limited list than any national formulary (e.g. *British National Formulary*) because the latter lists all licensed medicines that can be prescribed legally, while the former contains only those that the health-care organisation has approved for local use. The local committee may also be involved, with local specialists, in providing explicit protocols for management of clinical scenarios.

Prescribing in practice

Decision-making in prescribing

Prescribing should be based on a rational approach to a series of challenges (see Box 2.1).

Making a diagnosis

Ideally, prescribing should be based on a confirmed diagnosis but, in reality, many prescriptions are based on the balance of probability, taking into account the differential diagnosis (e.g. proton pump inhibitors for post-prandial retrosternal discomfort).

Establishing the therapeutic goal

The goals of treatment are usually clear, particularly when relieving symptoms (e.g. pain, nausea, constipation). Sometimes the goal is less obvious to the patient, especially when aiming to prevent future events (e.g. ACE inhibitors to prevent hospitalisation and extend life in chronic heart failure). Prescribers should be clear about the therapeutic goal against which they will judge success or failure of treatment. It is also important to establish that the value placed on this goal by the prescriber is shared by the patient (concordance).

Choosing the therapeutic approach

For many clinical problems, drug therapy is not absolutely mandated. Having taken the potential benefits and harms into account, prescribers must consider whether drug therapy is in the patient's interest and is preferred to no treatment or one of a range of alternatives (e.g. physiotherapy, psychotherapy, surgery). Assessing the balance of benefit and harm is often complicated and depends on various features associated with the patient, disease and drug (Box 2.17).

Choosing a drug

For most common clinical indications (e.g. type 2 diabetes, depression), more than one drug is available, often from more than one drug class. Although prescribers often have guidance about which represents the rational choice for the average patient, they still need to consider whether this is the optimal choice for the individual patient. Certain factors may influence the choice of drug:

Absorption

Patients may find some formulations easier to swallow than others or may be vomiting and require a drug available for parenteral administration.

Distribution

Distribution of a drug to a particular tissue sometimes dictates choice (e.g. tetracyclines and rifampicin are concentrated in the bile, and lincomycin and clindamycin in bones).

Metabolism

Drugs that are extensively metabolised should be avoided in severe liver disease (e.g. opioid analgesics).

Excretion

Drugs that depend on renal excretion for elimination (e.g. digoxin, aminoglycoside antibiotics) should be avoided in patients with impaired renal function if suitable alternatives exist.

Efficacy

Prescribers normally choose drugs with the greatest efficacy in achieving the goals of therapy (e.g. proton pump inhibitors rather than H_2-receptor antagonists). It may be appropriate, however, to compromise on efficacy if other drugs are more convenient, safer to use or less expensive.

Avoiding adverse effects

Prescribers should be wary of choosing drugs that are more likely to cause adverse effects (e.g. cephalosporins rather than alternatives for patients allergic to penicillin) or worsen coexisting conditions (e.g. β-blockers as treatment for angina in patients with asthma).

Features of the disease

This is most obvious when choosing antibiotic therapy, which should be based on the known or suspected sensitivity of the infective organism (p. 116).

Severity of disease

The choice of drug should be appropriate to disease severity (e.g. paracetamol for mild pain, morphine for severe pain).

Coexisting disease

This may be either an indication or a contraindication to therapy. Hypertensive patients might be prescribed a β-blocker if they also have left ventricular impairment but not if they have asthma.

Avoiding adverse drug interactions

Prescribers should avoid giving combinations of drugs that might interact, either directly or indirectly (see Box 2.11).

Patient adherence to therapy

Prescribers should choose drugs with a simple dosing schedule or easier administration (e.g. the ACE inhibitor lisinopril once daily rather than captopril 3 times daily for hypertension).

Cost

Prescribers should choose the cheaper drug (e.g. a generic or biosimilar) if two drugs are of equal efficacy and safety. Even if cost is not a concern for the individual patient, it is important to remember that unnecessary expenditure will ultimately limit choices for other prescribers and patients. Sometimes a more costly drug may be appropriate (e.g. if it yields improved adherence).

Genetic factors

There are already a small number of examples where genotype influences the choice of drug therapy (see Box 2.5).

Choosing a dosage regimen

Prescribers have to choose a dose, route and frequency of administration (dosage regimen) to achieve a steady-state drug concentration that provides sufficient exposure of the target tissue without producing toxic effects. Manufacturers draw up dosage recommendations based on average observations in many patients but the optimal regimen that will maximise the benefit to harm ratio for an individual patient is never certain.

i 2.17 Factors to consider when balancing benefits and harms of drug therapy

- Seriousness of the disease or symptom
- Efficacy of the drug
- Seriousness of potential adverse effects
- Likelihood of adverse effects
- Efficacy of alternative drugs or non-drug therapies
- Safety of alternative drugs or non-drug therapies

Rational prescribing involves treating each prescription as an experiment and gathering sufficient information to amend it if necessary. There are some general principles that should be followed, as described below.

Dose titration

Prescribers should generally start with a low dose and titrate this slowly upwards as necessary. This cautious approach is particularly important if the patient is likely to be more sensitive to adverse pharmacodynamic effects (e.g. delirium or postural hypotension in the elderly) or have altered pharmacokinetic handling (e.g. renal or hepatic impairment), and when using drugs with a low therapeutic index (e.g. benzodiazepines, lithium, digoxin). There are some exceptions, however. Some drugs must achieve therapeutic concentration quickly because of the clinical circumstance (e.g. antibiotics, glucocorticoids, carbimazole). When early effect is important but there may be a delay in achieving steady state because of a drug's long half-life (e.g. digoxin, warfarin, amiodarone), an initial loading dose is given prior to establishing the appropriate maintenance dose (see Fig. 2.4).

If adverse effects occur, the dose should be reduced or an alternative drug prescribed; in some cases, a lower dose may suffice if it can be combined with another synergistic drug (e.g. the immunosuppressant azathioprine reduces glucocorticoid requirements in patients with inflammatory disease). It is important to remember that the shape of the dose–response curve (see Fig. 2.2) means that higher doses may produce little added therapeutic effect and might increase the chances of toxicity.

Route

There are many reasons for choosing a particular route of administration (Box 2.18).

Frequency

Frequency of doses is usually dictated by a manufacturer's recommendation. Less frequent doses are more convenient for patients but result in greater fluctuation between peaks and troughs in drug concentration (see Fig. 2.4). This is relevant if the peaks are associated with adverse effects (e.g. dizziness with antihypertensives) or the troughs are associated with troublesome loss of effect (e.g. anti-Parkinsonian drugs). These problems can be tackled either by splitting the dose or by employing a modified-release formulation, if available.

Timing

For many drugs the time of administration is unimportant. There are occasionally pharmacokinetic or therapeutic reasons, however, for giving drugs at particular times (Box 2.19).

Formulation

For some drugs there is a choice of formulation, some for use by different routes. Some are easier to ingest, particularly by children (e.g. elixirs). The formulation is important when writing repeat prescriptions for drugs with a low therapeutic index that come in different formulations (e.g. lithium, phenytoin, theophylline). Even if the prescribed dose remains constant, an alternative formulation may differ in its absorption and bioavailability, and hence plasma drug concentration. These are examples of the small number of drugs that should be prescribed by specific brand name rather than 'generic' international non-proprietary name (INN).

i 2.18 Factors influencing the route of drug administration

Reason	Example
Only one route possible	Dobutamine (IV) Gliclazide (oral)
Patient adherence	Phenothiazines and thioxanthenes (2 weekly IM depot injections rather than daily tablets, in schizophrenia)
Poor absorption	Furosemide (IV rather than oral, in severe heart failure)
Rapid action	Haloperidol (IM rather than oral, in acute behavioural disturbance)
Vomiting	Phenothiazines (PR or buccal rather than oral, in nausea)
Avoidance of first-pass metabolism	Glyceryl trinitrate (SL, in angina pectoris)
Certainty of effect	Amoxicillin (IV rather than oral, in acute chest infection)
Direct access to the site of action (avoiding unnecessary systemic exposure)	Bronchodilators (INH rather than oral, in asthma) Local application of drugs to skin, eyes etc.
Ease of access	Diazepam (PR, if IV access is difficult in status epilepticus) Adrenaline (epinephrine) (IM, if IV access is difficult in acute anaphylaxis)
Comfort	Morphine (SC rather than IV in terminal care)

(IM = intramuscular; INH = by inhalation; IV = intravenous; PR = per rectum; SC = subcutaneous; SL = sublingual)

Duration

Some drugs require a single dose (e.g. thrombolysis post myocardial infarction), while for others the duration of the course of treatment is certain at the outset (e.g. antibiotics). For most, the duration will be largely at the prescriber's discretion and will depend on response and disease progression (e.g. analgesics, antidepressants). For many, the treatment will be long-term (e.g. insulin, antihypertensives, levothyroxine).

Involving the patient

Patients should, whenever possible, be engaged in making choices about drug therapy. Their beliefs and expectations affect the goals of therapy and help in judging the acceptable benefit/harm balance when selecting treatments. Very often, patients may wish to defer to the professional expertise of the prescriber. Nevertheless, they play key roles in adherence to therapy and in monitoring treatment, not least by providing early warning of adverse events. It is important for them to be provided with the necessary information to understand the choice that has been made, what to expect from the treatment, and any measurements that must be undertaken (Box 2.20).

A major drive to include patients has been the recognition that up to half of the drug doses for chronic preventative therapy are not taken. This is often termed 'non-compliance' but is more appropriately called 'non-adherence', to reflect a less paternalistic view of the doctor–patient relationship; it may or may not be intentional. Non-adherence to the dose regimen reduces the likelihood of benefits to the patient and can be costly in terms

2.19 Factors influencing the timing of drug therapy

Drug	Recommended timing	Reasons
Diuretics (e.g. furosemide)	Once in the morning	Night-time diuresis undesirable
Statins (e.g. simvastatin)	Once at night	HMG CoA reductase activity is greater at night
Antidepressants (e.g. amitriptyline)	Once at night	Allows adverse effects to occur during sleep
Salbutamol	Before exercise	Reduces symptoms in exercise-induced asthma
Glyceryl trinitrate Paracetamol	When required	Relief of acute symptoms only
Regular nitrate therapy (e.g. isosorbide mononitrate)	Eccentric dosing regimen (e.g. twice daily at 8 a.m. and 2 p.m.)	Reduces development of nitrate tolerance by allowing drug-free period each night
Aspirin	With food	Minimises gastrotoxic effects
Alendronate	Once in the morning before breakfast, sitting upright	Minimises risk of oesophageal irritation
Tetracyclines	2 hours before or after food or antacids	Divalent and trivalent cations chelate tetracyclines, preventing absorption
Hypnotics (e.g. temazepam)	Once at night	Maximises therapeutic effect and minimises daytime sedation
Antihypertensive drugs (e.g. amlodipine)	Once in the morning	Blood pressure is higher during the daytime

(HMG CoA = 3-hydroxy-3-methylglutaryl-coenzyme A)

2.20 What patients need to know about their medicines*

Knowledge	Comment
The reason for taking the medicine How the medicine works	Reinforces the goals of therapy
How to take the medicine	May be important for the effectiveness (e.g. inhaled salbutamol in asthma) and safety (e.g. alendronate for osteoporosis) of treatment
What benefits to expect	May help to support adherence or prompt review because of treatment failure
What adverse effects might occur	Discuss common and mild effects that may be transient and might not require discontinuation Mention rare but serious effects that might influence the patient's consent
Precautions that improve safety	Explain symptoms to report that might allow serious adverse effects to be averted, monitoring that will be required and potentially important drug–drug interactions
When to return for review	This will be important to enable monitoring

*Many medicines are provided with patient information leaflets, which the patient should be encouraged to read.

of wasted medicines and unnecessary health-care episodes. An important reason may be lack of concordance with the prescriber about the goals of treatment. A more open and shared decision-making process might resolve any misunderstandings at the outset and foster improved adherence, as well as improved satisfaction with health-care services and confidence in prescribers. Fully engaging patients in shared decision-making is sometimes constrained by various factors, such as limited consultation time and challenges in communicating complex numerical data.

Writing the prescription

The culmination of the planning described above is writing an accurate and legible prescription so that the drug will be dispensed and administered as planned (see 'Writing prescriptions' below).

Monitoring treatment effects

Rational prescribing involves monitoring for the beneficial and adverse effects of treatment so that the balance remains in favour of a positive outcome (see 'Monitoring drug therapy' below).

Stopping drug therapy

It is also important to review long-term treatment at regular intervals to assess whether continued treatment is required. Elderly patients are keen to reduce their medication burden and are often prepared to compromise on the original goals of long-term preventative therapy to achieve this.

Prescribing in special circumstances

Prescribing for patients with renal disease

Patients with renal impairment are readily identified by having a low estimated glomerular filtration rate (eGFR <60 mL/min) based on their serum creatinine, age, sex and ethnic group (p. 386). This group includes a large proportion of elderly patients. If a drug (or its active metabolites) is eliminated predominantly by the kidneys, it will tend to accumulate and so the maintenance dose must be reduced. For some drugs, renal impairment makes patients more sensitive to their adverse pharmacodynamic effects.

2.21 Some drugs that require extra caution in patients with renal or hepatic disease

Kidney disease	Liver disease
Pharmacodynamic effects enhanced	
ACE inhibitors and ARBs (renal impairment, hyperkalaemia)	Warfarin (increased anticoagulation because of reduced clotting factor synthesis)
Metformin (lactic acidosis)	Metformin (lactic acidosis)
Spironolactone (hyperkalaemia)	Chloramphenicol (bone marrow suppression)
NSAIDs (impaired renal function)	NSAIDs (gastrointestinal bleeding, fluid retention)
Sulphonylureas (hypoglycaemia)	Sulphonylureas (hypoglycaemia)
Insulin (hypoglycaemia)	Benzodiazepines (coma)
Pharmacokinetic handling altered (reduced clearance)	
Aminoglycosides (e.g. gentamicin)	Phenytoin
Vancomycin	Rifampicin
Digoxin	Propranolol
Lithium	Warfarin
Other antibiotics (e.g. ciprofloxacin)	Diazepam
Atenolol	Lidocaine
Allopurinol	Opioids (e.g. morphine)
Cephalosporins	
Methotrexate	
Opioids (e.g. morphine)	

(ACE = angiotensin-converting enzyme; ARB = angiotensin receptor blocker; NSAID = non-steroidal anti-inflammatory drug)

Examples of drugs that require extra caution in patients with renal disease are listed in Box 2.21.

Prescribing for patients with hepatic disease

The liver has a large capacity for drug metabolism and hepatic insufficiency has to be advanced before drug dosages need to be modified. Patients who may have impaired metabolism include those with jaundice, ascites, hypoalbuminaemia, malnutrition or encephalopathy. Hepatic drug clearance may also be reduced in acute hepatitis, in hepatic congestion due to cardiac failure, and in the presence of intrahepatic arteriovenous shunting (e.g. in hepatic cirrhosis). There are no good tests of hepatic drug-metabolising capacity or of biliary excretion, so dosage should be guided by the therapeutic response and careful monitoring for adverse effects. The presence of liver disease also increases the susceptibility to adverse pharmacological effects of drugs. Some drugs that require extra caution in patients with hepatic disease are listed in Box 2.21.

Prescribing for elderly patients

The issues around prescribing in the elderly are discussed in Box 2.22.

Prescribing for women who are pregnant or breastfeeding

Prescribing in pregnancy should be avoided if possible to minimise the risk of adverse effects in the fetus. Drug therapy in pregnancy may, however, be required either for a pre-existing problem (e.g. epilepsy, asthma, hypothyroidism) or for problems that arise during pregnancy (e.g. morning sickness, anaemia, prevention of neural tube defects, gestational diabetes, hypertension). About 35% of women take drug therapy at least once during pregnancy and 6% take drug therapy during the first trimester (excluding iron, folic acid and vitamins). The most commonly used drugs are simple analgesics, antibacterial drugs and antacids. Some considerations when prescribing in pregnancy are listed in Box 2.23.

2.22 Prescribing in old age

- **Reduced drug elimination**: partly due to impaired renal function.
- **Increased sensitivity to drug effects**: notably in the brain (leading to sedation or delirium) and as a result of comorbidities.
- **More drug interactions**: largely as a result of polypharmacy.
- **Lower starting doses and slower dose titration**: often required, with careful monitoring of drug effects.
- **Drug adherence**: may be poor because of cognitive impairment, difficulty swallowing (dry mouth) and complex polypharmacy regimens. Supplying medicines in pill organisers (e.g. dosette boxes or calendar blister packs), providing automatic reminders, and regularly reviewing and simplifying the drug regimen can help.
- **Some drugs that require extra caution, and their mechanisms**:
  - *Digoxin*: increased sensitivity of Na^+/K^+ pump; hypokalaemia due to diuretics; renal impairment favours accumulation → increased risk of toxicity.
  - *Antihypertensive drugs*: reduced baroreceptor function → increased risk of postural hypotension.
  - *Antidepressants, hypnotics, sedatives, tranquillisers*: increased sensitivity of the brain; reduced metabolism → increased risk of toxicity.
  - *Warfarin*: increased tendency to falls and injury and to bleeding from intra- and extracranial sites; increased sensitivity to inhibition of clotting factor synthesis → increased risk of bleeding.
  - *Clomethiazole, lidocaine, nifedipine, phenobarbital, propranolol, theophylline*: metabolism reduced → increased risk of toxicity.
  - *Non-steroidal anti-inflammatory drugs*: poor renal function → increased risk of renal impairment; susceptibility to gastrotoxicity → increased risk of upper gastrointestinal bleeding.

2.23 Prescribing in pregnancy

- **Teratogenesis**: a potential risk, especially when drugs are taken between 2 and 8 weeks of gestation (4–10 weeks from last menstrual period). Common teratogens include retinoids (e.g. isotretinoin), cytotoxic drugs, angiotensin-converting enzyme inhibitors, antiepileptics and warfarin. If there is inadvertent exposure, then the timing of conception should be established, counselling given and investigations undertaken for fetal abnormalities.
- **Adverse fetal effects in late gestation**: e.g. tetracyclines may stain growing teeth and bones; sulphonamides displace fetal bilirubin from plasma proteins, potentially causing kernicterus; opioids given during delivery may be associated with respiratory depression in the neonate.
- **Altered maternal pharmacokinetics**: extracellular fluid volume and V_d increase. Plasma albumin falls but other binding globulins (e.g. for thyroid and steroid hormones) increase. Glomerular filtration increases by approximately 70%, enhancing renal clearance. Placental metabolism contributes to increased clearance, e.g. of levothyroxine and glucocorticoids. The overall effect is a fall in plasma levels of many drugs.
- **In practice**:
  - Avoid any drugs unless the risk:benefit analysis is in favour of treating (usually the mother).
  - Use drugs for which there is some record of safety in humans.
  - Use the lowest dose for the shortest time possible.
  - Choose the least harmful drug if alternatives are available.

Drugs that are excreted in breast milk may cause adverse effects in the baby. Prescribers should always consult the summary of product characteristics for each drug or a reliable formulary when treating a pregnant woman or breastfeeding mother.

Writing prescriptions

A prescription is a means by which a prescriber communicates the intended plan of treatment to the pharmacist who dispenses a medicine and to a nurse or patient who administers it. It should be precise, accurate, clear and legible. The two main kinds of prescription are those written, dispensed and administered in hospital and those written in primary care (in the UK by a GP), dispensed at a community pharmacy and self-administered by the patient. The information supplied must include:

- the date
- the identification details of the patient
- the name of the drug
- the formulation
- the dose
- the frequency of administration
- the route and method of administration
- the amount to be supplied (primary care only)
- instructions for labelling (primary care only)
- the prescriber's signature.

Prescribing in hospital

Although GP prescribing is increasingly electronic, most hospital prescribing continues to be based around the prescription and administration record (the 'drug chart') (Fig. 2.7). A variety of charts are in use and prescribers must familiarise themselves with the local version. Most contain the following sections:

- *Basic patient information*: will usually include name, age, date of birth, hospital number and address. These details are often 'filled in' using a sticky addressograph label but this increases the risk of serious error.
- *Previous adverse reactions/allergies*: communicates important patient safety information based on a careful drug history and/or the medical record.
- *Other medicines charts*: notes any other hospital prescription documents that contain current prescriptions being received by the patient (e.g. anticoagulants, insulin, oxygen, fluids).
- *Once-only medications*: for prescribing medicines to be used infrequently, such as single-dose prophylactic antibiotics and other pre-operative medications.
- *Regular medications*: for prescribing medicines to be taken for a number of days or continuously, such as a course of antibiotics, antihypertensive drugs and so on.
- *'As required' medications*: for prescribing for symptomatic relief, usually to be administered at the discretion of the nursing staff (e.g. antiemetics, analgesics).

Prescribers should be aware of the risks of prescription error (Box 2.24 and see Box 2.13), ensure they have considered the rational basis for their prescribing decision described above, and then follow the guidance illustrated in Figure 2.7 in order to write the prescription. It is a basic principle that a prescription will be followed by a judgement as to its success or failure and any appropriate changes made (e.g. altered dosage, discontinuation or substitution).

i 2.24 High-risk prescribing moments

- Trying to amend an active prescription (e.g. altering the dose/timing) – *always avoid and start again*
- Writing up drugs in the immediate presence of more than one prescription chart or set of notes – *avoid*
- Allowing one's attention to be diverted in the middle of completing a prescription – *avoid*
- Prescribing 'high-risk' drugs (e.g. anticoagulants, opioids, insulin, sedatives) – *ask for help if necessary*
- Prescribing parenteral drugs – *take care*
- Rushing prescribing (e.g. in the midst of a busy ward round) – *avoid*
- Prescribing unfamiliar drugs – *consult the formulary and ask for help if necessary*
- Transcribing multiple prescriptions from an expired chart to a new one – *take care to review the rationale for each medicine*
- Writing prescriptions based on information from another source such as a referral letter (the list may contain errors and some of the medicines may be the cause of the patient's illness) – *review the justification for each as if it is a new prescription*
- Writing up 'to take out' drugs (because these will become the patient's regular medication for the immediate future) – *take care and seek advice if necessary*
- Calculating drug doses – *ask a colleague to perform an independent calculation or use approved electronic dose calculators*
- Prescribing sound-alike or look-alike drugs (e.g. chlorphenamine and chlorpromazine) – *take care*

Hospital discharge ('to take out') medicines

Most patients will be prescribed a short course of their medicines at discharge. This prescription is particularly important because it usually informs future therapy at the point of transfer of prescribing responsibility to primary care. Great care is required to ensure that this list is accurate. It is particularly important to ensure that any hospital medicines that should be stopped are not included and that those intended to be administered for a short duration only are clearly identified. It is also important for any significant ADRs experienced in hospital to be recorded and any specific monitoring or review identified.

Prescribing in primary care

Most of the considerations above are equally applicable to primary care (GP) prescriptions. In many health-care systems, community prescribing is electronic, making issues of legibility irrelevant and often providing basic decision support to limit the range of doses that can be written and highlight potential drug interactions. Important additional issues more relevant to GP prescribing are:

- *Formulation*. The prescription needs to carry information about the formulation for the dispensing pharmacist (e.g. tablets or oral suspension).
- *Amount to be supplied*. In the hospital the pharmacist will organise this. Elsewhere it must be specified either as the precise number of tablets or as the duration of treatment. Creams and ointments should be specified in grams and lotions in mL.
- *Controlled drugs*. Prescriptions for 'controlled' drugs (e.g. opioid analgesics, with potential for drug abuse) are subject to additional legal requirements. In the UK, they

PRESCRIPTION AND ADMINISTRATION RECORD

Standard Chart

Hospital/Ward: W26	Consultant: Maxwell	Name of patient: John Smith	
Weight: 78 Kg	Height: 1.84 m	Hospital number: WGH5522589	
If rewritten, date: 14. 2.18		D.O.B.: 16/10/64	
DISCHARGE PRESCRIPTION Date completed:–	Completed by:–	(Attach printed label here)	

OTHER MEDICINES CHARTS		PREVIOUS ADVERSE REACTIONS (This must be completed before prescribing on this chart)			
Date	Type of chart	Medicine	Description of reaction	Completed by	Date
14. 2.18	Oxygen	Penicillin	Serious reaction (hospitalised) age 15	S. Jones	14. 2.18
14. 2.18	Warfarin	Cefalexin	Rash (discontinued) 2006	S. Jones	14. 2.18

CODES FOR NON-ADMINISTRATION OF PRESCRIBED MEDICINE

If a dose is not administered as prescribed, intial and enter a code in the column with a circle drawn round the code according to the reason as shown below. **Inform the responsible doctor of the appropriate timescale.**

1. Patient refuses	6. Vomiting/nausea
2. Patient not present	7. Time varied on doctor's instructions
3. Medicines not available – CHECK ORDERED	8. Once-only/as-required medicine given
4. Asleep/drowsy	9. Dose withheld on doctor's instructions
5. Administration route not available – CHECK FOR ALTERNATIVE	10. Possible adverse reaction/side-effect

B

ONCE-ONLY MEDICINES

Date	Time	Medicine (approved name)	Dose	Route	Prescriber – sign and print	Time given	Given by
14. 2.18	16.00	MORPHINE SULFATE	5 mg	IV	S. JONES	16.20	ST
14. 2.18	16.00	GLYCERYL TRINITRATE	2 mg	Buccal	S. JONES	16.10	DK
14. 2.18	16.00	METOCLOPRAMIDE	10 mg	IV	S. JONES	16.20	ST

Fig. 2.7 Example of a hospital prescription and administration record ('drug chart'). A *Front page.* The correct identification of the patient is critical to reducing the risk of an administration error. This page also clearly identifies other prescriptions charts in use and previous adverse reactions to drugs to minimise the risk of repeated exposure. Note also the codes employed by the nursing staff to indicate reasons why drugs may not have been administered. The patient's name and date of birth should be written on each page of the chart. The patient's weight and height may be required to calculate safe doses for many drugs with narrow therapeutic indices. B *'Once-only medicines'.* This area is used for prescribing medicines that are unlikely to be repeated on a regular basis. Note that the prescriber has written the **names of all drugs** legibly in block capitals. The generic international non-proprietary name (INN) should be used in preference to the brand name (e.g. write 'SIMVASTATIN', not 'ZOCOR'). The only exceptions are when variation occurs in the properties of alternative branded formulations (e.g. modified-release preparations of drugs such as lithium, theophylline, phenytoin and nifedipine) or when the drug is a combination product with no generic name (e.g. Kliovance). The only acceptable abbreviations for **drug dose** units are 'g' and 'mg'. 'Units' (e.g. of insulin or heparin) and 'micrograms' must always be written in full, never as 'U' or 'μg' (nor 'mcg', nor 'ug'). For liquid preparations write the dose in mg; 'mL' can be written only for a combination product (e.g. Gaviscon liquid) or if the strength is not expressed in weight (e.g. adrenaline (epinephrine) 1 in 1000). Use numbers/figures (e.g. 1 or 'one') to denote use of a sachet/enema but avoid prescribing numbers of tablets without specifying their strength. Always include the dose of inhaled drugs in addition to stating numbers of 'puffs', as strengths can vary. Widely accepted abbreviations for **route of administration** are: intravenous – 'IV'; intramuscular – 'IM'; subcutaneous – 'SC'; sublingual – 'SL'; per rectum – 'PR'; per vaginam – 'PV'; nasogastric – 'NG'; inhaled – 'INH'; and topical – 'TOP'. 'ORAL' is preferred to per oram – 'PO'. Care should be taken in specifying 'RIGHT' or 'LEFT' for eye and ear drops. The prescriber should sign and print their name clearly so that they can be identified by colleagues. The prescription should be dated and have an administration time. The nurse who administered the prescription has signed to confirm that the dose has been administered.

must contain the address of the patient and prescriber (not necessary on most hospital forms), the form and the strength of the preparation, and the total quantity of the preparation/number of dose units in both words and figures.

- *'Repeat prescriptions'*. A large proportion of GP prescribing involves 'repeat prescriptions' for chronic medication. These are often generated automatically, although the prescriber remains responsible for regular review and for ensuring that the benefit-to-harm ratio remains favourable.

Monitoring drug therapy

Prescribers should measure the effects of the drug, both beneficial and harmful, to inform decisions about dose titration (up or down), discontinuation or substitution of treatment. Monitoring can be achieved subjectively by asking the patient about symptoms or, more objectively, by measuring a clinical effect. Alternatively, if the pharmacodynamic effects of the drug are difficult to assess, the plasma drug concentration may be measured, on the basis that it will be closely related to the effect of the drug (see Fig. 2.2).

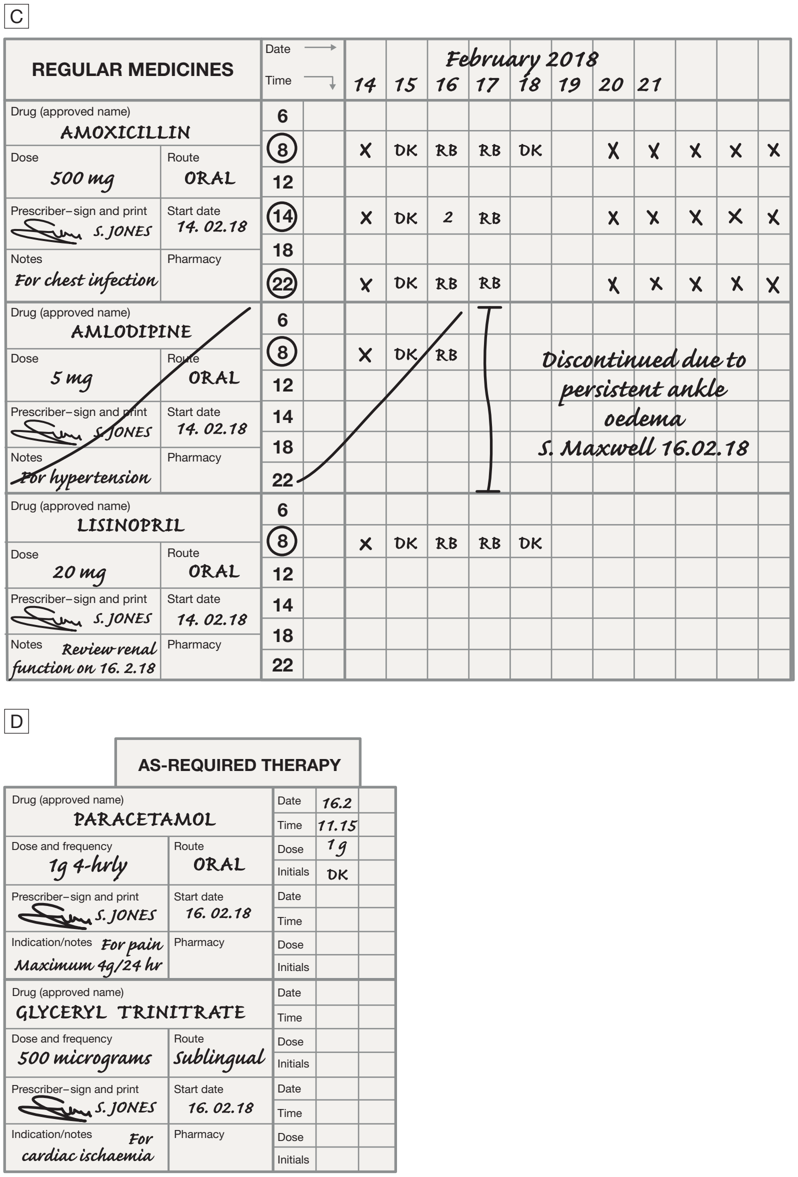

Fig. 2.7, cont'd C *'Regular medicines'.* This area is used for prescribing medicines that are going to be given regularly. In addition to the name, dose and route, a **frequency of administration** is required for each medicine. Widely accepted Latin abbreviations for dose frequency are: once daily – 'OD'; twice daily – 'BD'; 3 times daily – 'TDS'; 4 times daily – 'QDS'; as required – 'PRN'; in the morning – 'OM' (omni mane); at night – 'ON' (omni nocte); and immediately – 'stat'. The hospital chart usually requires specific times to be identified for regular medicines that coincide with nursing drug rounds and these can be circled. If treatment is for a known time period, cross off subsequent days when the medicine is not required. The **'notes' box** can be used to communicate additional important information (e.g. whether a medicine should be taken with food, type of inhaler device used, and anything else that the drug dispenser should know). State here the times for peak/trough plasma levels for drugs requiring therapeutic monitoring. Prescriptions should be **discontinued** by drawing a vertical line at the point of discontinuation, horizontal lines through the remaining days on the chart, and diagonal lines through the drug details and administration boxes. This action should be signed and dated and a supplementary note written to explain it (e.g. describing any adverse effect). In this example, amlodipine has been discontinued because of ankle oedema. There is room for the ward pharmacist to sign to indicate that the prescription has been reviewed and that a supply of the medicine is available. The administration boxes allow the nurse to sign to confirm that the dose has been given. Note that these boxes also allow for recording of reasons for non-administration (in this example '2' indicates that the patient was not present on the ward at the time) and the prevention of future administration by placing an 'X' in the box. D *'As-required medicines'.* These prescriptions leave the administration of the drug to the discretion of the nursing staff. The prescription must describe clearly the indication, frequency, minimal time interval between doses, and maximum dose in any 24-hour period (in this case, the maximum daily dose of paracetamol is 4 g).

Clinical and surrogate endpoints

Ideally, clinical endpoints are measured directly and the drug dosage titrated to achieve the therapeutic goal and avoid toxicity (e.g. control of ventricular rate in a patient with atrial fibrillation). Sometimes this is impractical because the clinical endpoint is a future event (e.g. prevention of myocardial infarction by statins or resolution of a chest infection with antibiotics); in these circumstances, it may be possible to select a 'surrogate' endpoint that will predict success or failure. This may be an intermediate step in the pathophysiological process (e.g. serum cholesterol as a surrogate for risk of myocardial infarction) or a

i 2.25 Drugs commonly monitored by plasma drug concentration

Drug	Half-life (hrs)*	Comment
Digoxin	36	Steady state takes several days to achieve. Samples should be taken 6 hrs post dose. Measurement is useful to confirm the clinical impression of toxicity or non-adherence but clinical effectiveness is better assessed by ventricular heart rate. Risk of toxicity increases progressively at concentrations >1.5 μg/L, and is likely at concentrations >3.0 μg/L (toxicity is more likely in the presence of hypokalaemia)
Gentamicin	2	Measure pre-dose trough concentration (should be <1 μg/mL) to ensure that accumulation (and the risk of nephrotoxicity and ototoxicity) is avoided; see Fig. 6.18 (p. 122)
Levothyroxine	>120	Steady state may take up to 6 weeks to achieve (p. 640)
Lithium	24	Steady state takes several days to achieve. Samples should be taken 12 hrs post dose. Target range 0.4–1 mmol/L
Phenytoin	24	Measure pre-dose trough concentration (should be 10–20 mg/L) to ensure that accumulation is avoided. Good correlation between concentration and toxicity. Concentration may be misleading in the presence of hypoalbuminaemia
Theophylline (oral)	6	Steady state takes 2–3 days to achieve. Samples should be taken 6 hrs post dose. Target concentration is 10–20 mg/L but its relationship with bronchodilator effect and adverse effects is variable
Vancomycin	6	Measure pre-dose trough concentration (should be 10–15 mg/L) to ensure clinical efficacy and that accumulation and the risk of nephrotoxicity are avoided (p. 123)

*Half-lives vary considerably with different formulations and between patients.

measurement that follows the pathophysiology, even if it is not a key factor in its progression (e.g. serum C-reactive protein as a surrogate for resolution of inflammation in chest infection). Such surrogates are sometimes termed 'biomarkers'.

Plasma drug concentration

The following criteria must be met to justify routine monitoring by plasma drug concentration:

- Clinical endpoints and other pharmacodynamic (surrogate) effects are difficult to monitor.
- The relationship between plasma concentration and clinical effects is predictable.
- The therapeutic index is low. For drugs with a high therapeutic index, any variability in plasma concentrations is likely to be irrelevant clinically.

Some examples of drugs that fulfil these criteria are listed in Box 2.25.

Measurement of plasma concentration may be useful in planning adjustments of drug dose and frequency of administration; to explain an inadequate therapeutic response (by identifying subtherapeutic concentration or incomplete adherence); to establish whether a suspected ADR is likely to be caused by the drug; and to assess and avoid potential drug interactions.

Timing of samples in relation to doses

The concentration of drug rises and falls during the dosage interval (see Fig. 2.4B). Measurements made during the initial absorption and distribution phases are unpredictable because of the rapidly changing concentration, so samples are usually taken at the end of the dosage interval (a 'trough' or 'pre-dose' concentration). This measurement is normally made in steady state, which usually takes five half-lives to achieve after the drug is introduced or the dose changed (unless a loading dose has been given).

Interpreting the result

A target range is provided for many drugs, based on average thresholds for therapeutic benefit and toxicity. Inter-individual variability means that these can be used only as a guide. For instance, in a patient who describes symptoms that could be consistent with toxicity but has a drug concentration in the top half of the target range, toxic effects should still be suspected. Another important consideration is that some drugs are heavily protein-bound (e.g. phenytoin) but only the unbound drug is pharmacologically active. Patients with hypoalbuminaemia may therefore have a therapeutic or even toxic concentration of unbound drug, despite a low 'total' concentration.

Clinical genetics

We have entered a genomic era. Powerful new technologies are driving forward transformational change in health care. Genetic sequencing has evolved from the targeted sequencing of a single gene to the parallel sequencing of multiple genes. In addition to improving the chances of identifying a genetic cause of rare diseases, these technologies are increasingly directing therapies and, in the future, are likely to be used in the diagnosis and prevention of common diseases such as diabetes. In this chapter we explore the fundamentals of genomics, the basic principles underlying these new genomic technologies and how the data generated can be applied safely for patient benefit. We will review the use of genomic technology across a breadth of medical specialties, including obstetrics, paediatrics, oncology and infectious disease, and consider how health care is likely to be transformed by technology over the coming decade. Finally, we will consider the ethical impact that these technologies are likely to have, both for the individual and for their wider family.

The fundamental principles of genomics

The packaging of genes: DNA, chromatin and chromosomes

Genes are functional units encoded in double-stranded deoxyribonucleic acid (DNA), packaged as chromosomes and located in the nucleus of the cell: a membrane-bound compartment found in all cells except erythrocytes and platelets (Fig. 3.1). DNA consists of a linear sequence of just four bases: adenine (A,) cytosine (C), thymine (T) and guanine (G.) It forms a 'double helix', a twisted ladder-like structure formed from two complementary strands of DNA joined by hydrogen bonds between bases on the opposite strand that can form only between a C and a G base and an A and a T base. It is this feature of DNA that enables faithful DNA replication and is the basis for many of the technologies designed to interrogate the genome: when the DNA double helix 'unzips', one strand can act as a template for the creation of an identical strand.

A single copy of the human genome comprises approximately 3.1 billion base pairs of DNA, wound around proteins called histones. The unit consisting of 147 base pairs wrapped around four different histone proteins is called the nucleosome. Sequences of nucleosomes (resembling a string of beads) are wound and packaged to form chromatin: tightly wound, densely packed chromatin is called heterochromatin and open, less tightly wound chromatin is called euchromatin.

The chromatin is finally packaged into the chromosomes. Humans are diploid organisms: the nucleus contains two copies of the genome, visible microscopically as 23 chromosome pairs (known as the karyotype). Chromosomes 1 through to 22 are known as the autosomes and consist of identical chromosomal pairs. The 23rd 'pair' of chromosomes are the two sex chromosomes: females have two X chromosomes and males an X and Y chromosome. A normal female karyotype is therefore written as 46,XX and a normal male is 46,XY.

From DNA to protein

Genes are functional elements on the chromosome that are capable of transmitting information from the DNA template via the production of messenger ribonucleic acid (mRNA) to the production of proteins. The human genome contains over 20 000 genes, although many of these are inactive or silenced in different cell types, reflecting the variable gene expression responsible for cell-specific characteristics. The central dogma is the pathway describing the basic steps of protein production: transcription, splicing, translation and protein modification (Fig. 3.2). Although this is now recognised as an over-simplification (contrary to this linear relationship, a single gene will often encode many different proteins), it remains a useful starting point to explore protein production.

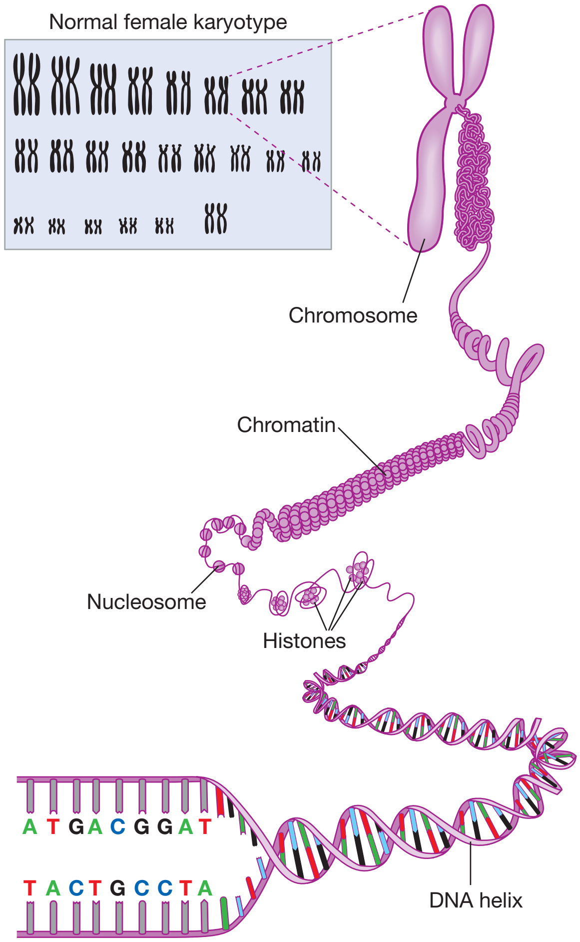

Fig. 3.1 The packaging of DNA, genes and chromosomes. From bottom to top: the double helix and the complementary DNA bases; chromatin; and a normal female chromosome pattern – the karyotype.

Transcription: DNA to messenger RNA

Transcription describes the production of ribonucleic acid (RNA) from the DNA template. For transcription to commence, an enzyme called RNA polymerase binds to a segment of DNA at the start of the gene: the promoter. Once bound, RNA polymerase moves along one strand of DNA, producing an RNA molecule complementary to the DNA template. In protein-coding genes this is known as messenger RNA (mRNA). A DNA sequence close to the end of the gene, called the polyadenylation signal, acts as a signal for termination of the RNA transcript (Fig. 3.3).

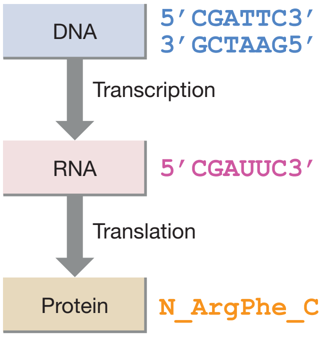

Fig. 3.2 The central dogma of protein production. Double-stranded DNA as a template for single-stranded RNA, which codes for the production of a peptide chain of amino acids. Each of these chains has an orientation. For DNA and RNA, this is 5′ to 3′. For peptides, this is N-terminus to C-terminus.

RNA differs from DNA in three main ways:

- RNA is single-stranded.
- The sugar residue within the nucleotide is ribose, rather than deoxyribose.
- It contains uracil (U) in place of thymine (T).

The activity of RNA polymerase is regulated by transcription factors. These proteins bind to specific DNA sequences at the promoter or to enhancer elements that may be many thousands of base pairs away from the promoter; a loop in the chromosomal DNA brings the enhancer close to the promoter, enabling the bound proteins to interact. The human genome encodes more than 1200 different transcription factors. Mutations within transcription factors, promoters and enhancers can cause disease. For example, the blood disorder alpha-thalassaemia is usually caused by gene deletions (see p. 954 and Box 3.4). However, it can also result from a mutation in an enhancer located more than 100 000 base pairs (bp) from the α-globin gene promoter, leading to greatly reduced transcription.

Gene activity, or expression, is influenced by a number of complex interacting factors, including the accessibility of the gene promoter to transcription factors. DNA can be modified by the addition of a methyl group to cytosine molecules (methylation). If DNA methylation occurs in promoter regions, transcription is silenced, as methyl cytosines are usually not available for transcription factor binding. A second mechanism determining promoter accessibility is the structural configuration of chromatin. In open chromatin, called euchromatin, gene promoters are accessible to RNA polymerase and transcription factors; therefore it is transcriptionally active. This contrasts with heterochromatin, which is densely packed and transcriptionally silent. The chromatin configuration is determined by modifications (such as methylation or acetylation) of specific amino acid residues of histone protein tails.

Modifications of DNA and histones are termed epigenetic ('epi-' meaning 'above' the genome), as they do not alter the primary sequence of the DNA code but have biological significance in chromosomal function. Abnormal epigenetic changes are increasingly recognised as important events in the progression of cancer, allowing expression of normally silenced genes that result in cancer cell de-differentiation and proliferation. They also afford therapeutic targets. For instance, the histone deacetylase inhibitor vorinostat has been successfully used to treat cutaneous T-cell lymphoma, due to the re-expression of genes that had

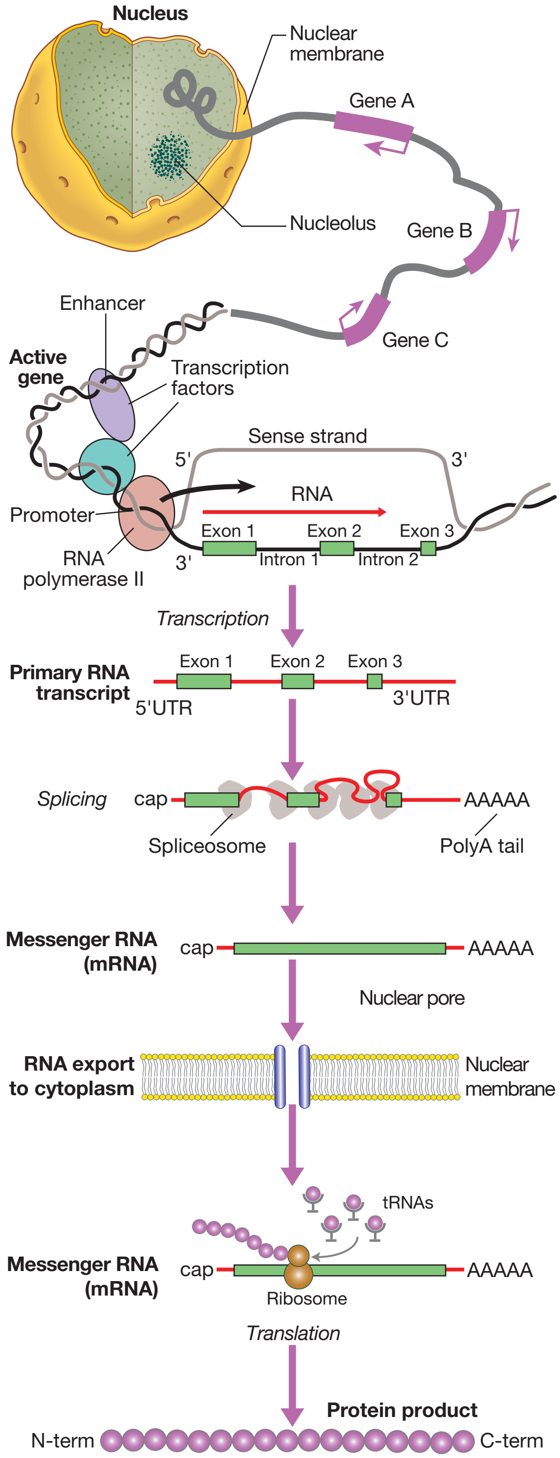

Fig. 3.3 RNA synthesis and its translation into protein. Gene transcription involves binding of RNA polymerase II to the promoter of genes being transcribed with other proteins (transcription factors) that regulate the transcription rate. The primary RNA transcript is a copy of the whole gene and includes both introns and exons, but the introns are removed within the nucleus by splicing and the exons are joined to form the messenger RNA (mRNA). Prior to export from the nucleus, a methylated guanosine nucleotide is added to the 5′ end of the RNA ('cap') and a string of adenine nucleotides is added to the 3′ ('polyA tail'). This protects the RNA from degradation and facilitates transport into the cytoplasm. In the cytoplasm, the mRNA binds to ribosomes and forms a template for protein production. (tRNA = transfer RNA; UTR = untranslated region)

previously been silenced in the tumour. These genes encode transcription factors that promote T-cell differentiation as opposed to proliferation, thereby causing tumour regression.

RNA splicing, editing and degradation

Transcription produces an RNA molecule that is a copy of the whole gene, termed the primary or nascent transcript. This nascent transcript then undergoes splicing, whereby regions not required to make protein (the intronic regions) are removed while those segments that are necessary for protein production (the exonic regions) are retained and rejoined.

Splicing is a highly regulated process that is carried out by a multimeric protein complex called the spliceosome. Following splicing, the mRNA molecule is exported from the nucleus and used as a template for protein synthesis. Many genes produce more than one form of mRNA (and thus protein) by a process termed alternative splicing, in which different combinations of exons are joined together. Different proteins from the same gene can have entirely distinct functions. For example, in thyroid C cells the calcitonin gene produces mRNA encoding the osteoclast inhibitor calcitonin (p. 634), but in neurons the same gene produces an mRNA with a different complement of exons via alternative splicing that encodes a neurotransmitter, calcitonin-gene-related peptide (p. 772).

Translation and protein production

Following splicing, the segment of mRNA containing the code that directs synthesis of a protein product is called the open reading frame (ORF). The inclusion of a particular amino acid in the protein is specified by a codon composed of three contiguous bases. There are 64 different codons with some redundancy in the system: 61 codons encode one of the 20 amino acids, and the remaining three codons – UAA, UAG and UGA (known as stop codons) – cause termination of the growing polypeptide chain. ORFs in humans most commonly start with the amino acid methionine. All mRNA molecules have domains before and after the ORF called the 5′ untranslated region (UTR) and 3′UTR, respectively. The start of the 5′UTR contains a cap structure that protects mRNA from enzymatic degradation, and other elements within the 5′UTR are required for efficient translation. The 3′UTR also contains elements that regulate efficiency of translation and mRNA stability, including a stretch of adenine bases known as a polyA tail (see Fig. 3.3).

The mRNAs then leave the nucleus via nuclear pores and associate with ribosomes, the sites of protein production (see Fig. 3.3). Each ribosome consists of two subunits (40S and 60S), which comprise non-coding rRNA molecules (see Fig. 3.9, p. 50) complexed with proteins. During translation, a different RNA molecule known as transfer RNA (tRNA) binds to the ribosome. The tRNAs deliver amino acids to the ribosome so that the newly synthesised protein can be assembled in a stepwise fashion. Individual tRNA molecules bind a specific amino acid and 'read' the mRNA ORF via an 'anticodon' of three nucleotides that is complementary to the codon in mRNA (see Fig. 3.3). A proportion of ribosomes is bound to the membrane of the endoplasmic reticulum (ER), a complex tubular structure that surrounds the nucleus.

Proteins synthesised on these ribosomes are translocated into the lumen of the ER, where they undergo folding and processing. From here, the protein may be transferred to the Golgi apparatus, where it undergoes post-translational modifications, such as glycosylation (covalent attachment of sugar moieties), to form the mature protein that can be exported into the cytoplasm or packaged into vesicles for secretion. The clinical importance of post-translational modification of proteins is shown by the severe developmental, neurological, haemostatic and soft tissue abnormalities that are associated with the many different congenital disorders of glycosylation. Post-translational modifications can also be disrupted by the synthesis of proteins with abnormal amino acid sequences. For example, the most common mutation in cystic fibrosis (ΔF508) results in an abnormal protein that cannot be exported from the ER and Golgi (see Box 3.4).

Non-coding RNA

Approximately 4500 genes in humans encode non-coding RNAs (ncRNA) rather than proteins. There are various categories of ncRNA, including transfer RNA (tRNA), ribosomal RNA (rRNA), ribozymes and microRNA (miRNA). The miRNAs, which number over 1000, have a role in post-translational gene expression: they bind to mRNAs, typically in the 3′UTR, promoting target mRNA degradation and gene silencing. Together, miRNAs affect over half of all human genes and have important roles in normal development, cancer and common degenerative disorders. This is the subject of considerable research interest at present.

Cell division, differentiation and migration

In normal tissues, molecules such as hormones, growth factors and cytokines provide the signal to activate the cell cycle: a controlled programme of biochemical events that culminates in cell division. In all cells of the body, except the gametes (the sperm and egg cells, also known as the germ line), mitosis completes cell division, resulting in two diploid daughter cells. In contrast, the sperm and eggs cells complete cell division with meiosis, resulting in four haploid daughter cells (Fig. 3.4).

The stages of cell division in the non-germ-line, somatic cells are shown below:

- *Cells not committed to mitosis* are said to be in G_0.
- *Cells committed to mitosis* must go through the preparatory phase of interphase consisting of G_1, S and G_2:
  - G_1 (first gap): synthesis of the cellular components necessary to complete cell division
  - S (synthesis): DNA replication producing identical copies of each chromosome called the sister chromatids
  - G_2 (second gap): repair of any errors in the replicated DNA before proceeding to mitosis.
- *Mitosis* (M) consists of four phases:
  - Prophase: the chromosomes condense and become visible, the centrioles move to opposite ends of the cell and the nuclear membrane disappears.
  - Metaphase: the centrioles complete their migration to opposite ends of the cell and the chromosomes – consisting of two identical sister chromatids – line up at the equator of the cell.
  - Anaphase: spindle fibres attach to the chromosome and pull the sister chromatids apart.
  - Telophase: the chromosomes decondense, the nuclear membrane reforms and two daughter cells – each with 46 chromosomes – are formed.

The progression from one phase to the next is tightly controlled by cell-cycle checkpoints. For example, the checkpoint between

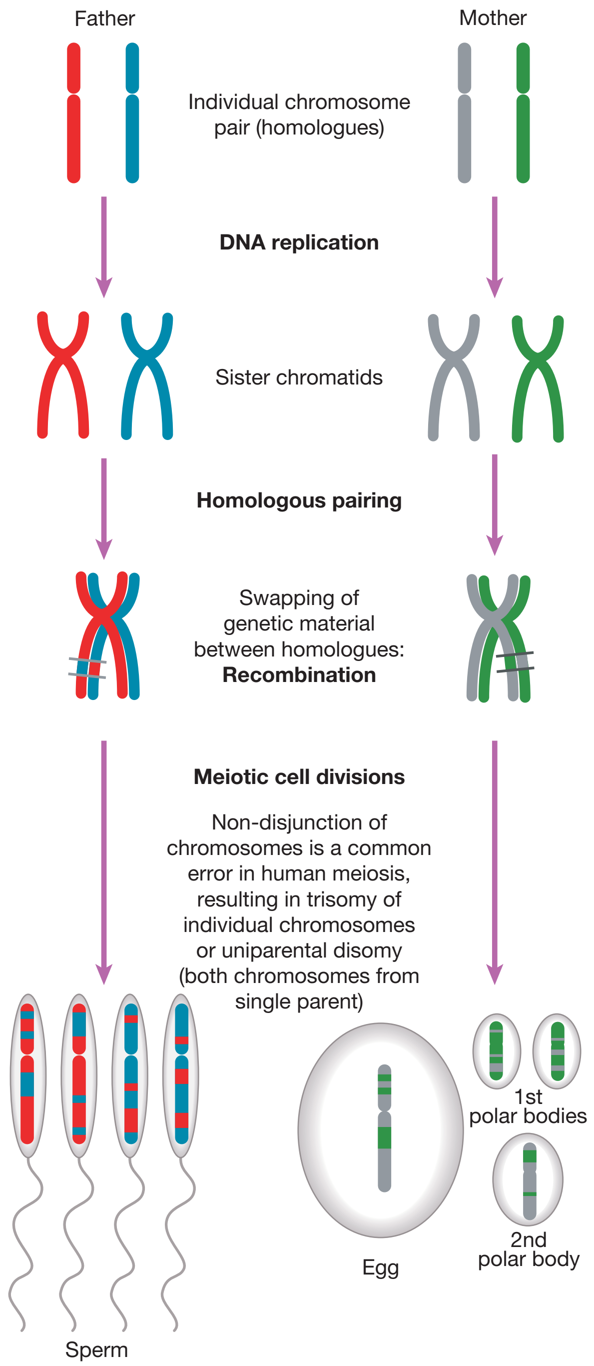

Fig. 3.4 Meiosis and gametogenesis: the main chromosomal stages of meiosis in both males and females. A single homologous pair of chromosomes is represented in different colours. The final step is the production of haploid germ cells. Each round of meiosis in the male results in four sperm cells; in the female, however, only one egg cell is produced, as the other divisions are sequestered on the periphery of the mature egg as peripheral polar bodies.

G_2 and mitosis ensures that all damaged DNA is repaired prior to segregation of the chromosomes. Failure of these control processes is a crucial driver in the pathogenesis of cancer, as discussed on page 1316.

- *Meiosis* is a special, gamete-specific, form of cell division (Fig. 3.4). Like mitosis, meiosis consists of four phases (prophase, metaphase, anaphase and telophase) but differs from mitosis in the following ways:
  - It consists of two separate cell divisions known as meiosis I and meiosis II.
  - It reduces the chromosome number from the diploid to the haploid number via a tetraploid stage, i.e. from 46 to 92 (MI S) to 46 (MI M) to 23 (MII M) chromosomes, so that when a sperm cell fertilises the egg, the resulting zygote will return to a diploid, 46, chromosome complement. This reduction to the haploid number occurs at the end of meiosis II.
  - The 92 chromosome stage consists of 23 homologous pairs of sister chromatids, which then swap genetic material, a process known as recombination. This occurs at the end of MI prophase and ensures that the chromosome that a parent passes to his or her offspring is a mix of the chromosomes that the parent inherited from his or her own mother and father.

The individual steps in meiotic cell division are similar in males and females. However, the timing of the cell divisions is very different. In females, meiosis begins in fetal life but does not complete until after ovulation. A single meiotic cell division can thus take more than 40 years to complete. As women become older, the separation of chromosomes at meiosis II becomes less efficient. That is why the risk of trisomies (p. 44) due to non-disjunction grows greater with increasing maternal age. In males, meiotic division does not begin until puberty and continues throughout life. In the testes, both meiotic divisions are completed in a matter of days.

Cell death, apoptosis and senescence

With the exception of stem cells, human cells have only a limited capacity for cell division. The Hayflick limit is the number of divisions a cell population can go through in culture before division stops and enters a state known as senescence. This ‘biological clock’ is of great interest in the study of the normal ageing process. Rare human diseases associated with premature ageing, called progeric syndromes, have been very helpful in identifying the importance of DNA repair mechanisms in senescence (p. 1034). For example, in Werner’s syndrome, a DNA helicase (an enzyme that separates the two DNA strands) is mutated, leading to failure of DNA repair and premature ageing. A distinct mechanism of cell death is seen in apoptosis, or programmed cell death.

Apoptosis is an active process that occurs in normal tissues and plays an important role in development, tissue remodelling and the immune response. The signal that triggers apoptosis is specific to each tissue or cell type. This signal activates enzymes, called caspases, which actively destroy cellular components, including chromosomal DNA. This degradation results in cell death, but the cellular corpse contains characteristic vesicles called apoptotic bodies. The corpse is then recognised and removed by phagocytic cells of the immune system, such as macrophages, in a manner that does not provoke an inflammatory response.

A third mechanism of cell death is necrosis. This is a pathological process in which the cellular environment loses one or more of the components necessary for cell viability. Hypoxia is probably the most common cause of necrosis.

Genomics, health and disease

Classes of genetic variant

There are many different classes of variation in the human genome, categorised by the size of the DNA segment involved and/or by the mechanism giving rise to the variation.

Nucleotide substitutions

The substitution of one nucleotide for another is the most common type of genomic variation. Depending on their frequency and functional consequences, these changes are known as point mutations or single nucleotide polymorphisms (SNPs). They occur by misincorporation of a nucleotide during DNA synthesis or by chemical modification of the base. When these substitutions occur within ORFs of a protein-coding gene, they are further classified into:

- *synonymous* – resulting in a change in the codon without altering the amino acid
- *non-synonymous* (also known as a missense mutation) – resulting in a change in the codon and the encoded amino acid
- *stop gain* (or *nonsense mutation*) – introducing a premature stop codon and resulting in truncation of the protein
- *splicing* – taking place at splice sites that most frequently occur at the junction between an intron and an exon.

These different types of mutation are illustrated in Box 3.1 and examples are shown in Figures 3.5 and 3.6.

Insertions and deletions

One or more nucleotides may be inserted or lost in a DNA sequence, resulting in an insertion/deletion (indel) polymorphism or mutation (Box 3.1 and Fig. 3.5). If a multiple of three nucleotides is involved, this is in-frame. If an indel change affects one or two nucleotides within the ORF of a protein-coding gene, this can have serious consequences because the triple nucleotide sequence of the codons is disrupted, resulting in a frameshift mutation. The effect on the gene is typically severe because the amino acid sequence is totally disrupted.

i 3.1 Classes of genetics variant

The classes of genetic variant can be illustrated using the sentence 'THE FAT FOX WAS ILL COS SHE ATE THE OLD CAT'

Synonymous	
Silent polymorphism with no amino acid change	THE FAT FOX WAS ILL COS SHE ATE THE OLD <u>K</u>AT where the C is replaced with a K but the meaning remains the same
Non-synonymous	
Causing an amino acid change	THE FAT <u>B</u>OX WAS ILL COS SHE ATE THE OLD CAT where the F of FOX is replaced by a B and the original meaning of the sentence is lost
Stop gain (also called a nonsense mutation)	
Causing the generation of a premature stop codon	THE <u>C</u>AT where the F of FAT is replaced by a C generating a premature stop codon
Indel	
Where bases are either inserted or deleted; disruption of the reading frame is dependent on the number of bases inserted or deleted	THE FAT FOX WAS <u>ILL</u> ILL COS SHE ATE THE OLD CAT where the insertion of three bases results in maintenance of the reading frame THE FAT FOX <u>WA</u>W ASI LLC OSS HEA TET HEO LDC AT where the insertion of two bases results in disruption of the reading frame

A	DNA	ATG GCC GGG AAG TGT CGT GGT GTT	Normal
	mRNA	AUG GCC GGG AAG UGU CGU GGU GUU

Fig. 3.5 Different types of mutation affecting coding exons. A Normal sequence. B A synonymous nucleotide substitution changing the third base of a codon; the resulting amino acid sequence is unchanged. C A missense mutation in which the nucleotide substitution results in a change in a single amino acid from the normal sequence (AAG) encoding lysine to glutamine (CAG). D Insertion of a G residue (boxed) causes a frameshift mutation, completely altering the amino acid sequence downstream. This usually results in a loss-of-function mutation. E A nonsense mutation resulting in a single nucleotide change from a lysine codon (AAG) to a premature stop codon (TAG).

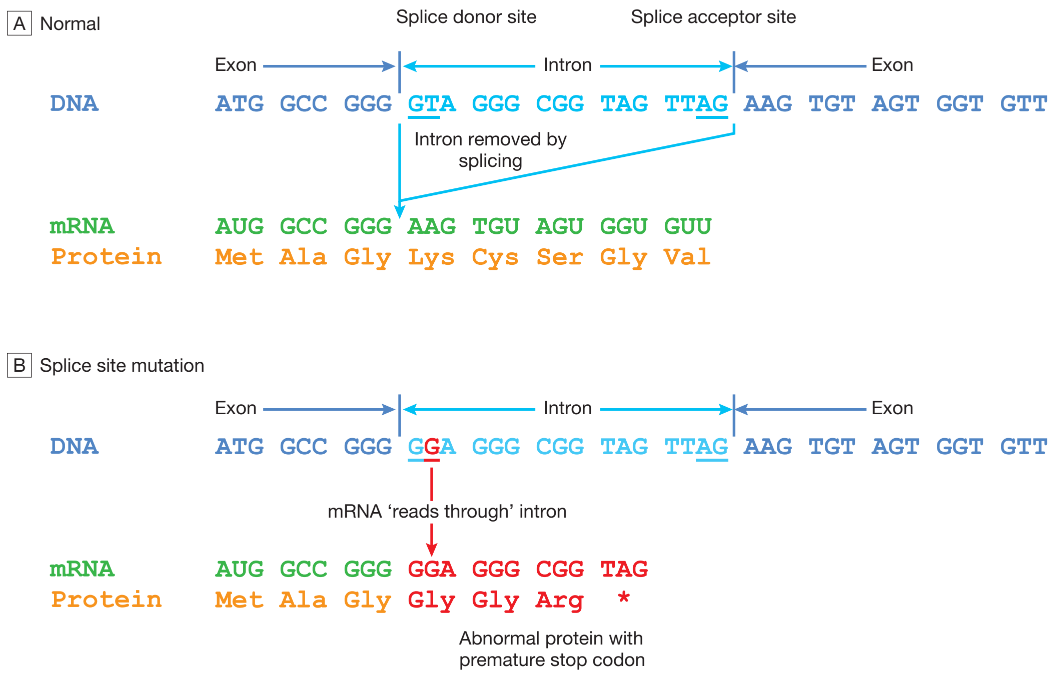

Fig. 3.6 Splice site mutations. A The normal sequence is shown, illustrating two exons, and intervening intron (blue) with splice donor (AG) and splice acceptor sites (GT) underlined. Normally, the intron is removed by splicing to give the mature messenger RNA that encodes the protein. B In a splice site mutation the donor site is mutated. As a result, splicing no longer occurs, leading to read-through of the mRNA into the intron, which contains a premature termination codon downstream of the mutation.

i 3.2 Diseases associated with triplet and other repeat expansions*

	Repeat	No. of repeats: Normal	No. of repeats: Mutant	Gene	Gene location	Inheritance
Coding repeat expansion						
Huntington's disease	[CAG]	6–34	>35	*Huntingtin*	4p16	AD
Spinocerebellar ataxia (type 1)	[CAG]	6–39	>40	*Ataxin*	6p22–23	AD
Spinocerebellar ataxia (types 2, 3, 6, 7)	[CAG]	Various	Various	Various	Various	AD
Dentatorubral-pallidoluysian atrophy	[CAG]	7–25	>49	*Atrophin*	12p12–13	AD
Machado–Joseph disease	[CAG]	12–40	>67	*MJD*	14q32	AD
Spinobulbar muscular atrophy	[CAG]	11–34	>40	Androgen receptor	Xq11–12	XL recessive
Non-coding repeat expansion						
Myotonic dystrophy	[CTG]	5–37	>50	*DMPK-3′UTR*	19q13	AD
Friedreich's ataxia	[GAA]	7–22	>200	*Frataxin-intronic*	9q13	AR
Progressive myoclonic epilepsy	$[CCCCGCCCCGCG]_{4–8}$	2–3	>25	*Cystatin B-5′UTR*	21q	AR
Fragile X mental retardation	[CGG]	5–52	>200	*FMR1–5′UTR*	Xq27	XL dominant
Fragile site mental retardation 2 (FRAXE)	[GCC]	6–35	>200	*FMR2*	Xq28	XL, probably recessive

*The triplet repeat diseases fall into two major groups: those with disease stemming from expansion of $[CAG]_n$ repeats in coding DNA, resulting in multiple adjacent glutamine residues (polyglutamine tracts), and those with non-coding repeats. The latter tend to be longer. Unaffected parents usually display 'pre-mutation' allele lengths that are just above the normal range. (AD/AR = autosomal dominant/recessive; UTR = untranslated region; XL = X-linked)

Simple tandem repeat mutations

Variations in the length of simple tandem repeats of DNA are thought to arise as the result of slippage of DNA during meiosis and are termed microsatellite (small) or minisatellite (larger) repeats. These repeats are unstable and can expand or contract in different generations. This instability is proportional to the size of the original repeat, in that longer repeats tend to be more unstable. Many microsatellites and minisatellites occur in introns or in chromosomal regions between genes and have no obvious adverse effects. However, some genetic diseases are caused by microsatellite repeats that result in duplication of amino acids within the affected gene product or affect gene expression (Box 3.2).

Copy number variations

Variation in the number of copies of an individual segment of the genome from the usual diploid (two copies) content can be categorised by the size of the segment involved. Rarely, individuals may gain (trisomy) or lose (monosomy) a whole chromosome. Such numerical chromosome anomalies most commonly occur by a process known as non-disjunction, where pairs of homologous chromosomes do not separate at meiosis II (p. 40). Common trisomies include Down's syndrome (trisomy 21), Edward's syndrome (trisomy 18) and Patau's syndrome (trisomy 13). Monosomy of the autosomes (present in all the cells, as opposed to in a mosaic distribution) does not occur but Turner's syndrome, in which there is monosomy for the X chromosome, affects approximately 1 in 2500 live births (Box 3.3).

Large insertions or deletions of chromosomal DNA also occur and are usually associated with a learning disability and/or congenital malformations. Such structural chromosomal anomalies usually arise as the result of one of two different processes:

- non-homologous end-joining
- non-allelic homologous recombination.

Random double-stranded breaks in DNA are a necessary process in meiotic recombination and also occur during mitosis at a predictable rate. The rate of these breaks is dramatically increased by exposure to ionising radiation. When such breaks take place, they are usually repaired accurately by DNA repair mechanisms within the cell. However, in a proportion of breaks, segments of DNA that are not normally contiguous will be joined ('non-homologous end-joining'). If the joined fragments are from different chromosomes, this results in a translocation. If they are from the same chromosome, this will result in either inversion, duplication or deletion of a chromosomal fragment (Fig. 3.7). Large insertions and deletions may be cytogenetically visible as chromosomal deletions or duplications. If the anomalies are too small to be detected by microscopy, they are termed microdeletions and microduplications. Many microdeletion syndromes have been described and most result from non-allelic homologous recombination between repeats of highly similar DNA sequences, which leads to recurrent chromosome anomalies – and clinical syndromes – occurring in unrelated individuals (Fig. 3.7 and Box 3.3).

Consequences of genomic variation

The consequence of an individual mutation depends on many factors, including the mutation type, the nature of the gene product and the position of the variant in the protein. Mutations can have profound or subtle effects on gene and cell function. Variations that have profound effects are responsible for 'classical' genetic diseases, whereas those with subtle effects may contribute to the pathogenesis of common disease where there is a genetic component, such as diabetes.

- *Neutral variants* have no effect on quality or type of protein produced.
- *Loss-of-function mutations* result in loss or reduction in the normal protein function. Whole-gene deletions are the archetypal loss-of-function variants but stop-gain or indel mutations (early in the ORF), missense mutations affecting a critical domain and splice-site mutations can also result in loss of protein function.

3.3 Chromosome and contiguous gene disorders

Disease	Locus	Incidence	Clinical features
Numerical chromosomal abnormalities			
Down's syndrome (trisomy 21)	47,XY,+21 or 47,XX+21	1 in 800	Characteristic facies, IQ usually <50, congenital heart disease, reduced life expectancy
Edwards' syndrome (trisomy 18)	47,XY,+18 or 47,XX,+18	1 in 6000	Early lethality, characteristic skull and facies, frequent malformations of heart, kidney and other organs
Patau's syndrome (trisomy 13)	47,XY,+13 or 47, XX,+13	1 in 15 000	Early lethality, cleft lip and palate, polydactyly, small head, frequent congenital heart disease
Klinefelter's syndrome	47,XXY	1 in 1000	Phenotypic male, infertility, gynaecomastia, small testes (p. 660)
XYY	47,XYY	1 in 1000	Usually asymptomatic, some impulse control problems
Triple X syndrome	47,XXX	1 in 1000	Usually asymptomatic, may have reduced IQ
Turner's syndrome	45,X	1 in 5000	Phenotypic female, short stature, webbed neck, coarctation of the aorta, primary amenorrhoea (p. 659)
Recurrent deletions, microdeletions and contiguous gene defects			
Di George/velocardiofacial syndrome	22q11.2	1 in 4000	Cardiac outflow tract defects, distinctive facial appearance, thymic hypoplasia, cleft palate and hypocalcaemia. Major gene seems to be *TBX1* (cardiac defects and cleft palate)
Prader–Willi syndrome	15q11–q13	1 in 15 000	Distinctive facial appearance, hyperphagia, small hands and feet, distinct behavioural phenotype. Imprinted region, deletions on paternal allele in 70% of cases
Angelman's syndrome	15q11–q13	1 in 15 000	Distinctive facial appearance, absent speech, electroencephalogram (EEG) abnormality, characteristic gait. Imprinted region, deletions on maternal allele encompassing *UBE3A*
Williams' syndrome	7q11.23	1 in 10 000	Distinctive facial appearance, supravalvular aortic stenosis, learning disability and infantile hypercalcaemia. Major gene for supravalvular aortic stenosis is *elastin*
Smith–Magenis syndrome	17p11.2	1 in 25 000	Distinctive facial appearance and behavioural phenotype, self-injury and rapid eye movement (REM) sleep abnormalities. Major gene seems to be *RAI1*

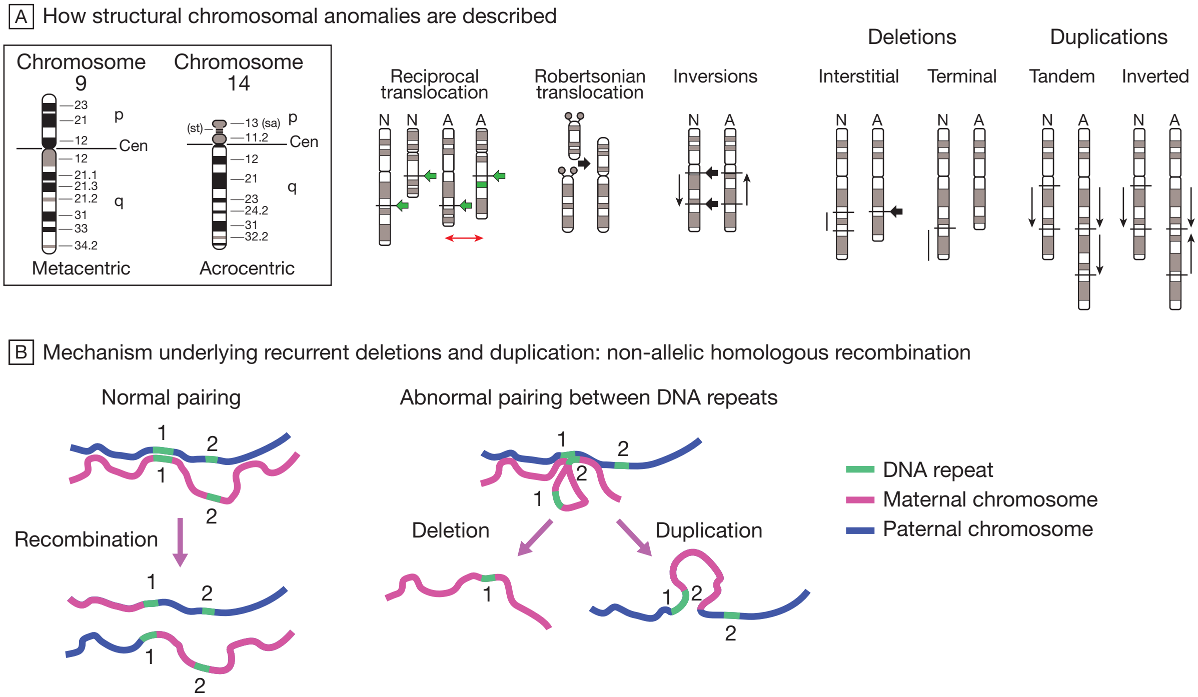

Fig. 3.7 Chromosomal analysis and structural chromosomal disorders. **A** Human chromosomes can be classed as metacentric if the centromere is near the middle, or acrocentric if the centromere is at the end. The bands of each chromosome are given a number, starting at the centromere and working out along the short (p) arm and long (q) arm. Translocations and inversions are balanced structural chromosome anomalies where no genetic material is missing but it is in the wrong order. Translocations can be divided into reciprocal (direct swap of chromosomal material between non-homologous chromosomes) and Robertsonian (fusion of acrocentric chromosomes). Deletions and duplications can also occur due to non-allelic homologous recombination (illustrated in part B). Deletions are classified as interstitial if they lie within a chromosome, and terminal if the terminal region of the chromosome is affected. Duplications can be either in tandem (where the duplicated fragment is inserted next to the region that is duplicated and orientated in the correct direction) or inverted (where the duplicated fragment is in the wrong direction). (N = normal; A = abnormal) **B** A common error of meiotic recombination, known as non-allelic homologous recombination, can occur (right panel), resulting in a deletion on one chromosome and a duplication in the homologous chromosome. The error is induced by tandem repeats in the DNA sequences (green), which can misalign and bind to each other, thereby 'fooling' the DNA into thinking the pairing prior to recombination is correct.

- *Gain-of-function mutations* result in a gain of protein function. They are typically non-synonymous mutations that alter the protein structure, leading to activation/alteration of its normal function through causing either an interaction with a novel substrate or a change in its normal function.
- *Dominant negative mutations* are the result of non-synonymous mutations or in-frame deletions/duplications but may also, less frequently, be caused by triplet repeat expansion mutations. Dominant negative mutations are heterozygous changes that result in the production of an abnormal protein that interferes with the normal functioning of the wild-type protein.

Normal genomic variation

We each have 5–50 million variants in our genome, occurring approximately every 300 bases. These variants are mostly polymorphisms, arising in more than 1% of the population; they have no or subtle effects on gene and cell function, and are not associated with a high risk of disease. Polymorphisms can occur within exons, introns or the intergenic regions that comprise 98–99% of the human genome. Each of the classes of genetic variant discussed on page 42 is present in the genome as a common polymorphism. However, the most frequent is the single nucleotide polymorphism, or SNP (pronounced 'snip'), describing the substitution of a single base.

Polymorphisms and common disease

The protective and detrimental polymorphisms associated with common disease have been identified primarily through genome-wide association studies (GWAS, p. 56) and are the basis for many direct-to-consumer tests that purport to determine individual risk profiles for common diseases or traits such as cardiovascular disease, diabetes and even male-pattern baldness! An example is the polymorphism in the gene *SLC2A9* that not only explains a significant proportion of the normal population variation in serum urate concentration but also predisposes 'high-risk' allele carriers to the development of gout. However, the current reality is that, until we have a more comprehensive understanding of the full genomic landscape and knowledge of the complete set of detrimental and protective polymorphisms, we cannot accurately assess risk.

Evolutionary selection

Genetic variants play an important role in evolutionary selection, with advantageous variants resulting in positive selection via improved reproductive fitness, and variations that decrease

reproductive fitness becoming excluded through evolution. Given this simple paradigm, it would be tempting to assume that common mutations are all advantageous and all rare mutations are pathogenic. Unfortunately, it is often difficult to classify any common mutation as either advantageous or deleterious – or, indeed, neutral. Mutations that are advantageous in early life and thus enhance reproductive fitness may be deleterious in later life. There may be mutations that are advantageous for survival in particular conditions (e.g. famine or pandemic) that may be disadvantageous in more benign circumstances by causing a predisposition to obesity or autoimmune disorders.

Constitutional genetic disease

Familial genetic disease is caused by constitutional mutations, which are inherited through the germ line. However, different mutations in the same gene can have different consequences, depending on the genetic mechanism underlying that disease. About 1% of the human population carries constitutional mutations that cause disease.

Constructing a family tree

The family tree – or pedigree – is a fundamental tool of the clinical geneticist, who will routinely take a three-generation family history, on both sides of the family, enquiring about details of all medical conditions in family members, consanguinity, dates of birth and death, and any history of pregnancy loss or infant death. The basic symbols and nomenclature used in drawing a pedigree are shown in Figure 3.8.

Patterns of disease inheritance

Autosomal dominant inheritance

Take some time to draw out the following pedigree:

Anne is referred to Clinical Genetics to discuss her personal history of colon cancer (she was diagnosed at the age of 46 years) and family history of colon/endometrial cancer: her mother was diagnosed with endometrial cancer at the age of 60 years and her cousin through her healthy maternal aunt was diagnosed with colon cancer in her fifties. Both her maternal grandmother and grandfather died of 'old age'. There is no family history of note on her father's side of the family. He has one brother and both his parents died of old age, in their eighties. Anne has two healthy daughters, aged 12 and 14 years, and a healthy full sister.

This family history is typical of an autosomal dominant condition (Fig. 3.8): in this case, a colon/endometrial cancer susceptibility syndrome known as Lynch's syndrome, associated with disruption of one of the mismatch repair genes: *MSH2*, *MSH6*, *MLH1* and *PMS2* (see p. 830 and Box 3.11, p. 57).

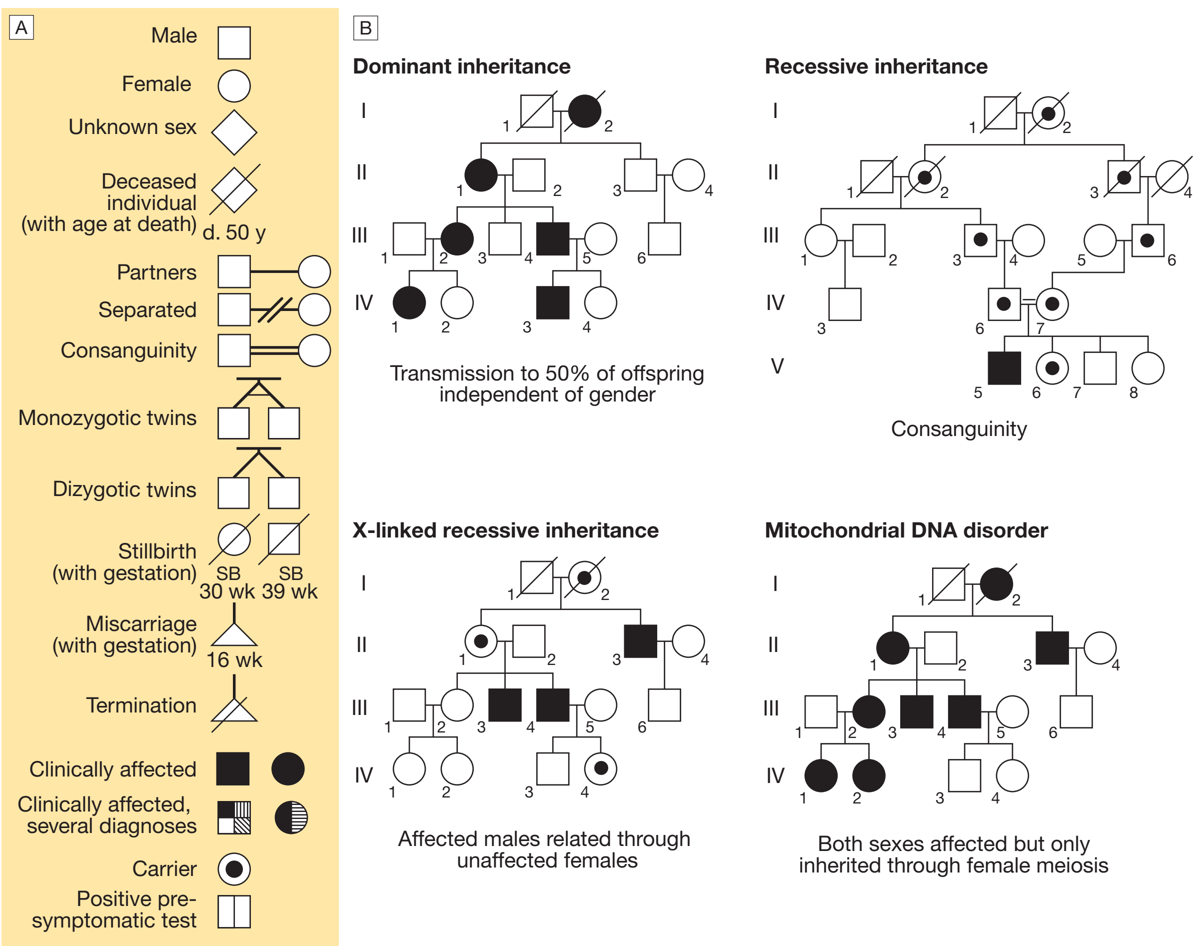

Fig. 3.8 Drawing a pedigree and patterns of inheritance. **A** The main symbols used to represent pedigrees in diagrammatic form. **B** The main modes of disease inheritance (see text for details).

Features of an autosomal dominant pedigree include:

- There are affected individuals in each generation (unless the mutation has arisen de novo, i.e. for the first time in an affected individual). However, variable penetrance and expressivity can influence the number of affected individuals and the severity of disease in each generation. Penetrance is defined as the proportion of individuals bearing a mutated allele who develop the disease phenotype. The mutation is said to be fully penetrant if all individuals who inherit a mutation develop the disease. Expressivity describes the level of severity of each aspect of the disease phenotype.
- Males and females are usually affected in roughly equal numbers (unless the clinical presentation of the condition is gender-specific, such as an inherited susceptibility to breast and/or ovarian cancer).

The offspring risk for an individual affected with an autosomal dominant condition is 1 in 2 (or 50%). This offspring risk is true for each pregnancy, since half the affected individual gametes (sperm or egg cells) will contain the affected chromosome/gene and half will contain the normal chromosome/gene.

There is a long list of autosomal dominant conditions, some of which are shown in Box 3.4.

i 3.4 Genetic conditions dealt with by clinicians in other specialties

Name of condition	Gene	Reference
Autosomal dominant conditions		
Autosomal dominant polycystic kidney disease (ADPKD)	*PKD1* (85%), *PKD2* (15%)	p. 405 Box 15.28, p. 415
Tuberous sclerosis	*TSC1* *TSC2*	p. 1264 p. 1264
Marfan's syndrome	*FBN1*	p. 508
Long QT syndrome	*KCNQ1*	p. 476
Brugada's syndrome	*SCN5A*	p. 477
Neurofibromatosis type 1	*NF1*	p. 1131 Box 25.77, p. 1132
Neurofibromatosis type 2	*NF2*	p. 1131 Box 25.77, p. 1132
Hereditary spherocytosis	*ANK1*	p. 947
Vascular Ehlers–Danlos syndrome (EDS type 4)	*COL3A1*	p. 970
Hereditary haemorrhagic telangiectasia	*ENG, ALK1, GDF2*	p. 970
Osteogenesis imperfecta	*COL1A1*, *COL1A2*	p. 1055
Charcot–Marie–Tooth disease	*PMP22, MPZ, GJB1*	p. 1140
Hereditary neuropathy with liability to pressure palsies	*PMP22*	
Autosomal recessive conditions		
Familial Mediterranean fever	*MEFV*	p. 81
Mevalonic aciduria (mevalonate kinase deficiency)	*MVK*	p. 81
Autosomal recessive polycystic kidney disease (ARPKD)	*PKHD1*	Box 15.28, p. 415
Kartagener's syndrome (primary ciliary dyskinesia)	*DNAI1*	Box 17.30, p. 578
Cystic fibrosis	*CFTR1*	p. 580 Box 17.30, p. 578 p. 842
Pendred's syndrome	*SLC26A4*	p. 650
Congenital adrenal hyperplasia-21 hydroxylase deficiency	*CYP21A*	p. 676 Box 18.27, p. 658
Haemochromatosis	*HFE*	p. 895
Wilson's disease	*ATP7B*	p. 896
Alpha$_1$-antitrypsin deficiency	*SERPINA1*	p. 897
Gilbert's syndrome	*UGT1A1*	p. 897
Benign recurrent intrahepatic cholestasis	*ATP8B1*	p. 902
Alpha-thalassaemia	*HBA1*, *HBA2*	p. 951 p. 954
Beta-thalassaemia	*HBB*	p. 951 p. 953
Sickle cell disease	*HBB*	p. 951
Spinal muscular atrophy	*SMN1*	p. 1117
X-linked conditions		
Alport's syndrome	*COL4A5*	Box 15.28, p. 415 p. 403
Primary agammaglobulinaemia	*BTK*	p. 78
Haemophilia A (factor VIII deficiency)	*F8*	p. 971
Haemophilia B (factor IX deficiency)	*F9*	p. 973
Duchenne muscular dystrophy	*DMD*	p. 1143 and Box 25.91

Autosomal recessive inheritance

As above, take some time to draw a pedigree representing the following:

Mr and Mrs Kent, a non-consanguineous couple, are referred because their son, Jamie, had severe neonatal liver disease. Included among the many investigations that the paediatric hepatologist undertook was testing for α_1-antitrypsin deficiency (Box 3.5). Jamie was shown to have the PiZZ phenotype. Testing confirmed both parents as carriers with PiMZ phenotypes. In the family, Jamie has an older sister who has no medical problems. Mr Kent is one of four children with two brothers and a sister and Mrs Kent has a younger brother. Both sets of grandparents are alive and well. There is no family history of α_1-antitrypsin deficiency.

This family history is characteristic of an autosomal recessive disorder (Fig. 3.8), where both alleles of a gene must be mutated before the disease is manifest in an individual; an affected individual inherits one mutant allele from each of their parents, who are therefore healthy carriers for the condition. An autosomal recessive condition might be suspected in a family where:

- Males and females are affected in roughly equal proportions.
- Parents are blood related; this is known as consanguinity. Where there is consanguinity, the mutations are usually homozygous, i.e. the same mutant allele is inherited from both parents.
- Individuals within one sibship in one generation are affected and so the condition can appear to have arisen 'out of the blue'.

Approximately 1 in 4 children born to carriers of an autosomal recessive condition will be affected. The offspring risk for carrier parents is therefore 25% and the chances of an unaffected child, with an affected sibling, being a carrier is 2/3.

Examples of some autosomal recessive conditions, discussed elsewhere in this book, are shown in Box 3.4.

X-linked inheritance

The following is an exemplar of an X-linked recessive pedigree (Fig. 3.8):

Edward has a diagnosis of Duchenne muscular dystrophy (DMD, Box 3.6). His parents had suspected the diagnosis when he was 3 years old because he was not yet walking and there was a family history of DMD: Edward's maternal uncle had been affected and died at the age of 24 years. Edward's mother has no additional siblings. After Edward demonstrated a very high creatinine kinase level, the paediatrician also requested genetic testing, which identified a deletion of exons 2–8 of the dystrophin gene. Edward has a younger, healthy sister and grandparents on both sides of the family are well, although the maternal grandmother has recently developed a cardiomyopathy. Edward's father has an older sister and an older brother who are both well.

Genetic diseases caused by mutations on the X chromosome have specific characteristics:

- X-linked diseases are mostly recessive and restricted to males who carry the mutant allele. This is because males

i 3.5 Alpha$_1$-antitrypsin deficiency

Inheritance pattern

- Autosomal recessive

Genetic cause

- Two common mutations in the *SERPINA1* gene: p.Glu342Lys and p.Glu264Val

Prevalence

- 1 in 1500–3000 of European ancestry

Clinical presentation

- Variable presentation from neonatal period through to adulthood
- Neonatal period: prolonged jaundice with conjugated hyperbilirubinaemia or (rarely) liver disease
- Adulthood: pulmonary emphysema and/or cirrhosis. Rarely, the skin disease, panniculitis, develops

Disease mechanism

- *SERPINA1* encodes α_1-antitrypsin, which protects the body from the effects of neutrophil elastase. The symptoms of α_1-antitrypsin deficiency result from the effects of this enzyme attacking normal tissue

Disease variants

- M variant: if an individual has normal *SERPINA1* genes and produces normal levels of α_1-antitrypsin, they are said to have an M variant
- S variant: p.Glu264Val mutation results in α_1-antitrypsin levels reduced to about 40% of normal
- Z variant: p.Glu342Lys mutation results in very little α_1-antitrypsin
- PiZZ: individuals who are homozygous for the p.Glu342Lys mutation are likely to have α_1-antitrypsin deficiency and the associated symptoms
- PiZS: individuals who are compound heterozygous for p.Glu342Lys and p.Glu264Val are likely to be affected, especially if they smoke, but usually to a milder degree

i 3.6 Duchenne muscular dystrophy*

Inheritance pattern

- X-linked recessive

Genetic cause

- Mutations or deletions encompassing/within the *DMD* (dystrophin) gene located at Xp21

Prevalence

- 1 in 3000–4000 live male births

Clinical presentation

- Delayed motor milestones
- Speech delay
- Grossly elevated creatine kinase (CK) levels (in the thousands)
- Ambulation is usually lost between the ages of 7 and 13 years
- Lifespan is reduced with a mean age of death, usually from respiratory failure, in the mid-twenties
- Cardiomyopathy affects almost all boys with Duchenne muscular dystrophy and some female carriers

Disease mechanism

- *DMD* encodes dystrophin, a major structural component of muscle
- Dystrophin links the internal cytoskeleton to the extracellular matrix

Disease variants

- Becker muscular dystrophy, although a separate disease, is also caused by mutations in the dystrophin gene
- In Duchenne muscular dystrophy, there is no dystrophin protein, whereas in Becker muscular dystrophy there is a reduction in the amount or alteration in the size of the dystrophin protein

*See also page 1143.

have only one X chromosome, whereas females have two (see Fig. 3.1). However, occasionally, female carriers may exhibit signs of an X-linked disease due to a phenomenon called skewed X-inactivation. All female embryos, at about 100 cells in size, stably inactivate one of their two X chromosomes in each cell. Where this inactivation is random, approximately 50% of the cells will express the genes from one X chromosome and 50% of cells will express genes from the other. Where there is a mutant gene, there is often skewing away from the associated X chromosome, resulting in an unaffected female carrier. However, if, by chance, there is a disproportionate inactivation of the normal X chromosome with skewing towards the mutant allele, then an affected female carrier may be affected (albeit more mildly than males).
- The gene can be transmitted from female carriers to their sons: in families with an X-linked recessive condition, there are often a number of affected males related through unaffected females.
- Affected males cannot transmit the condition to their sons (but all their daughters would be carriers).

The risk of a female carrier having an affected child is 25% or half of her male offspring.

Mitochondrial inheritance

The mitochondrion is the main site of energy production within the cell. Mitochondria arose during evolution via the symbiotic association with an intracellular bacterium. They have a distinctive structure with functionally distinct inner and outer membranes. Mitochondria produce energy in the form of adenosine triphosphate (ATP). ATP is mostly derived from the metabolism of glucose and fat (Fig. 3.9). Glucose cannot enter mitochondria directly but is first metabolised to pyruvate via glycolysis. Pyruvate is then imported into the mitochondrion and metabolised to acetyl-co-enzyme A (acetyl-CoA). Fatty acids are transported into the mitochondria following conjugation with carnitine and are sequentially catabolised by a process called β-oxidation to produce acetyl-CoA. The acetyl-CoA from both pyruvate and fatty acid oxidation is used in the citric acid (Krebs) cycle – a series of enzymatic reactions that produces CO_2, the reduced form of nicotinamide adenine dinucleotide (NADH) and the reduced form of flavine adenine dinucleotide ($FADH_2$). Both NADH and $FADH_2$ then donate electrons to the respiratory chain. Here these elections are transferred via a complex series of reactions, resulting in the formation of a proton gradient across the inner mitochondrial membrane. The gradient is used by an inner mitochondrial membrane protein, ATP synthase, to produce ATP, which is then transported to other parts of the cell. Dephosphorylation of ATP is used to produce the energy required for many cellular processes.

Each mitochondrion contains 2–10 copies of a 16-kilobase (kB) double-stranded circular DNA molecule (mtRNA). This mtDNA contains 13 protein-coding genes, all involved in the respiratory chain, and the ncRNA genes required for protein synthesis within the mitochondria (Fig. 3.9). The mutational rate of mtDNA is relatively high due to the lack of protection by chromatin. Several mtDNA diseases characterised by defects in ATP production have been described. Mitochondria are most numerous in cells with high metabolic demands, such as muscle, retina and the basal ganglia, and these tissues tend to be the ones most severely affected in mitochondrial diseases (Box 3.7). There are many other mitochondrial diseases that are caused by mutations in nuclear genes, which encode proteins that are then imported into the mitochondrion and are critical for energy production, e.g. most forms of Leigh's syndrome (although Leigh's syndrome may also be caused by a mitochondrial gene mutation).

The inheritance of mtDNA disorders is characterised by transmission from females, but males and females generally are equally affected (see Fig. 3.8). Unlike the other inheritance patterns mentioned above, mitochondrial inheritance has nothing to do with meiosis but reflects the fact that mitochondrial DNA is transmitted by oöcytes: sperm do not contribute mitochondria to the zygote. Mitochondrial disorders tend to be variable in penetrance and expressivity within families, and this is mostly accounted for by the fact that only a proportion of multiple mtDNA molecules within mitochondria contain the causal mutation (the degree of mtDNA heteroplasmy).

Imprinting

Several chromosomal regions (loci) have been identified where gene expression is inherited in a parent-of-origin-specific manner;

i 3.7 The structure of the respiratory chain complexes and the diseases associated with their dysfunction

Complex	Enzyme	nDNA subunits[1]	mtDNA subunits[2]	Diseases
I	NADH dehydrogenase	38	7	MELAS, MERRF bilateral striatal necrosis, LHON, myopathy and exercise intolerance, Parkinsonism, Leigh's syndrome, exercise myoglobinuria, leucodystrophy/myoclonic epilepsy
II	Succinate dehydrogenase	4	0	Phaeochromocytoma, Leigh's syndrome
III	Cytochrome bc_1 complex	10	1	Parkinsonism/MELAS, cardiomyopathy, myopathy, exercise myoglobinuria, Leigh's syndrome
IV	Cytochrome c oxidase	10	3	Sideroblastic anaemia, myoclonic ataxia, deafness, myopathy, MELAS, MERRF mitochondrial encephalomyopathy, motor neuron disease-like, exercise myoglobinuria, Leigh's syndrome
V	ATP synthase	14	2	Leigh's syndrome, NARP, bilateral striatal necrosis

[1]nDNA subunits. [2]mtDNA subunits = number of different protein subunits in each complex that are encoded in the nDNA and mtDNA, respectively.
(ATP = adenosine triphosphate; LHON = Leber hereditary optic neuropathy; MELAS = myopathy, encephalopathy, lactic acidosis and stroke-like episodes; MERRF = myoclonic epilepsy and ragged red fibres; mtDNA = mitochondrial DNA; NADH = the reduced form of nicotinamide adenine dinucleotide; NARP = neuropathy, ataxia and retinitis pigmentosa; nDNA = nuclear DNA)

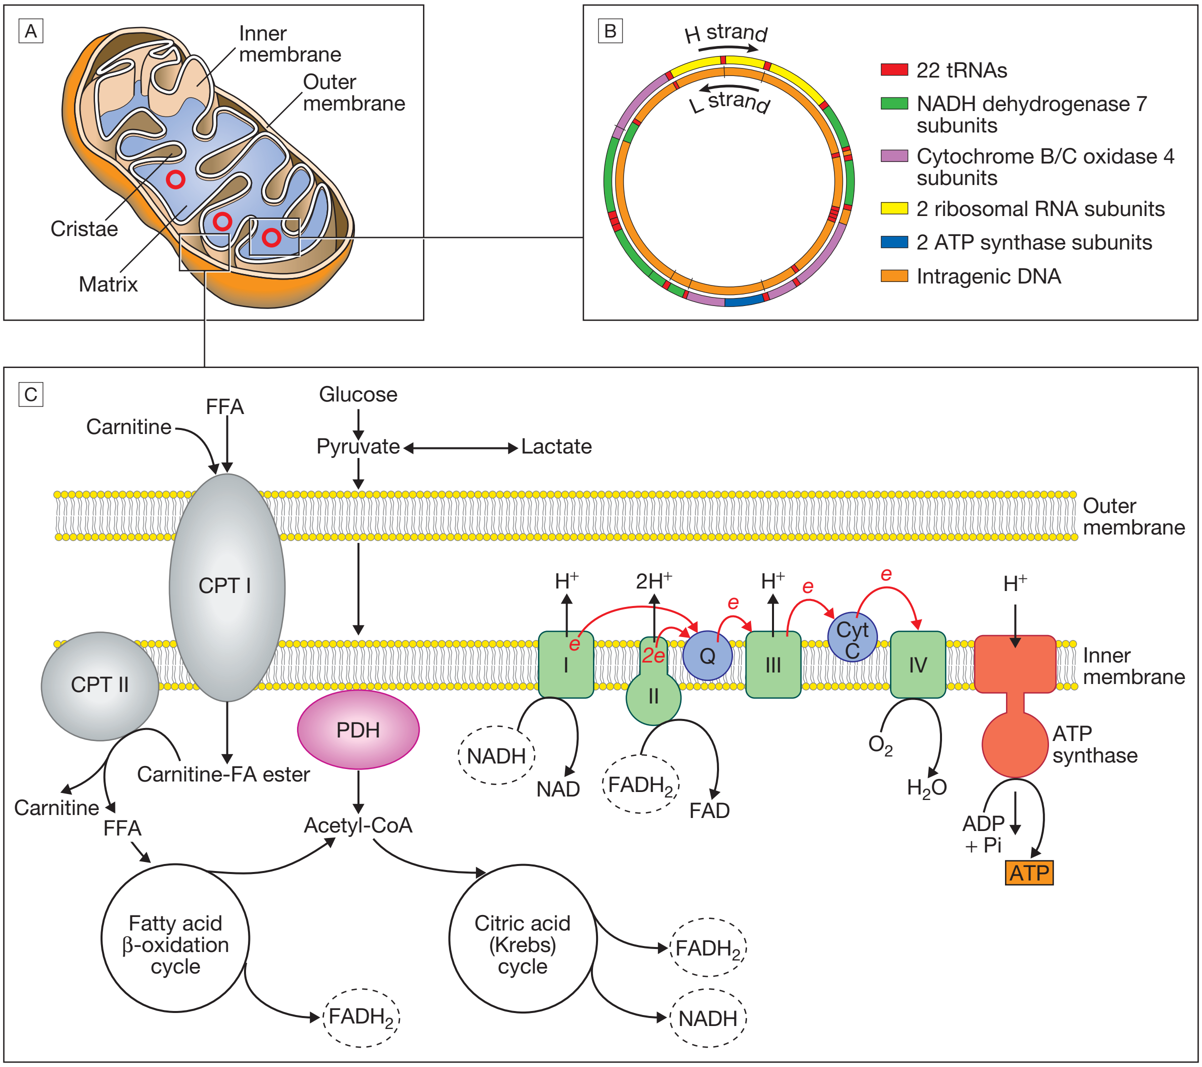

Fig. 3.9 Mitochondria. **A** Mitochondrial structure. There is a smooth outer membrane surrounding a convoluted inner membrane, which has inward projections called cristae. The membranes create two compartments: the inter-membrane compartment, which plays a crucial role in the electron transport chain, and the inner compartment (or matrix), which contains mitochondrial DNA and the enzymes responsible for the citric acid (Krebs) cycle and the fatty acid β-oxidation cycle. **B** Mitochondrial DNA. The mitochondrion contains several copies of a circular double-stranded DNA molecule, which has a non-coding region, and a coding region that encodes the genes responsible for energy production, mitochondrial transfer RNA (tRNA) molecules and mitochondrial ribosomal RNA (rRNA) molecules. (ATP = adenosine triphosphate; NADH = the reduced form of nicotinamide adenine dinucleotide) **C** Mitochondrial energy production. Fatty acids enter the mitochondrion conjugated to carnitine by carnitine-palmityl transferase type 1 (CPT I) and, once inside the matrix, are unconjugated by CPT II to release free fatty acids (FFA). These are broken down by the β-oxidation cycle to produce acetyl-co-enzyme A (acetyl-CoA). Pyruvate can enter the mitochondrion directly and is metabolised by pyruvate dehydrogenase (PDH) to produce acetyl-CoA. The acetyl-CoA enters the Krebs cycle, leading to the production of NADH and flavine adenine dinucleotide (reduced form) ($FADH_2$), which are used by proteins in the electron transport chain to generate a hydrogen ion gradient across the inter-membrane compartment. Reduction of NADH and $FADH_2$ by proteins I and II, respectively, releases electrons (e), and the energy released is used to pump protons into the inter-membrane compartment. Coenzyme Q_{10}/ubiquinone (Q) is an intensely hydrophobic electron carrier that is mobile within the inner membrane. As electrons are exchanged between proteins in the chain, more protons are pumped across the membrane, until the electrons reach complex IV (cytochrome oxidase), which uses the energy to reduce oxygen to water. The hydrogen ion gradient is used to produce ATP by the enzyme ATP synthase, which consists of a proton channel and catalytic sites for the synthesis of ATP from ADP. When the channel opens, hydrogen ions enter the matrix down the concentration gradient, and energy is released that is used to make ATP.

these are called imprinted loci. Within these loci the paternally inherited gene may be active while the maternally inherited may be silenced, or vice versa. Mutations within imprinted loci lead to an unusual pattern of inheritance where the phenotype is manifest only if inherited from the parent who contributes the transcriptionally active allele. Examples of imprinting disorders are given in Box 3.8.

Somatic genetic disease

Somatic mutations are not inherited but instead occur during post-zygotic mitotic cell divisions at any point from embryonic development to late adult life. An example of this phenomenon is polyostotic fibrous dysplasia (McCune–Albright syndrome), in

i 3.8 Imprinting disorders

Disorder	Locus	Genes	Notes
Beckwith–Wiedemann syndrome	11p15	*CDKN1C*, *IGF2*, *H19*	Increased growth, macroglossia, hemihypertrophy, abdominal wall defects, ear lobe pits/creases and increased susceptibility to developing childhood tumours
Prader–Willi syndrome	15q11–q13	*SNRPN*, *Necdin* and others	Obesity, hypogonadism and learning disability. Lack of paternal contribution (due to deletion of paternal 15q11–q13, or inheritance of both chromosome 15q11–q13 regions from the mother)
Angelman's syndrome (AS)	15q11–q13	*UBE3A*	Severe mental retardation, ataxia, epilepsy and inappropriate laughing bouts. Due to loss-of-function mutations in the maternal *UBE3A* gene. The neurological phenotype results because most tissues express both maternal and paternal alleles of *UBE3A*, whereas the brain expresses predominantly the maternal allele
Pseudohypoparathyroidism (p. 664)	20q13	*GNAS1*	Inheritance of the mutation from the mother results in hypocalcaemia, hyperphosphataemia, raised parathyroid hormone (PTH) levels, ectopic calcification, obesity, delayed puberty and shortened 4th and 5th metacarpals (the syndrome known as Albright's hereditary osteodystrophy, AHO). When the mutation is inherited from the father, PTH, calcium and phosphate levels are normal but the other features are present (pseudopseudohypoparathyroidism, p. 664). These differences are due to the fact that, in the kidney (the main target organ through which PTH regulates serum calcium and phosphate), the paternal allele is silenced and the maternal allele is expressed, whereas both alleles are expressed in other tissues.

which a somatic mutation in the G_S alpha gene causes constitutive activation of downstream signalling, resulting in focal lesions in the skeleton and endocrine dysfunction (p. 1055).

The most important example of human disease caused by somatic mutations is cancer (see Ch. 33). Here, 'driver' mutations occur within genes that are involved in regulating cell division or apoptosis, resulting in abnormal cell growth and tumour formation. The two general categories of cancer-causing mutation are gain-of-function mutations in growth-promoting genes (oncogenes) and loss-of-function mutations in growth-suppressing genes (tumour suppressor genes). Whichever mechanism is acting, most tumours require an initiating mutation in a single cell that can then escape from normal growth controls. This cell replicates more frequently or fails to undergo programmed death, resulting in clonal expansion. As the size of the clone increases, one or more cells may acquire additional mutations that confer a further growth advantage, leading to proliferation of these subclones, which may ultimately result in aggressive metastatic cancer. The cell's complex self-regulating machinery means that more than one mutation is usually required to produce a malignant tumour (see Fig. 33.3, p. 1318). For example, if a mutation results in activation of a growth factor gene or receptor, then that cell will replicate more frequently as a result of autocrine stimulation. However, this mutant cell will still be subject to normal cell-cycle checkpoints to promote DNA integrity in its progeny. If additional mutations in the same cell result in defective cell-cycle checkpoints, however, it will rapidly accumulate further mutations, which may allow completely unregulated growth and/or separation from its matrix and cellular attachments and/or resistance to apoptosis. As cell growth becomes increasingly dysregulated, cells de-differentiate, lose their response to normal tissue environment and cease to ensure appropriate mitotic chromosomal segregation. These processes combine to generate the classical malignant characteristics of disorganised growth, variable levels of differentiation, and numerical and structural chromosome abnormalities. An increase in somatic mutation rate can occur on exposure to external mutagens, such as ultraviolet light or cigarette smoke, or if the cell has defects in DNA repair systems. Cancer is thus a disease that affects the fundamental processes of molecular and cell biology.

Interrogating the genome: the changing landscape of genomic technologies

Looking at chromosomes

The analysis of metaphase chromosomes by light microscopy was the mainstay of clinical cytogenetic analysis for decades, the aim being to detect gain or loss of whole chromosomes (aneuploidy) or large chromosomal segments (>4 million bp). More recently, genome-wide microarrays (array comparative genomic hybridisation or array CGH) have replaced chromosome analysis, allowing rapid and precise detection of segmental gain or loss of DNA throughout the genome (see Box 3.3). Microarrays consist of grids of multiple wells containing short DNA sequences (reference DNA) that are complementary to known sequences in the genome. Patient and reference DNA are each labelled with a coloured fluorescent dye (generally, patient DNA is labelled with a green fluorescent dye and reference DNA with a red fluorescent dye) and added to the microarray grid. Where there is an equal quantity of patient and reference DNA bound to the spot, this results in yellow fluorescence. Where there is too much patient DNA (representing a duplication of a chromosome region), the spot will be greener; it will be more red (appears orange) where there is 2 : 1 ratio of the control:patient DNA (representing heterozygous deletion of a chromosome region; Fig. 3.10).

Array CGH and other array-based approaches can detect small chromosomal deletions and duplications. They are also generally more sensitive than conventional karyotyping at detecting mosaicism (where there are two or more populations of cells, derived from a single fertilised egg, with different genotypes).

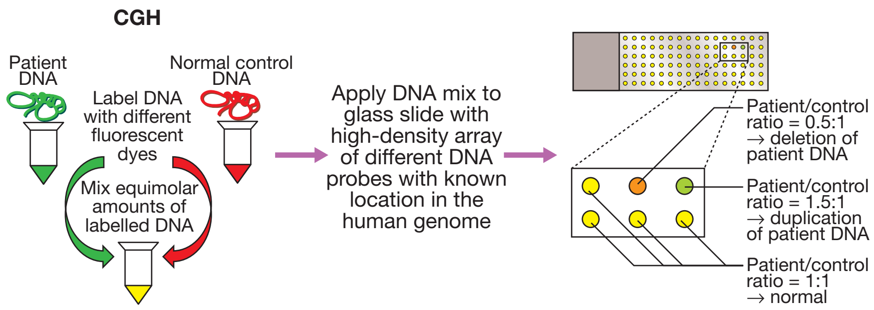

Fig. 3.10 Detection of chromosome abnormalities by comparative genomic hybridisation (CGH). Deletions and duplications are detected by looking for deviation from the 1 : 1 ratio of patient and control DNA in a microarray. Ratios in excess of 1 indicate duplications, whereas ratios below 1 indicate deletions.

However, array-based approaches will not detect balanced chromosome rearrangements where there is no loss or gain of genes/chromosome material, such as balanced reciprocal translocations, or a global increase in copy number, such as triploidy.

The widespread use of array-based approaches has brought a number of challenges for clinical interpretation, including the identification of copy number variants (CNVs) of uncertain clinical significance, CNVs of variable penetrance and incidental findings. A CNV of uncertain clinical significance describes a loss or gain of chromosome material where there are insufficient data to conclude whether or not it is associated with a learning disability and/or medical problems. While this uncertainty can be difficult to prepare families for and can be associated with considerable anxiety, it is likely that there will be greater clarity in the future as we generate larger CNV datasets.

A CNV of variable penetrance, also known as a neurosusceptibility locus, describes a chromosome deletion or duplication associated with a lower threshold for manifesting a learning disability or autistic spectrum disorder. CNVs of variable penetrance are therefore identified at greater frequencies among individuals with a learning disability and/or autistic spectrum disorder than in the general population. The current understanding is that additional modifying factors (genetic, environmental or stochastic) must influence the phenotypic expression of these neurosusceptibility loci.

Finally, an incidental CNV finding describes a deletion or duplication encompassing a gene or genes that are causative of a phenotype or risk unrelated to the presenting complaint. For instance, if, through the array CGH investigation for an intellectual disability, a deletion encompassing the *BRCA1* gene were identified, this would be considered an incidental finding.

Looking at genes

Gene amplification: polymerase chain reaction

The polymerase chain reaction (PCR) is a fundamental laboratory technique that amplifies targeted sections of the human genome for further analyses – most commonly, DNA sequencing. The method utilises thermal cycling: repeated cycles of heating and cooling allow the initial separation of double-stranded DNA into two single strands (known as denaturation), each of which serves as a template during the subsequent replication step, guided by primers designed to anneal to a specific genomic region. This cycle of heating/cooling and denaturation/replication is repeated many times, resulting in the exponential amplification of DNA between primer sites (Fig. 3.11).

Gene sequencing

In the mid-1970s, a scientist called Fred Sanger pioneered a DNA sequencing technique ('Sanger sequencing') that determined the precise order and nucleotide type (thymine, cytosine, adenine and guanine) in a molecule of DNA. Modern Sanger sequencing uses fluorescently labelled, chain-terminating nucleotides that are sequentially incorporated into the newly synthesised DNA, generating multiple DNA chains of differing lengths. These DNA chains are subject to capillary electrophoresis, which separates them by size, allowing the fragments to be 'read' by a laser and producing a sequence chromatogram that corresponds to the target sequence (Fig. 3.12). Although transformative, Sanger sequencing was difficult and costly to scale, as exemplified by the Human Genome Project, which took 12 years to sequence the entire human genome at a cost approaching 3 billion dollars. Recently, DNA sequencing has been transformed again by a group of technologies collectively known as 'next-generation sequencing' (NGS; Fig. 3.13). This refers to a family of post-Sanger sequencing technologies that utilise the same five basic principles:

- *Library preparation*: DNA samples are fragmented (by enzyme cleavage or ultrasound) and then modified with a custom adapter sequence.
- *Amplification*: the library fragment is amplified to produce DNA clusters, each originating from a single DNA fragment. Each cluster will act as a single sequencing reaction.
- *Capture*: if an entire genome is being sequenced, this step will not be included. The capture step is required if targeted resequencing is necessary, such as for a panel gene test or an exome (Box 3.9).
- *Sequencing*: each DNA cluster is simultaneously sequenced and the data from each captured; this is known as a 'read' and is usually between 50 and 300 bases long sequenced (see Box 3.10 for a detailed description of the three most commonly used sequencing methods: synthesis, ligation and ion semiconductor sequencing).
- *Alignment and variant identification*: specialised software analyses read sequences and compares the data to a reference template. This is known as 'alignment' or 'mapping' and, although there are 3 billion bases in the

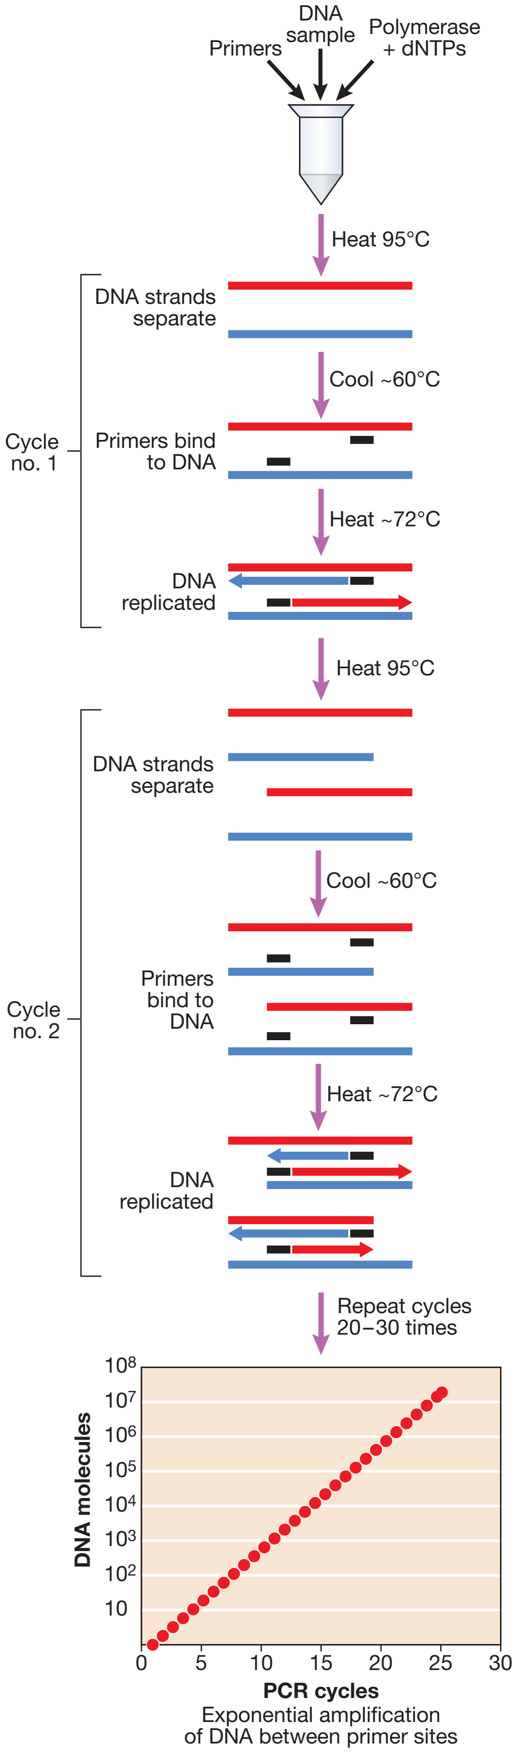

Fig. 3.11 The polymerase chain reaction (PCR). PCR involves adding a tiny amount of the patient's DNA to a reaction containing primers (short oligonucleotides 18–21 bp in length, which bind to the DNA flanking the region of interest) and deoxynucleotide phosphates (dATP, dCTP, dGTP, dTTP), which are used to synthesise new DNA and a heat-stable polymerase. The reaction mix is first heated to 95°C, which causes the double-stranded DNA molecules to separate. The reaction is then cooled to 50–60°C, which allows the primers to bind to the target DNA. The reaction is then heated to 72°C, at which point the polymerase starts making new DNA strands. These cycles are repeated 20–30 times, resulting in exponential amplification of the DNA fragment between the primer sites. The resulting PCR products can then be used for further analysis – most commonly, DNA sequencing (see Fig. 3.12).

human genome, allows the remarkably accurate determination of the genomic origin where a read consists of 25 nucleotides or more. Variants are identified as differences between the read and the reference genome. For instance, if there is a different nucleotide in half the reads at a given position compared to the reference genome, this is likely to represent a heterozygous base substitution. The number of reads that align at a given point is called the 'depth' or 'coverage'. The higher the read depth, the more accurate the variant call. However, in general, a depth of 30 or more reads is generally accepted as producing diagnostic-grade results.

Rather than sequencing only one small section of DNA at a time, NGS allows the analysis of many hundreds of thousands of DNA strands in a single experiment and so is also commonly referred to as multiple parallel sequencing technology. Today's NGS machines can sequence the entire human genome in a single day at a cost approaching 1000 US dollars.

NGS capture

Although we now have the capability to sequence the entire genome in a single experiment, whole-genome sequencing is not always the optimal use of NGS. NGS capture refers to the 'pull-down' of a targeted region of the genome and may constitute several to several hundred genes associated with a given phenotype (a gene panel), the exons of all known coding genes (an exome), or the exons of all coding genes known to be associated with disease (a clinical exome). Each of these targeted resequencing approaches is associated with a number of advantages and disadvantages (see Box 3.9). In order for NGS to be used for optimal patient benefit, it is essential for the clinician to have a good understanding of which test is the best one to request in any given clinical presentation.

Challenges of NGS technologies

Genomic technologies have the potential to transform the way that we practise medicine, and ever faster and cheaper DNA sequencing offers increasing opportunities to prevent, diagnose and treat disease. However, genomic technologies are not without their challenges: for instance, storing the enormous quantities of data generated by NGS. While the A, C, T and G of our genomic code could be stored on the memory of a smartphone, huge computers, able to store several petabytes of data (where 1 petabyte is 1 million gigabytes of data), are required to store the information needed to generate each individual's genome.

Even if we can store and handle these huge datasets successfully, we then need to be able to sift through the millions of

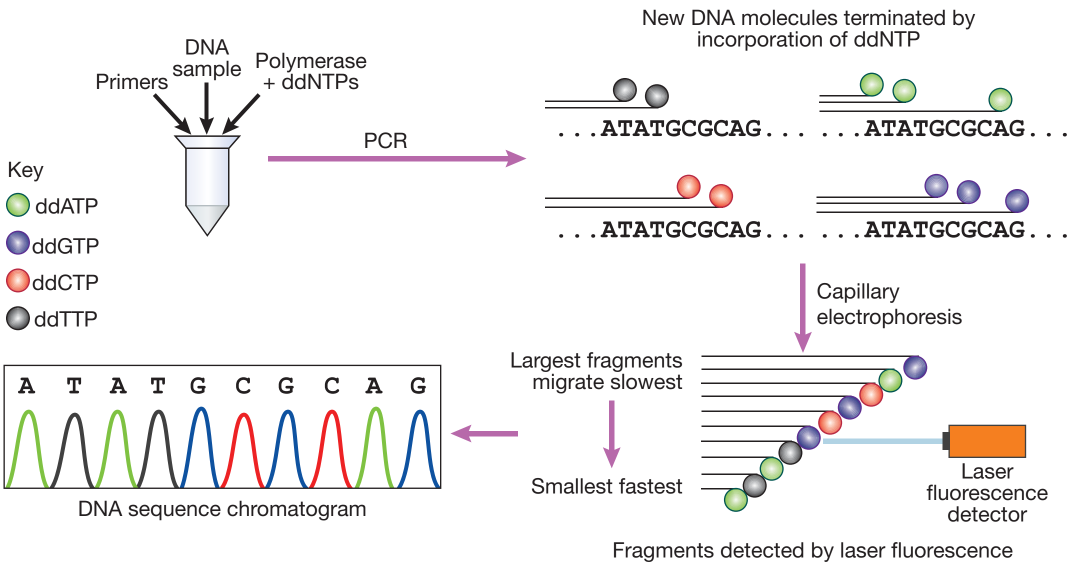

Fig. 3.12 Sanger sequencing of DNA, which is very widely used in DNA diagnostics. This is performed using PCR-amplified fragments of DNA corresponding to the gene of interest. The sequencing reaction is carried out with a combination dNTP and fluorescently labelled di-deoxy-dNTP (ddATP, ddTTP, ddCTP and ddGTP), which become incorporated into the newly synthesised DNA, causing termination of the chain at that point. The reaction products are then subject to capillary electrophoresis and the different-sized fragments are detected by a laser, producing a sequence chromatogram that corresponds to the target DNA sequence.

i 3.9 The advantages and disadvantages of whole-genome sequencing, whole-exome sequencing and gene panels

Test	Advantages	Disadvantages
Whole-genome sequencing (WGS)	The most comprehensive analysis of the genome available More even coverage of genes, allowing better identification of dosage abnormalities Will potentially detect all gene mutations, including intronic mutations	More expensive to generate and store Will detect millions of variants in non-coding DNA, which can be very difficult to interpret Associated with a greater risk of identifying incidental findings Shallow sequencing (few reads per gene) and so less sensitive and less able to detect mosaicism
Whole-exome sequencing (WES)	Cheaper than whole-genome sequencing Analysis is not restricted to only those genes known to cause a given condition Fewer variants detected than in WGS and so easier interpretation Deeper sequencing than WGS increases sensitivity and detection of mosaicism	Less even coverage of the genome and so dosage abnormalities are more difficult to detect Less comprehensive analysis (1–2% of the genome) than WGS Increased risk of identifying incidental findings over targeted gene sequencing
Gene panels	Cost-effective Very deep sequencing, increasing the chances of mosaicism being detected Fewer variants detected and so data easier to interpret As analysis is restricted to known genes, the likelihood of a variant being pathogenic is greatly increased	Will only detect variation in genes known to cause a given condition Difficult to add new genes to the panel as they are discovered

normal variants to identify the single (or, rarely, several) pathogenic, disease-causing mutation. While this can, to an extent, be achieved through the application of complex algorithms, these take time and considerable expertise to develop and are not infallible.

Furthermore, even after these data have been sifted by bioinformaticians, it is highly likely that clinicians will be left with some variants for which there are insufficient data to enable their definitive categorisation as either pathogenic or non-pathogenic. This may be because we simply do not know enough about the gene, because the particular variant has not previously been reported and/or it is identified in an unaffected parent. These variants must be interpreted with caution and, more usually, their interpretation will require input from a genetics expert in the context of the clinical presentation, where an 'innocent until proven guilty' approach is often adopted.

Finally, if we are to interrogate the entire genome or even the exome, it is foreseeable that we will routinely identify 'incidental' or secondary findings – in other words, findings not related to the initial diagnostic question. The UK has so far advocated a conservative approach to incidental findings.

Uses of NGS

NGS is now frequently used, within diagnostic laboratories, to identify base substitutions and indels (although the latter were

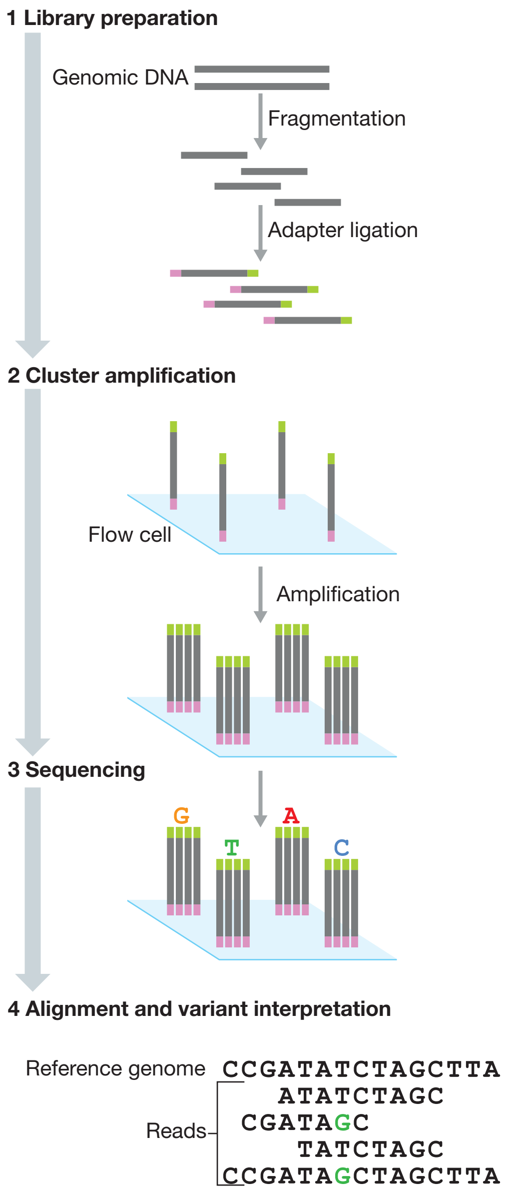

Fig. 3.13 Sequencing by synthesis as used in the Illumina system. (1) Library preparation: DNA is fragmented and specialist adapters are ligated to the fragmented ends. (2) Cluster amplification: the library is loaded to a flow cell and the adapters hybridise to the flow-cell surface. Each bound fragment is hybridised. (3) Sequencing. (4) Alignment and variant interpretation: reads are aligned to a reference sequence using complex software and differences between reference and case genomes are identified.

initially problematic). The current NGS challenge is to detect large deletions or duplications spanning several hundreds or thousands of bases and therefore exceeding any single read. Increasingly, however, this dosage analysis is being achieved using sophisticated computational methods, negating the need for more traditional technologies such as array CGH. Additional potential uses of NGS include detection of balanced and unbalanced translocations and mosaicism: NGS has proved remarkably sensitive at detecting the latter when there is high read coverage for a given region. Of note, however,

3.10 Next-generation sequencing methods

Sequencing by synthesis (Fig. 3.13)

- The most frequently used NGS method
- Used in Illumina systems (commonly used in diagnostic laboratories)
- Uses fluorescently labelled, terminator nucleotides that are sequentially incorporated into a growing DNA chain
- Library DNA samples (fragmented DNA flanked by DNA adapter sequences) are anchored to a flow cell by hybridisation of the DNA adapter sequence to probes on the flow-cell surface
- Amplification occurs by washing the flow cell in a mixture containing all four fluorescently labelled terminator nucleotides: A, C, T and G
- Once the nucleotide, complementary to the first base of the DNA template, is incorporated, no further nucleotides can be added until the mixture is washed away
- The nucleotide terminator is shed and the newly incorporated nucleotide reverts to a regular, non-fluorescent nucleotide that can be extended
- The process is then repeated with the incorporation of a second base etc.
- Sequencing by synthesis is therefore space- and time-dependent: a sensor will detect the order of fluorescent emissions for each spot on the plate (representing the cluster) and determine the sequence for that read

Sequencing by ligation

- Used in SOLiD systems
- Uses DNA ligase rather than DNA polymerase (as is used in sequencing by synthesis) and short oligonucleotides (as opposed to single nucleotides)
- Library DNA samples are washed in a mixture containing oligonucleotide probes representing 4–16 dinucleotide sequences. Only one nucleotide in the probe is fluorescently labelled
- The complementary oligo probes will hybridise, using DNA ligase, to the target sequence, initially at a primer annealed to the anchor site and then progressively along the DNA strand
- After incorporation of each probe, fluorescence is measured and the dye is cleaved off
- Eventually, a new strand is synthesised (composed of a series of the oligo probes)
- A new strand is then synthesised but is offset by one nucleotide
- The process is repeated a number of times (5 rounds in the SOLiD system), providing overlapping templates that are analysed and a composite of the target sequence determined

Ion semiconductor sequencing

- When a nucleotide is incorporated into a growing DNA strand, a hydrogen ion is released that can be detected by an alteration in the pH of the solution. This hydrogen ion release forms the basis of ion semiconductor sequencing
- Each amplified DNA cluster is located above a semiconductor transistor, capable of detecting differences in the pH of the solution
- The DNA cluster is washed in a mixture containing only one type of nucleotide
- If the correct nucleotide, complementary to the next base on the DNA template, is in the mixture and incorporated, a hydrogen ion is released and detected
- If a homopolymer (sequence of two or more identical nucleotides) is present, this will be detected as a decrease in pH proportionate to the number of identical nucleotides in the sequence

NGS is still not able to interrogate the epigenome (and so will not identify conditions caused by a disruption of imprinting, such as Beckwith–Wiedemann, Silver–Russell, Angelman's and Prader–Willi syndromes) and will not detect triplet repeat expansions such as those that cause Huntington's disease,

myotonic dystrophy and fragile X syndrome (see Boxes 3.8 and 3.2).

Third-generation sequencing

Increasingly, third-generation or single-molecule sequencing is entering the diagnostic arena. As with next- or second-generation sequencing, a number of different platforms are commercially available. One of the most successful is SMRT technology (single-molecule sequencing in real time), developed by Pacific Biosciences. This system utilises a single-stranded DNA molecule (as compared to the amplified clusters used in NGS), which acts as a template for the sequential incorporation, using a polymerase, of fluorescently labelled nucleotides. As each complementary nucleotide is added, the fluorescence (and therefore the identity of the nucleotide) is recorded before it is removed and another nucleotide is added.

A key advantage of third-generation sequencing is the long length of the read it generates: in the region of 10–15 kilobases. It is also cheaper than NGS, as fewer reagents are required. Given these inherent advantages, third-generation sequencing is likely to supersede NGS in the near future. Given the confusion surrounding the terminology of NGS and third-generation sequencing, these technologies are increasingly referred to as ‘massively parallel sequencing’.

Genomics and clinical practice

Genomics and health care

Genomics in rare neurodevelopmental disorders

Although, by definition, the diagnosis of a rare disorder is made infrequently, rare diseases, when considered together, affect about 3 million people in the UK, the majority of whom are children. NGS has transformed the ability to diagnose individuals affected by a rare disease. Whereas previously, when we were restricted to the sequential analysis of single genes, a clinician would need to make a clinical diagnosis in order to target testing, NGS allows the interrogation of multiple genes in a single experiment. This might be done through a gene panel, a clinical exome or an exome (see Box 3.9 and p. 53), and has increased the diagnostic yield in neurodevelopmental disorders to approximately 30%. Not only does the identification of the genetic cause of a rare disorder potentially provide families with answers, prognostic information and the opportunity to meet and derive support from other affected families but also it can provide valuable information for those couples planning further children and wishing to consider prenatal testing in the future.

Genomics and common disease

Most common disorders are determined by interactions between a number of genes and the environment. In this situation, the genetic contribution to disease is termed polygenic. Until recently, very little progress had been made in identifying the genetic variants that predispose to common disorders, but this has been changed by the advent of genome-wide association studies. A GWAS typically involves genotyping many (> 500 000) genetic markers (SNPs) spread across the genome in a large group of individuals with the disease and in controls. By comparing the SNP genotypes in cases and controls, it is possible to identify regions of the genome, and therefore genes, more strongly associated with a given SNP profile and therefore more likely to contribute to the disease under study.

Genomics and obstetrics

Prenatal genetic testing may be performed where a pregnancy is considered at increased risk of being affected with a genetic condition, either because of the ultrasound/biochemical screening results or because of the family history. While invasive tests, such as amniocentesis and chorionic villus sampling, have been the mainstay of prenatal diagnosis for many years, they are increasingly being superseded by non-invasive testing of cell-free fetal DNA (cffDNA), originating from placental trophoblasts and detectable in the maternal circulation from 4–5 weeks’ gestation; it is present in sufficient quantities for testing by 9 weeks.

- *Non-invasive prenatal testing (NIPT)*: the sequencing and quantification, using NGS, of cffDNA chromosome-specific DNA sequences to identify trisomy 13, 18 or 21. The accuracy of NIPT in detecting pregnancy-specific aneuploidy approaches 98%. A false-negative result can occur when there is too little cffDNA (possibly due to early gestation or high maternal body mass index) or when aneuploidy has arisen later in development and is confined to the embryo and not represented in the placenta. False positives can occur with confined placental mosaicism (describing aneuploidy in the placenta, not the fetus) or with an alternative cause of aneuploidy in the maternal circulation, such a cell-free tumour DNA.
- *Non-invasive prenatal diagnosis (NIPD)*: the identification of a fetal single-gene defect that either has been paternally inherited or has arisen de novo and so is not identifiable in the maternal genome. Examples of conditions that are currently amenable to NIPD include achondroplasia and the craniosynostoses. Increasingly, however, NIPD is being used for autosomal recessive conditions such as cystic fibrosis, where parents are carriers for different mutations. The free fetal DNA is tested to see whether the paternal mutation is identified and, if absent, the fetus is not affected. If the paternal mutation is identified, however, a definitive invasive test is required to determine whether the maternal mutation has also been inherited and the fetus is affected.

Where a genetic diagnosis is known in a family, a couple may opt to undertake pre-implantation genetic diagnosis (PGD). PGD is used as an adjunct to in vitro fertilisation and involves the genetic testing of a single cell from a developing embryo, prior to implantation.

Genomics and oncology

Until recently, individuals were stratified to genetic testing if they presented with a personal and/or family history suggestive of an inherited cancer predisposition syndrome (Box 3.11). Relevant clinical information included the age of cancer diagnosis and number/type of tumours. For example, the diagnosis of bilateral breast cancer in a woman in her thirties with a mother who had ovarian cancer in her forties is suggestive of *BRCA1/2*-associated familial breast/ovarian cancer. In many familial cancer syndromes, somatic mutations act together with an inherited mutation to cause specific cancers (p. 50). Familial cancer syndromes may be due to germ-line loss-of-function mutations in tumour suppressor genes encoding DNA repair enzymes or proto-oncogenes. At the cellular level, loss of one copy of a tumour suppressor

3.11 Inherited cancer predisposition syndromes

Syndrome name	Gene	Associated cancers	Additional clinical features
Birt–Hogg–Dubé syndrome	*FLCN*	Renal tumour (oncocytoma, chromophobe (and mixed), renal cell carcinoma)	Fibrofolliculoma Trichodiscoma Pulmonary cysts
Breast/ovarian hereditary susceptibility	*BRCA1* *BRCA2*	Breast carcinoma Ovarian carcinoma Pancreatic carcinoma Prostate carcinoma	
Cowden's syndrome	*PTEN*	Breast carcinoma Thyroid carcinoma Endometrial carcinoma	Macrocephaly Intellectual disability/autistic spectrum disorder Trichilemmoma Acral keratosis Papillomatous papule Thyroid cyst Lipoma Haemangioma Intestinal hamartoma
Gorlin's syndrome/basal cell naevus syndrome	*PTCH1*	Basal cell carcinoma Medulloblastoma	Odontogenic keratocyst Palmar or plantar pits Falx calcification Rib abnormalities (e.g. bifid, fused or missing ribs) Macrocephaly Cleft lip/palate
Li–Fraumeni syndrome	*TP53*	Sarcoma (e.g. osteosarcoma, chondrosarcoma, rhabdomyosarcoma) Breast carcinoma Brain cancer (esp. glioblastoma) Adrenocortical carcinoma Brain	
Lynch's syndrome/ hereditary non-polyposis colon cancer	*MLH1* *MSH2* *MSH6* *PMS2*	Colorectal carcinoma (majority right-sided) Endometrial carcinoma Gastric carcinoma Cholangiocarcinoma Ovarian carcinoma (esp. mucinous)	
Multiple endocrine neoplasia 1	*MEN1*	Parathyroid tumour Endocrine pancreatic tumour Anterior pituitary tumour	Lipoma Facial angiofibroma

Retinoblastoma, familial	*RB1*	Retinoblastoma Osteosarcoma	

gene does not have any functional consequences, as the cell is protected by the remaining normal copy. However, a somatic mutation affecting the normal allele is likely to occur in one cell at some point during life, resulting in complete loss of tumour suppressor activity and a tumour developing by clonal expansion of that cell. This two-hit mechanism (one inherited, one somatic) for cancer development is known as the Knudson hypothesis. It explains why tumours may not develop for many years (or ever) in some members of these cancer-prone families. In DNA repair diseases, the inherited mutations increase the somatic mutation rate. Autosomal dominant mutations in genes encoding components of specific DNA repair systems are relatively common causes of familial colon cancer and breast cancer (e.g. *BRCA1*).

Increasingly, genetics is moving into the mainstream, becoming integrated into routine oncological care as new gene-specific treatments are introduced. Testing for a genetic predisposition

to cancer is therefore moving from the domain of clinical genetics, where it has informed diagnosis, cascade treatment and screening/prophylactic management, to oncology, where it is informing the immediate management of the patient following cancer diagnosis. This is exemplified by *BRCA1* and *BRCA2* (*BRCA1/2*)-related breast cancer. Previously, women with a mutation in either the *BRCA1* or *BRCA2* gene would have received similar first-line chemotherapy to women with a sporadic breast cancer without a known genetic association. More recently, it has been shown that *BRCA1/2* mutation-positive tumours are sensitive to poly ADP ribose polymerase (PARP) inhibitors. PARP inhibitors block the single-strand break-repair pathway. In a *BRCA1/2* mutation-positive tumour – with compromised double-strand break repair – the additional loss of the single-strand break-repair pathway will drive the cell towards apoptosis. Indeed, PARP inhibitors have been shown to be so effective at destroying *BRCA1/2* mutation-positive tumour cells, and with such minimal side-effects, that *BRCA1/2* gene testing is increasingly determining patient management. It is likely, with a growing understanding of the genomic architecture of tumours, increasing accessibility of NGS and an expanding portfolio of gene-directed therapies, that testing for many of the other inherited cancer susceptibility genes will, in time, move into the mainstream.

Genomics in infectious disease

NGS technologies are also transforming infectious disease. Given that a microbial genome can be sequenced within a single day at a current cost of less than 100 US dollars, microbiologists are able to identify a causative microorganism and target effective treatment rapidly and accurately. Moreover, microbial genome sequencing enables the effective surveillance of infections to reduce and prevent transmission. Finally, an understanding of the microbial genome will drive the development of vaccines and antibiotics, essential in an era characterised by increasing microbial resistance to established antibiotic agents.

Treatment of genetic disease

Pharmacogenomics

Pharmacogenomics is the science of dissecting the genetic determinants of drug kinetics and effects using information from the human genome. For more than 50 years, it has been appreciated that polymorphic mutations within genes can affect individual responses to some drugs, such as loss-of-function mutations in *CYP2D6* that cause hypersensitivity to debrisoquine, an adrenergic-blocking medication formerly used for the treatment of hypertension, in 3% of the population. This gene is part of a large family of highly polymorphic genes encoding cytochrome P450 proteins, mostly expressed in the liver, which determine the metabolism of a host of specific drugs. Polymorphisms in the *CYP2D6* gene also determine codeine activation, while those in the *CYP2C9* gene affect warfarin inactivation. Polymorphisms in these and other drug metabolic genes determine the persistence of drugs and, therefore, should provide information about dosages and toxicity. With the increasing use of NGS, genetic testing for assessment of drug response is seldom employed routinely, but in the future it may be possible to predict the best specific drugs and dosages for individual patients based on genetic profiling: so-called ‘personalised medicine’. An example is the enzyme thiopurine methyltransferase (TPMT), which catabolises azathioprine, a drug that is used in the treatment of autoimmune diseases and in cancer chemotherapy. Genetic screening for polymorphic variants of TPMT can be useful in identifying patients who have increased sensitivity to the effects of azathioprine and who can be treated with lower doses than normal.

Gene therapy and genome editing

Replacing or repairing mutated genes (gene therapy) is challenging in humans. Retroviral-mediated ex vivo replacement of the defective gene in bone marrow cells for the treatment of severe combined immune deficiency syndrome (p. 79) has been successful. The major problems with clinical use of virally delivered gene therapy have been oncogenic integration of the exogenous DNA into the genome and severe immune response to the virus.

Other therapies for genetic disease include PTC124, a compound that can ‘force’ cells to read through a mutation that results in a premature termination codon in an ORF with the aim of producing a near-normal protein product. This therapeutic approach could be applied to any genetic disease caused by nonsense mutations.

The most exciting development in genetics for a generation has been the discovery of accurate, efficient and specific techniques to enable editing of the genome in cells and organisms. This technology is known as CRISPR/Cas9 (clustered regularly interspaced short palindromic repeats and CRISPR-associated) genome editing. It is likely that ex vivo correction of genetic disease will become commonplace over the next few years. In vivo correction is not yet possible and will take much longer to become part of clinical practice.

Induced pluripotent stem cells and regenerative medicine

Adult stem-cell therapy has been in wide use for decades in the form of bone marrow transplantation. The identification of adult stem cells for other tissues, coupled with the ability to purify and maintain such cells in vitro, now offers exciting therapeutic potential for other diseases. It was recently discovered that many different adult cell types can be trans-differentiated to form cells (induced pluripotent stem cells or iPS cells) with almost all the characteristics of embryonal stem cells derived from the early blastocyst. In mammalian model species, such cells can be taken and used to regenerate differentiated tissue cells, such as in heart and brain. They have great potential both for the development of tissue models of human disease and for regenerative medicine.

Pathway medicine

The ability to manipulate pathways that have been altered in genetic disease has tremendous therapeutic potential for Mendelian disease, but a firm understanding of both disease pathogenesis and drug action at a biochemical level is required. An exciting example has been the discovery that the vascular pathology associated with Marfan’s syndrome is due to the defective fibrillin molecules causing up-regulation of transforming growth factor (TGF)-β signalling in the vessel wall. Losartan is an antihypertensive drug that is marketed as an angiotensin II receptor antagonist. However, it also acts as a partial antagonist of TGF-β signalling and is effective in preventing aortic dilatation in a mouse model of Marfan’s syndrome, showing promising effects in early human clinical trials.

Ethics in a genomic age

As genomic technology is increasingly moving into mainstream clinical practice, it is essential for clinicians from all specialties to appreciate the complexities of genetic testing and consider whether genetic testing is the right thing to do in a given clinical scenario. To exemplify the ethical considerations associated with genetic testing, it may be helpful to think about them in the context of a clinical scenario. As you read the scenario, try to think what counselling/ethical issues might arise.

A 32-year-old woman is referred to discuss *BRCA2* testing; she is currently pregnant with her second child (she already has a 2-year-old daughter) and has an identical twin sister. Her mother, a healthy 65-year-old with Ashkenazi Jewish ancestry, participated in direct-to-consumer testing (DCT) for 'a bit of fun' and a *BRCA2* mutation – common in the Ashkenazi Jewish population – was identified. There is no significant cancer family history of note.

Consider the following issues:

- *Pre-symptomatic/predictive testing*: this describes testing for a known familial gene mutation in an unaffected individual (compared with diagnostic testing, where genetic testing is undertaken in an affected individual). Although this could be considered for the unaffected patient, in the current scenario any testing would also have implications for her identical twin sister. This needs to be fully explored with the patient and her sister prior to testing. There is also the potential issue of predictive testing in the patient's first child. A fundamental tenet in clinical genetics is that predictive genetic testing should be avoided in childhood for adult-onset conditions. This is because, if no benefit to the patient is accrued through childhood testing, it is better to retain the child's right to decide for herself, when she is old enough, whether she wishes to participate in genetic testing or not.
- *Prenatal testing*: the principles behind predictive genetic testing in childhood can be extended to prenatal testing, i.e. if a pregnancy is being continued, a baby should not be tested for an adult-onset condition that cannot be prevented or treated in childhood. However, prenatal testing itself is hugely controversial and there is much debate as to how severe a condition should be to justify prenatal diagnosis, which would determine ongoing pregnancy decisions.
- *DCT*: while DCT can be interesting and empowering for individuals wishing to find out more about their genetic backgrounds, it also has several drawbacks. Perhaps the main one is that, unlike face-to-face genetic counselling (which usually precedes any genetic testing, certainly where there are serious health implications for the individual and their family, such as is associated with *BRCA1/2* mutations), DCT is undertaken in isolation with no direct access to professional support. Furthermore, in addition to some (common) single-gene mutations, such as the founder *BRCA1/2* mutations frequently identified in the Ashkenazi Jewish population and discussed in this example, current DCT packages utilise a series of SNPs to determine an overall risk profile; they evaluate the number of detrimental and protective SNPs for a given disease. However, given that only a minority of the risk SNPs have so far been characterised, this is often inaccurate. Individuals may be falsely reassured that they are not at increased risk of a genetic condition despite a family history suggesting otherwise, resulting in inadequate surveillance and/or management.

The ethical considerations listed in this clinical scenario give just a flavour of some of the issues frequently encountered in clinical genetics. They are not meant to be an exhaustive summary and whole textbooks and meetings are devoted to the discussion of hugely complex ethical issues in genetics. However, a guiding principle is that, although each counselling situation will be unique with specific communication and ethical challenges, a genetic result is permanent and has implications for the whole family, not just the individual. Where possible, therefore, an informed decision regarding genetic testing should be taken by a competent adult following counselling by an experienced and appropriately trained clinician.

Clinical immunology

The immune system has evolved to identify and destroy pathogens while minimising damage to host tissue. Despite the ancient observation that recovery from an infectious disease frequently results in protection against that condition, the existence of the immune system as a functional entity was not recognised until the end of the 19th century. More recently, it has become clear that the immune system not only protects against infection but also regulates tissue repair following injury, and when dysregulated, governs the responses that can lead to autoimmune and auto-inflammatory diseases. Dysfunction or deficiency of the immune response can lead to a wide variety of diseases that may potentially involve every organ system in the body.

The aim of this chapter is to provide a general understanding of the immune system, how it contributes to human disease and how manipulation of the immune system can be put to therapeutic use. A review of the key components of the immune response is followed by sections that illustrate the clinical presentation of the most common forms of immune dysfunction: immune deficiency, inflammation, autoimmunity and allergy. More detailed discussion of individual conditions can be found in the relevant organ-specific chapters of this book.

Functional anatomy and physiology

The immune system consists of an intricately linked network of lymphoid organs, cells and proteins that are strategically placed to protect against infection (Fig. 4.1). Immune defences are normally categorised into the innate immune response, which provides immediate protection against an invading pathogen, and the adaptive or acquired immune response, which takes more time to develop but confers exquisite specificity and long-lasting protection.

The innate immune system

Innate defences against infection include anatomical barriers, phagocytic cells, soluble molecules such as complement and acute phase proteins, and natural killer cells. The innate immune system recognises generic microbial structures present on non-mammalian tissue and can be mobilised within minutes. A specific stimulus will elicit essentially identical responses in different individuals, in contrast with adaptive antibody and T-cell responses, which vary greatly between individuals.

Physical barriers

The tightly packed keratinised cells of the skin physically limit colonisation by microorganisms. The hydrophobic oils that are secreted by sebaceous glands further repel water and microorganisms, and microbial growth is inhibited by the skin's low pH and low oxygen tension. Sweat also contains lysozyme, an enzyme that destroys the structural integrity of bacterial cell walls; ammonia, which has antibacterial properties; and several

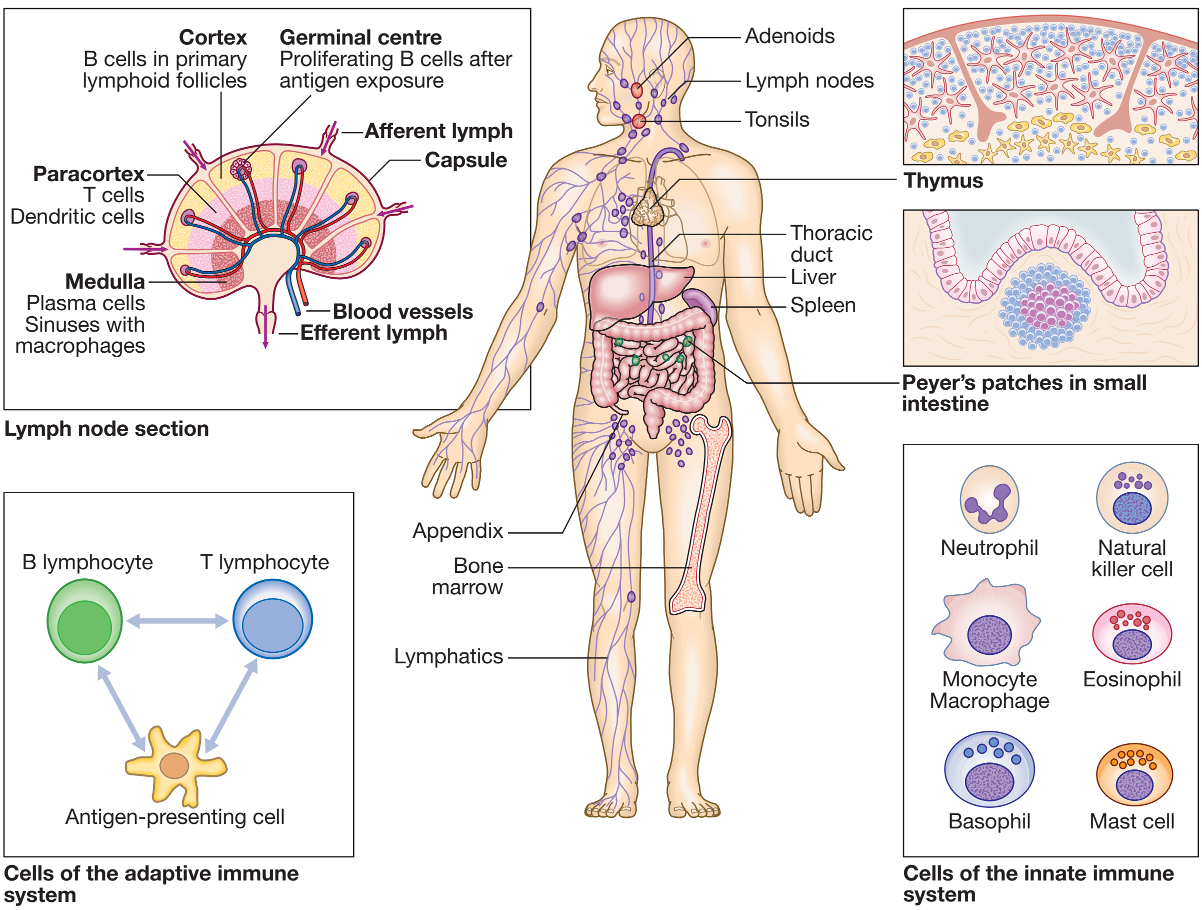

Fig. 4.1 Anatomy of the immune system.

antimicrobial peptides such as defensins. Similarly, the mucous membranes of the respiratory, gastrointestinal and genitourinary tracts provide a physical barrier to infection. Secreted mucus traps invading pathogens, and immunoglobulin A (IgA), generated by the adaptive immune system, prevents bacteria and viruses attaching to and penetrating epithelial cells. As in the skin, lysozyme and antimicrobial peptides within mucosal membranes directly kill invading pathogens, and lactoferrin acts to starve invading bacteria of iron. Within the respiratory tract, cilia directly trap pathogens and contribute to removal of mucus, assisted by physical manœuvres such as sneezing and coughing. In the gastrointestinal tract, hydrochloric acid and salivary amylase chemically destroy bacteria, while normal peristalsis and induced vomiting or diarrhoea assist clearance of invading organisms.

The microbiome, which is made up of endogenous commensal bacteria, provides an additional constitutive defence against infection. Approximately 10^{14} bacteria normally reside at epithelial surfaces in symbiosis with the human host (p. 102). They compete with pathogenic microorganisms for scarce resources, including space and nutrients, and produce fatty acids and bactericidins that inhibit the growth of many pathogens. In addition, recent research has demonstrated that commensal bacteria help to shape the immune response by inducing specific regulatory T cells within the intestine. Eradication of the normal flora with broad-spectrum antibiotics commonly results in opportunistic infection by organisms such as *Clostridium difficile*, which rapidly colonise an undefended ecological niche.

These constitutive barriers are highly effective, but if external defences are breached by a wound or pathogenic organism, the specific soluble proteins and cells of the innate immune system are activated.

Phagocytes

Phagocytes ('eating cells') are specialised cells that ingest and kill microorganisms, scavenge cellular and infectious debris, and produce inflammatory molecules that regulate other components of the immune system. They include neutrophils, monocytes and macrophages, and are particularly important for defence against bacterial and fungal infections. Phagocytes express a wide range of surface receptors, including pattern recognition receptors (PRRs), which recognise pathogen-associated molecular patterns (PAMPs) on invading microorganisms, allowing their identification. The PRRs include Toll-like receptors, nucleotide oligomerisation domain (NOD) protein-like receptors and mannose receptors, whereas the PAMPs they recognise are molecular motifs not present on mammalian cells, including bacterial cell wall components, bacterial DNA and viral double-stranded RNA. While phagocytes can recognise microorganisms through PRRs alone, engulfment of microorganisms is greatly enhanced by opsonisation. Opsonins include acute phase proteins produced by the liver, such as C-reactive protein and complement. Antibodies generated by the adaptive immune system also act as opsonins. They bind both to the pathogen and to phagocyte receptors, acting as a bridge between the two to facilitate phagocytosis (Fig. 4.2). This is followed by intracellular pathogen destruction and downstream activation of pro-inflammatory genes, resulting in the generation of pro-inflammatory cytokines as discussed below.

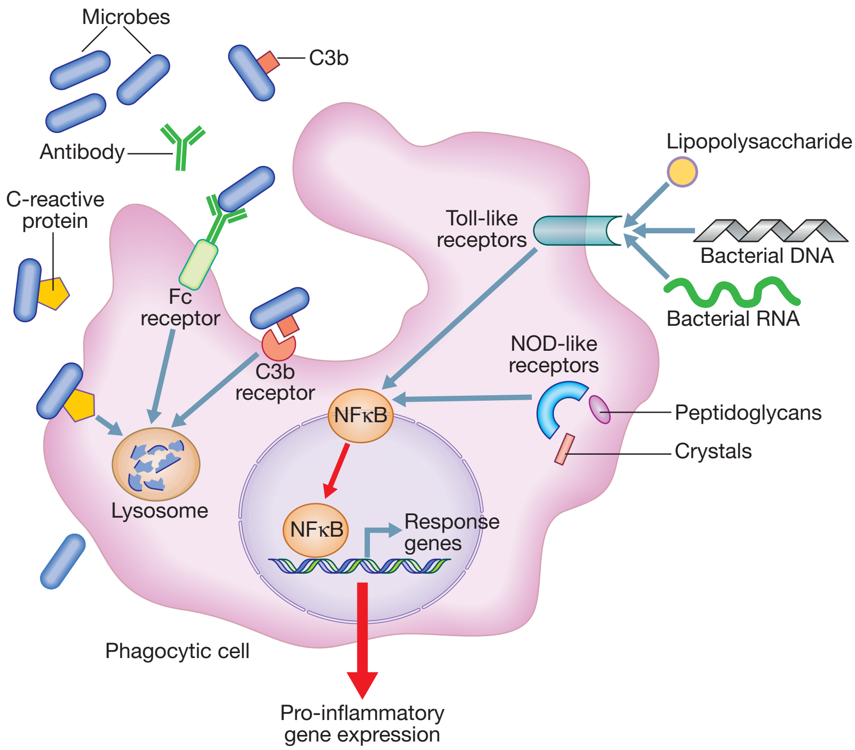

Fig. 4.2 Phagocytosis and opsonisation. Phagocytosis of microbes can be augmented by several opsonins, such as C-reactive protein, antibodies and complement fragments like C3b, which enhance the ability of phagocytic cells to engulf microorganisms and destroy them. Phagocytes also recognise components of microbes, such as lipopolysaccharide, peptidoglycans, DNA and RNA, collectively as pathogen-associated molecular patterns (PAMPs). These activate pattern recognition receptors (PRRs), such as Toll-like receptors and nucleotide oligomerisation domain (NOD)-like receptors, which promote inflammatory gene expression through the nuclear factor kappa beta (NFκB) pathway. Uric acid and other crystals can also promote inflammation through the NOD pathway.

Neutrophils

Neutrophils, also known as polymorphonuclear leucocytes, are derived from the bone marrow and circulate freely in the blood. They are short-lived cells with a half-life of 6 hours, and are produced at the rate of 10^{11} cells daily. Their functions are to kill microorganisms, to facilitate rapid transit of cells through tissues, and to amplify the immune response non-specifically. These functions are mediated by enzymes contained in granules, which also provide an intracellular milieu for the killing and degradation of microorganisms.

Two main types of granule are recognised: primary or azurophil granules, and the more numerous secondary or specific granules. Primary granules contain myeloperoxidase and other enzymes important for intracellular killing and digestion of ingested microbes. Secondary granules are smaller and contain lysozyme, collagenase and lactoferrin, which can be released into the extracellular space. Enzyme production is increased in response to infection, which is reflected by more intense granule staining on microscopy, known as 'toxic granulation'.

Changes in damaged or infected cells trigger local production of inflammatory molecules and cytokines. These cytokines stimulate the production and maturation of neutrophils in the bone marrow, and their release into the circulation. Neutrophils are recruited to specific sites of infection by chemotactic agents, such as interleukin 8 (IL-8), and by activation of local endothelium. Up-regulation of cellular adhesion molecules on neutrophils and the endothelium also facilitates neutrophil migration. The transit of neutrophils through the blood stream is responsible for the rise in neutrophil count that occurs in early infection. Once present within infected tissue, activated neutrophils seek out and engulf invading microorganisms. These are initially enclosed within membrane-bound vesicles, which fuse with cytoplasmic granules to form the phagolysosome. Within this protected compartment, killing of the organism occurs through a combination of oxidative and non-oxidative killing. Oxidative killing, also known as the respiratory burst, is mediated by the nicotinamide adenine dinucleotide phosphate (NADPH)–oxidase enzyme complex, which converts oxygen into reactive oxygen species such as hydrogen peroxide and superoxide that are lethal to microorganisms. The myeloperoxidase enzyme within neutrophils produces hypochlorous acid, which is a powerful oxidant and antimicrobial agent. Non-oxidative (oxygen-independent) killing occurs through the release of bactericidal enzymes into the phagolysosome. Each enzyme has a distinct antimicrobial spectrum, providing broad coverage against bacteria and fungi.

An additional, recently identified form of neutrophil-mediated killing is neutrophil extracellular trap (NET) formation. Activated neutrophils can release chromatin with granule proteins such as elastase to form an extracellular matrix that binds to microbial proteins. This can immobilise or kill microorganisms without requiring phagocytosis. The process of phagocytosis and NET formation (NETosis) depletes neutrophil glycogen reserves and is followed by neutrophil death. As the cells die, their contents are released and lysosomal enzymes degrade collagen and other components of the interstitium, causing liquefaction of closely adjacent tissue. The accumulation of dead and dying neutrophils results in the formation of pus, which, if extensive, may lead to abscess formation.

Monocytes and macrophages

Monocytes are the precursors of tissue macrophages. They are produced in the bone marrow and enter the circulation, where they constitute about 5% of leucocytes. From the blood stream they migrate to peripheral tissues, where they differentiate into tissue macrophages and reside for long periods. Specialised populations of tissue macrophages include Kupffer cells in the liver, alveolar macrophages in the lung, mesangial cells in the kidney, and microglial cells in the brain. Macrophages, like neutrophils, are capable of phagocytosis and killing of microorganisms but also play an important role in the amplification and regulation of the inflammatory response (Box 4.1). They are particularly important in tissue surveillance and constantly survey their immediate surroundings for signs of tissue damage or invading organisms.

i 4.1 Functions of macrophages

Amplification of the inflammatory response
- Stimulate the acute phase response (through production of IL-1 and IL-6)
- Activate vascular endothelium (IL-1, TNF-α)
- Stimulate neutrophil maturation and chemotaxis (IL-1, IL-8)
- Stimulate monocyte chemotaxis

Killing of microorganisms
- Phagocytosis
- Microbial killing through oxidative and non-oxidative mechanisms

Clearance, resolution and repair
- Scavenging of necrotic and apoptotic cells
- Clearance of toxins and other inorganic debris
- Tissue remodelling (elastase, collagenase, matrix proteins)
- Down-regulation of inflammatory cytokines
- Wound healing and scar formation (IL-1, platelet-derived growth factor, fibroblast growth factor)

Link between innate and adaptive immune systems
- Activate T cells by presenting antigen in a recognisable form
- T cell-derived cytokines increase phagocytosis and microbicidal activity of macrophages in a positive feedback loop

(IL = interleukin; TNF = tumour necrosis factor)

Dendritic cells

Dendritic cells are specialised antigen-presenting cells that are present in tissues in contact with the external environment, such as the skin and mucosal membranes. They can also be found in an immature state in the blood. They sample the environment for foreign particles and, once activated, carry microbial antigens to regional lymph nodes, where they interact with T cells and B cells to initiate and shape the adaptive immune response.

Cytokines

Cytokines are signalling proteins produced by cells of the immune system and a variety of other cell types. More than 100 have been identified. Cytokines have complex and overlapping roles in cellular communication and regulation of the immune response. Subtle differences in cytokine production, particularly at the initiation of an immune response, can have a major impact on outcome. Cytokines bind to specific receptors on target cells and activate downstream intracellular signalling pathways, ultimately leading to changes in gene transcription and cellular function. Two important signalling pathways are illustrated in Figure 4.3. The nuclear factor kappa B (NFκB) pathway is activated by tumour necrosis factor (TNF), by other members of the TNF superfamily such as receptor activator of nuclear kappa B ligand

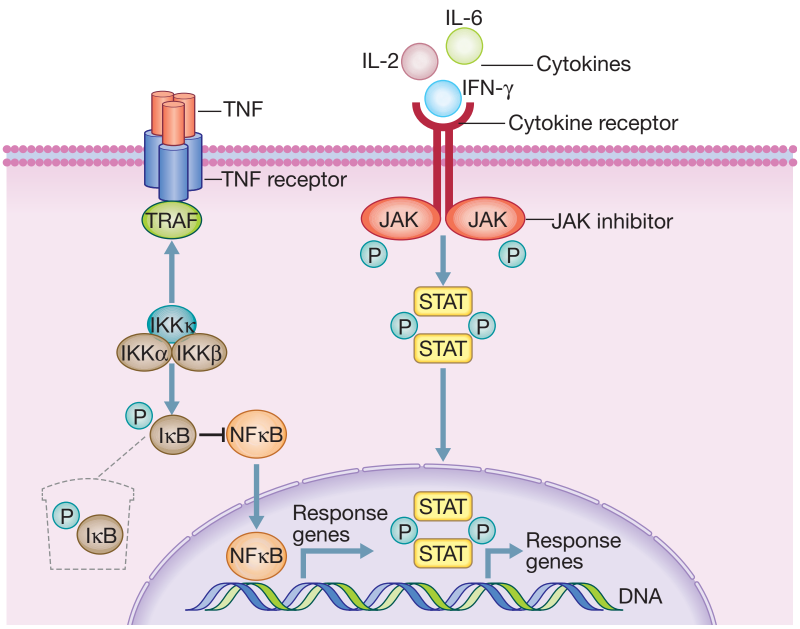

Fig. 4.3 Cytokines signalling pathways and the immune response. Cytokines regulate the immune response through binding to specific receptors that activate a variety of intracellular signalling pathways, two of which are shown. Members of the tumour necrosis factor (TNF) superfamily and the Toll-like receptors and NOD-like receptors (Fig. 4.2) signal through the nuclear factor kappa B (NFκB) pathway. Several other cytokines, including interleukin-2 (IL-2), IL-6 and interferons, employ the Janus kinase/ signal transducer and activator of transcription (JAK-STAT) pathway to regulate cellular function (see text for more details). (IκB = inhibitor of kappa B; IKK = I kappa B kinase; P = phosphorylation of the signalling protein; TRAF = tumour necrosis factor receptor-associated factor)

4

i 4.2 Important cytokines in the regulation of the immune response

Cytokine	Source	Actions	Biologic therapies
Interferon-alpha (IFN-α)	T cells and macrophages	Antiviral activity Activates NK cells, CD8+ T cells and macrophages	Recombinant IFN-α used in hepatitis C and some malignancies
Interferon-gamma (IFN-γ)	T cells and NK cells	Increases antimicrobial activity of macrophages Regulates cytokine production by T cells and macrophages	Used in chronic granulomatous disease
Tumour necrosis factor alpha (TNF-α)	Macrophages, NK cells and others, including T cells	Pro-inflammatory Increases expression of other cytokines and adhesion molecules Causes apoptosis of some target cells Directly cytotoxic	TNF-α inhibitors used in rheumatoid arthritis, inflammatory bowel disease, psoriasis and many other inflammatory conditions
Interleukin-1 (IL-1)	Macrophages and neutrophils	Stimulates neutrophil recruitment, fever, and T-cell and macrophage activation as part of the inflammatory response	IL-1 inhibitors used in systemic juvenile rheumatoid arthritis, periodic fever syndromes and acute gout
Interleukin-2 (IL-2)	CD4+ T cells	Stimulates proliferation and differentiation of antigen-specific T lymphocytes	
Interleukin-4 (IL-4)	CD4+ T cells	Stimulates maturation of B and T cells, and production of IgE antibody	Antibodies to IL-4 receptor used in severe atopic dermatitis
Interleukin-6 (IL-6)	Monocytes and macrophages	Stimulates neutrophil recruitment, fever, and T-cell and macrophage activation as part of the inflammatory response, stimulates maturation of B cells into plasma cells	Antibodies to IL-6 receptor used in rheumatoid arthritis
Interleukin-12 (IL-12)	Monocytes and macrophages	Stimulates IFN-γ and TNF-α release by T cells Activates NK cells	Antibody to p40 subunit of IL-12 used in psoriasis and psoriatic arthritis
Interleukin-17 (IL-17)	Th17 cells (T helper), NK cells, NK-T cells	Pro-inflammatory cytokine Involved in mucosal immunity and control of extracellular pathogens, synergy with IL-1 and TNF	Antibody to IL-17 used in psoriasis, psoriatic arthritis and ankylosing spondylitis
Interleukin-22 (IL-22)	Th17 cells	Induction of epithelial cell proliferation and antimicrobial proteins in keratinocytes	

(IgE = immunoglobulin E; NK = natural killer)

(RANKL; p. 985), and by the Toll-like receptors and NOD-like receptors (see Fig. 4.2). In the case of TNF superfamily members, receptor binding causes the inhibitor of kappa B kinase (IKK) complex of three proteins to be recruited to the receptor by binding TNF receptor-associated proteins (TRAF). This activates IKK, which in turn leads to phosphorylation of the inhibitor of nuclear factor kappa B protein (IκB), causing it to be degraded, and allowing NFκB to translocate to the nucleus and activate gene transcription. The Janus kinase/signal transducers and activators of transcription (JAK-STAT) pathway is involved in

transducing signals downstream of many cytokine receptors, including those for IL-2, IL-6 and interferon-gamma (IFN-γ). On receptor binding, JAK proteins are recruited to the intracellular portion of the receptor and are phosphorylated. These in turn phosphorylate STAT proteins, which translocate to the nucleus and activate gene transcription, altering cellular function. The function and disease associations of several important cytokines are shown in Box 4.2. Cytokine inhibitors are now routinely used in the treatment of autoimmune diseases, most of which are monoclonal antibodies to cytokines or their receptors. In addition, small-molecule inhibitors have been developed that inhibit the intracellular signalling pathways used by cytokines. These include the Janus kinase inhibitors tofacitinib and baracitinib, which are used in rheumatoid arthritis (p. 1026), and the tyrosine kinase inhibitor imatinib, which is used in chronic myeloid leukaemia (p. 959).

Integrins

Integrins are transmembrane proteins that play important roles in cell–cell and cell–matrix interactions. They mediate attachment of the cell to the extracellular matrix, signal transduction and cell migration. Their role in autoimmune disease has been extensively studied. Targeted therapy with a recombinant humanised anti-α4 integrin antibody, natalizumab, is an effective treatment for multiple sclerosis, which works by preventing immune cells from traversing the vascular endothelium and entering the central nervous system (p. 1109).

Complement

The complement system comprises a group of more than 20 tightly regulated, functionally linked proteins that act to promote inflammation and eliminate invading pathogens. Complement proteins are produced in the liver and are present in inactive form in the circulation. When the complement system is activated, it sets in motion a rapidly amplified biological cascade analogous to the coagulation cascade (p. 918).

There are three mechanisms by which the complement cascade can be activated (Fig. 4.4):

- *The alternate pathway* is triggered directly by binding of C3 to bacterial cell-wall components, such as lipopolysaccharide of Gram-negative bacteria and teichoic acid of Gram-positive bacteria.
- *The classical pathway* is initiated when two or more IgM or IgG antibody molecules bind to antigen. The associated conformational change exposes binding sites on the antibodies for the first protein in the classical pathway, C1, which is a multiheaded molecule that can bind up to six antibody molecules. Once two or more 'heads' of a C1 molecule are bound to antibody, the classical cascade is triggered. An important inhibitor of the classical pathway is C1 inhibitor (C1inh), as illustrated in Figure 4.4.
- *The lectin pathway* is activated by the direct binding of mannose-binding lectin to microbial cell surface carbohydrates. This mimics the binding of C1 to immune complexes and directly stimulates the classical pathway, bypassing the need for immune complex formation.

Activation of complement by any of these pathways results in activation of C3. This in turn activates the final common pathway, in which the complement proteins C5–C9 assemble to form the membrane attack complex (MAC). This can puncture the cell wall, leading to osmotic lysis of target cells. This step is particularly important in the defence against encapsulated bacteria such as *Neisseria* spp. and *Haemophilus influenzae.*

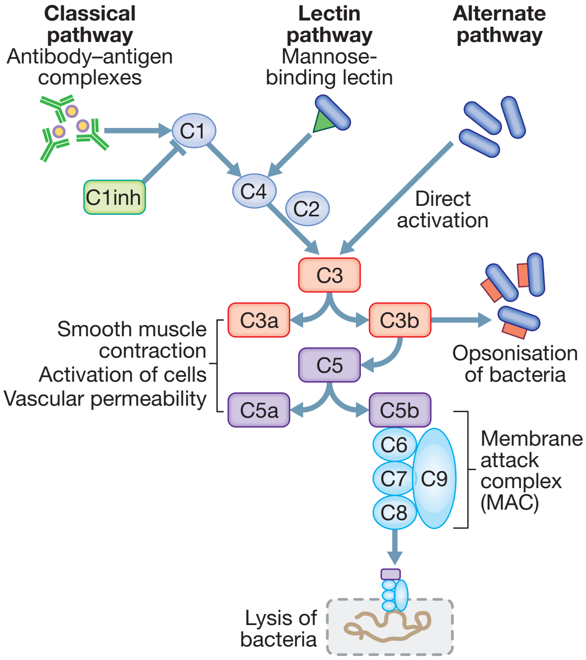

Fig. 4.4 The complement pathway. The classical pathway is activated by binding of antigen–antibody complexes to C1 but is blocked by C1 inhibitor (C1inh), whereas mannose-binding lectins, which are macromolecules that bind to various microorganisms, activate the pathway by binding C4. Bacteria can directly activate the pathway through C3, which plays a pivotal role in complement activation through all three pathways.

Complement fragments generated by activation of the cascade can also act as opsonins, rendering microorganisms more susceptible to phagocytosis by macrophages and neutrophils (see Fig. 4.2). In addition, they are chemotactic agents, promoting leucocyte trafficking to sites of inflammation. Some fragments act as anaphylotoxins, binding to complement receptors on mast cells and triggering release of histamine, which increases vascular permeability. The products of complement activation also help to target immune complexes to antigen-presenting cells, providing a link between the innate and the acquired immune systems. Finally, activated complement products dissolve the immune complexes that triggered the cascade, minimising bystander damage to surrounding tissues.

A monoclonal antibody directed against the central complement molecule C5, eculizumab, has been developed for therapeutic use in paroxysmal nocturnal haemoglobinuria and atypical haemolytic uraemic syndromes (p. 408). Invasive infection, including meningococcal sepsis, has been reported with eculizumab therapy, highlighting the importance of the complement system in preventing such infections.

Mast cells and basophils

Mast cells and basophils are bone marrow-derived cells that play a central role in allergic disorders. Mast cells reside predominantly in tissues exposed to the external environment, such as the skin and gut, while basophils circulate in peripheral blood and are recruited into tissues in response to inflammation. Both contain large cytoplasmic granules that enclose vasoactive substances such as histamine (see Fig. 4.14). Mast cells and

basophils express IgE receptors on their cell surface, which bind IgE antibody. On encounter with specific antigen, the cell is triggered to release histamine and other mediators present within the granules and to synthesise additional mediators, including leukotrienes, prostaglandins and cytokines. An inflammatory cascade is initiated that increases local blood flow and vascular permeability, stimulates smooth muscle contraction, and increases secretion at mucosal surfaces.

Natural killer cells

Natural killer (NK) cells are large granular lymphocytes that play a major role in defence against tumours and viruses. They exhibit features of both the adaptive and the innate immune systems in that they are morphologically similar to lymphocytes and recognise similar ligands, but they are not antigen-specific and cannot generate immunological memory. NK cells express a variety of cell surface receptors, some of which are stimulatory and others inhibitory. The effects of inhibitory receptors normally predominate. These recognise human leucocyte antigen (HLA) molecules that are expressed on normal nucleated cells, preventing NK cell-mediated attack, whereas the stimulatory receptors recognise molecules that are expressed primarily when cells are damaged. This allows NK cells to remain tolerant to healthy cells but not to damaged ones. When cells become infected by viruses or undergo malignant change, expression of HLA class I molecules on the cell surface can be down-regulated. This is an important mechanism by which these cells then evade adaptive T-lymphocyte responses. In this circumstance, however, NK cell defences becomes important, as down-regulation of HLA class I abrogates the inhibitory signals that normally prevent NK activation. The net result is NK attack on the abnormal target cell. NK cells can also be activated by binding of antigen–antibody complexes to surface receptors. This physically links the NK cell to its target in a manner analogous to opsonisation and is known as antibody-dependent cellular cytotoxicity (ADCC).

Activated NK cells can kill their targets in various ways. They secrete pore-forming proteins such as perforin into the membrane of the target cell, and proteolytic enzymes called granzymes into the target cell, which cause apoptosis. In addition, NK cells produce a variety of cytokines such as TNF-α and IFN-γ, which have direct antiviral and anti-tumour effects.

The adaptive immune system

If the innate immune system fails to provide effective protection against an invading pathogen, the adaptive immune system is mobilised (see Fig. 4.1). This has three key characteristics:

- It has exquisite specificity and can discriminate between very small differences in molecular structure.
- It is highly adaptive and can respond to an almost unlimited number of molecules.
- It possesses immunological memory, and changes consequent to initial activation by an antigen allow a more effective immune response on subsequent encounters.

There are two major arms of the adaptive immune response. Humoral immunity involves the production of antibodies by B lymphocytes, and cellular immunity involves the activation of T lymphocytes, which synthesise and release cytokines that affect other cells, as well as directly killing target cells. These interact closely with each other and with the components of the innate immune system to maximise effectiveness of the immune response.

Lymphoid organs

The primary lymphoid organs are involved in lymphocyte development. They include the bone marrow, where T and B lymphocytes differentiate from haematopoietic stem cells (p. 914) and where B lymphocytes also mature, and the thymus, the site of T-cell maturation (see Fig. 4.1). After maturation, lymphocytes migrate to the secondary lymphoid organs. These include the spleen, lymph nodes and mucosa-associated lymphoid tissue. These trap and concentrate foreign substances and are the major sites of interaction between naïve lymphocytes and microorganisms.

4

The thymus

The thymus is a bi-lobed structure in the anterior mediastinum, and is organised into cortical and medullary areas. The cortex is densely populated with immature T cells, which migrate to the medulla to undergo selection and maturation. The thymus is most active in the fetal and neonatal period, and involutes after puberty. Failure of thymic development is associated with profound T-cell immune deficiency (p. 79) but surgical removal of the thymus in childhood (usually during major cardiac surgery) is not associated with significant immune dysfunction.

The spleen

The spleen is the largest of the secondary lymphoid organs. It is highly effective at filtering blood and is an important site of phagocytosis of senescent erythrocytes, bacteria, immune complexes and other debris, and of antibody synthesis. It is important for defence against encapsulated bacteria, and asplenic individuals are at risk of overwhelming *Streptococcus pneumoniae* and *H. influenzae* infection (see Box 4.5).

Lymph nodes

These are positioned to maximise exposure to lymph draining from sites of external contact, and are highly organised (Fig. 4.1)

- The *cortex* contains primary lymphoid follicles, which are the site of B-lymphocyte interactions. When B cells encounter antigen, they undergo intense proliferation, forming germinal centres.
- The *paracortex* is rich in T lymphocytes and dendritic cells.
- The *medulla* is the major site of antibody-secreting plasma cells.
- Within the medulla there are many *sinuses,* which contain large numbers of macrophages.

Mucosa-associated lymphoid tissue

Mucosa-associated lymphoid tissue (MALT) consists of diffusely distributed lymphoid cells and follicles present along mucosal surfaces. It has a similar function to the more organised, encapsulated lymph nodes. They include the tonsils, adenoids and Peyer's patches in the small intestine.

Lymphatics

Lymphoid tissue is connected by a network of lymphatics, with three major functions: it provides access to lymph nodes, returns interstitial fluid to the venous system, and transports fat from the small intestine to the blood stream (see Fig. 14.13, p. 372). The lymphatics begin as blind-ending capillaries, which come together to form lymphatic ducts, entering and leaving regional lymph nodes as afferent and efferent ducts, respectively. They eventually coalesce and drain into the thoracic duct and left subclavian vein. Lymphatics may be either deep or superficial, and follow the distribution of major blood vessels.

Humoral immunity

Humoral immunity is mediated by B lymphocytes, which differentiate from haematopoietic stem cells in the bone marrow. Their major functions are to produce antibody and interact with T cells, but they are also involved in antigen presentation. Mature B lymphocytes can be found in the bone marrow, lymphoid tissue, spleen and, to a lesser extent, the blood stream. They express a unique immunoglobulin receptor on their cell surface, the B-cell receptor, which binds to soluble antigen targets (Fig. 4.5). Encounters with antigen usually occur within lymph nodes. If provided with appropriate cytokines and other signals from nearby T lymphocytes, antigen-specific B cells respond by rapidly proliferating in a process known as clonal expansion (Fig. 4.5). This is accompanied by a highly complex series of genetic rearrangements known as somatic hypermutation, which generates B-cell populations that express receptors with greater affinity for antigen than the original. These cells differentiate into either long-lived memory cells, which reside in the lymph nodes, or plasma cells, which produce antibody. Memory cells allow production of a more rapid and more effective response on subsequent exposure to that pathogen.

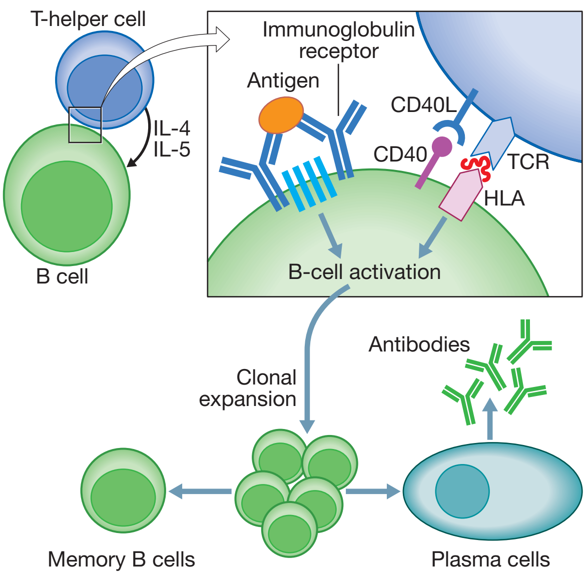

Fig. 4.5 B-cell activation. Activation of B cells is initiated through binding of an antigen with the immunoglobulin receptor on the cell surface. For activation to proceed, an interaction with T-helper cells is also required, providing additional signals through binding of CD40 ligand (CD40L) to CD40; an interaction between the T-cell receptor (TCR) and processed antigenic peptides presented by human leucocyte antigen (HLA) molecules on the B-cell surface; and cytokines released by the T-helper cells. Fully activated B cells undergo clonal expansion with differentiation towards plasma cells that produce antibody. Following activation, memory cells are generated that allow rapid antibody responses when the same antigen is encountered on a second occasion. (CD = cluster of differentiation; IL = interleukin)

Immunoglobulins

Immunoglobulins (Ig) play a central role in humoral immunity. They are soluble proteins produced by plasma cells and are made up of two heavy and two light chains (Fig. 4.6). The heavy chain determines the antibody class or isotype, such as IgG, IgA, IgM, IgE or IgD. Subclasses of IgG and IgA also occur. The antigen is recognised by the antigen-binding regions (F_{ab}) of both heavy and light chains, while the consequences of antibody binding are determined by the constant region of the heavy chain (F_c) (Box 4.3). Antibodies have several functions.

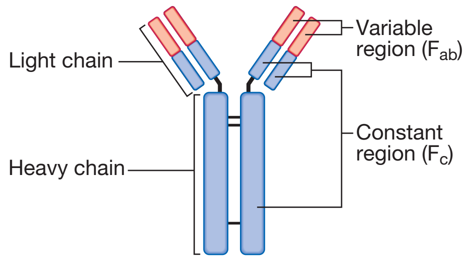

Fig. 4.6 The structure of an immunoglobulin (antibody) molecule. The variable region is responsible for antigen binding, whereas the constant region can interact with immunoglobulin receptors expressed on immune cells.

i 4.3 Classes and properties of antibody

Antibody	Concentration in adult serum	Complement activation*	Opsonisation	Presence in external secretions	Other properties
IgG	6.0–16.0 g/L	IgG1 +++ IgG2 + IgG3 +++	IgG1 ++ IgG3 ++	++	Four subclasses: IgG1, IgG2, IgG3, IgG4 Distributed equally between blood and extracellular fluid, and transported across placenta IgG2 is particularly important in defence against polysaccharides antigens
IgA	1.5–4.0 g/L	–	–	++++	Two subclasses: IgA1, IgA2 Highly effective at neutralising toxins Particularly important at mucosal surfaces
IgM	0.5–2.0 g/L	++++	–	+	Highly effective at agglutinating pathogens
IgE	0.003–0.04 g/L	–	–	–	Majority of IgE is bound to mast cells, basophils and eosinophils Important in allergic disease and defence against parasite infection
IgD	Not detected	–	–	–	Function in B-cell development

*Activation of the classical pathway, also called 'complement fixation'.

They facilitate phagocytosis by acting as opsonins (see Fig. 4.2) and facilitate cell killing by cytotoxic cells, particularly NK cells by antibody-dependent cellular cytotoxicity. Binding of antibodies to antigen can trigger activation of the classical complement pathway (see Fig. 4.4). In addition, antibodies can directly neutralise the biological activity of their antigen target. This is a particularly important feature of IgA antibodies, which act predominantly at mucosal surfaces.

The humoral immune response is characterised by immunological memory, in which the antibody response to successive exposures to an antigen is qualitatively and quantitatively improved from the first exposure. When a previously unstimulated or 'naïve' B lymphocyte is activated by antigen, the first antibody to be produced is IgM, which appears in the serum after 5–10 days. Depending on additional stimuli provided by T lymphocytes, other antibody classes (IgG, IgA and IgE) are produced 1–2 weeks later. If the memory B cell is subsequently re-exposed to the same antigen, the lag time between exposure and production of antibody is decreased to 2–3 days, the amount of antibody produced is increased, and the response is dominated by IgG antibodies of high affinity. Furthermore, in contrast to the initial antibody response, secondary antibody responses do not require additional input from T lymphocytes. This allows the rapid generation of highly specific responses on re-exposure to a pathogen and is an important mechanism in vaccine efficacy.

4

Cellular immunity

Cellular immunity is mediated by T lymphocytes, which play important roles in defence against viruses, fungi and intracellular bacteria. They also play an important immunoregulatory role, by orchestrating and regulating the responses of other components of the immune system. T-lymphocyte precursors differentiate from haematopoietic stem cells in the bone marrow and are exported to the thymus when they are still immature (see Fig. 4.1). Individual T cells express a unique receptor that is highly

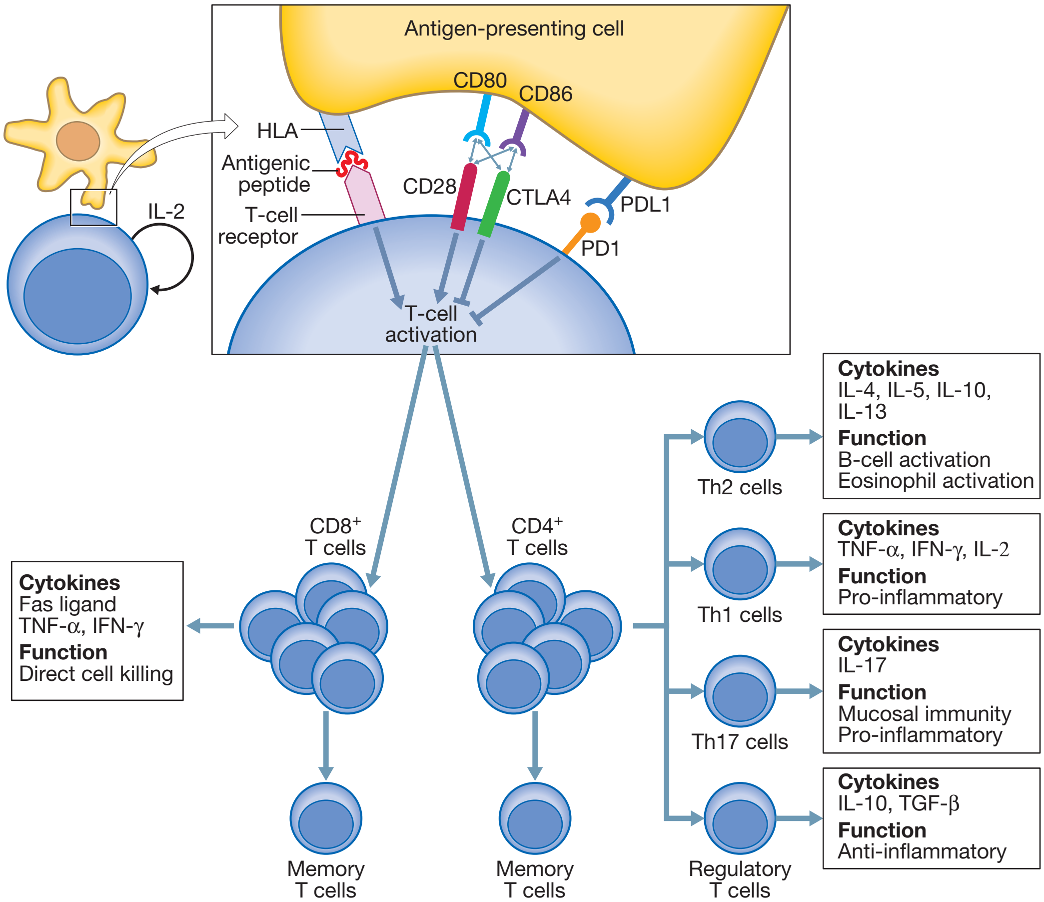

Fig. 4.7 T-cell activation. Activation of T cells is initiated when an antigenic peptide bound to a human leucocyte antigen (HLA) molecule on antigen-presenting cells interacts with the T-cell receptor expressed by T lymphocytes. Additional signals are required for T-cell activation, however. These include binding of the co-stimulatory molecules CD80 and CD86 with CD28 on the T cell, and interleukin 2 (IL-2), which is produced in an autocrine manner by T cells that are undergoing activation. Other molecules are present that can inhibit T-cell activation, however, including cytotoxic T-lymphocyte-associated protein 4 (CTLA4), which competes with CD28 for binding to CD80 and CD86; and PD1, which, by binding PDL1, is also inhibitory. Following activation, T cells proliferate and, depending on their subtype, have various functions with distinct patterns of cytokine production, as indicated. Memory cells are also generated that can mount a rapid immune response on encountering the same antigen. (CD = cluster of differentiation; CD40L = CD40 ligand; IFN-γ = interferon-gamma; IL = interleukin; PD1 = programmed cell death 1; PDL1 = programmed death ligand 1; TGF-β = transforming growth factor beta; TNF-α = tumour necrosis factor alpha)

specific for a single antigen. Within the thymus T cells undergo a process of stringent selection to ensure that autoreactive cells are destroyed. Mature T lymphocytes leave the thymus and expand to populate other organs of the immune system. It has been estimated that an individual possesses 10^7–10^9 T-cell clones, each with a unique T-cell receptor, ensuring at least partial coverage for any antigen encountered.

Unlike B cells, T cells cannot recognise intact protein antigens in their native form. Instead, the protein must be broken down into component peptides by antigen-presenting cells for presentation to T lymphocytes in association with HLA molecules on the antigen-presenting cell surface. This process is known as antigen processing and presentation, and it is the complex of peptide and HLA together that is recognised by individual T cells (Fig. 4.7). The structure of HLA molecules varies widely between individuals. Since each HLA molecule has the capacity to present a subtly different peptide repertoire to T lymphocytes, this ensures enormous diversity in recognition of antigens by the T-cell population. All nucleated cells have the capacity to process and present antigens, but cells with specialised antigen-presenting functions include dendritic cells, macrophages and B lymphocytes. These carry additional co-stimulatory molecules, such as CD80 and CD86, providing the necessary 'second signal' for full T-cell activation.

T lymphocytes can be divided into two subgroups on the basis of function and recognition of HLA molecules. These are designated $CD4^+$ and $CD8^+$ T cells, according to the 'cluster of differentiation' (CD) antigen number of key proteins expressed on their cell surface.

$CD8^+$ T lymphocytes

These cells recognise antigenic peptides in association with HLA class I molecules (HLA-A, HLA-B, HLA-C). They kill infected cells directly through the production of pore-forming molecules such as perforin and release of digesting enzymes triggering apoptosis of the target cell, and are particularly important in defence against viral infection.

$CD4^+$ T lymphocytes

These cells recognise peptides presented on HLA class II molecules (HLA-DR, HLA-DP and HLA-DQ) and have mainly immunoregulatory functions. They produce cytokines and provide co-stimulatory signals that support the activation of $CD8^+$ T lymphocytes and assist the production of mature antibody by B cells. In addition, their close interaction with phagocytes determines cytokine production by both cell types. $CD4^+$ lymphocytes can be further subdivided into subsets on the basis of the cytokines they produce:

- Th1 (T helper) cells typically produce IL-2, IFN-γ and TNF-α, and support the development of delayed-type hypersensitivity responses (p. 83).
- Th2 cells typically produce IL-4, IL-5, IL-10 and IL-13, and promote allergic responses (p. 84).
- T-regulatory cells (T regs) are a further subset of specialised $CD4^+$ lymphocytes that are important in actively suppressing activation of other cells and preventing autoimmune disease.
- Th17 cells are pro-inflammatory cells defined by their production of IL-17. They are related to regulatory T cells, and play a role in immune defence at mucosal surfaces

T-cell activation is regulated by a balance between co-stimulatory molecules, the second signal required for activation, and inhibitory molecules that down-regulate T-cell activity. One such inhibitory molecule, CTLA4, has been harnessed therapeutically in the form of abatacept, which is a fusion protein comprised of the Fc fragment of immunoglobulin linked to CTLA4. This is used to inhibit T-cell activation in rheumatoid arthritis and solid organ transplantation.

The inflammatory response

Inflammation is the response of tissues to injury or infection, and is necessary for normal repair and healing. This section focuses on the general principles of the inflammatory response and its multisystem manifestations. The role of inflammation in specific diseases is discussed in many other chapters of this book.

Acute inflammation

Acute inflammation is the result of rapid and complex interplay between the cells and soluble molecules of the innate immune system. The classical external signs include heat, redness, pain and swelling (Fig. 4.8). The inflammatory process is initiated by local tissue injury or infection. Damaged epithelial cells produce cytokines and antimicrobial peptides, causing early infiltration of phagocytic cells. Production of leukotrienes, prostaglandins, histamine, kinins, anaphylotoxins and inducible nitric oxide synthase also occurs within inflamed tissue. These mediators cause vasodilatation and increased vascular permeability, causing trafficking of fluid and cells into the affected tissue. In addition, pro-inflammatory cytokines, such as IL-1, TNF-α and IL-6 produced at the site of injury, are released systemically and act on the hypothalamus to cause fever, and on the liver to stimulate production of acute phase proteins.

The acute phase response

The acute phase response refers to the production of a variety of proteins by the liver in response to inflammatory stimuli. These proteins have a wide range of activities. Circulating levels of C-reactive protein (CRP) and serum amyloid A may be increased 1000-fold, contributing to host defence and stimulating repair and regeneration. Fibrinogen plays an essential role in wound healing, and α_1-antitrypsin and α_1-antichymotrypsin control the pro-inflammatory cascade by neutralising the enzymes produced by activated neutrophils, preventing widespread tissue destruction. In addition, antioxidants such as haptoglobin and manganese superoxide dismutase scavenge for oxygen free radicals, while increased levels of iron-binding proteins such as ferritin and lactoferrin decrease the iron available for uptake by bacteria (p. 941). Immunoglobulins are not acute phase proteins but are often increased in chronic inflammation.

Septic shock

Septic shock is the clinical manifestation of overwhelming inflammation (p. 196). It is characterised by excessive production of pro-inflammatory cytokines by macrophages, causing hypotension, hypovolaemia and tissue oedema. In addition, uncontrolled neutrophil activation causes release of proteases and oxygen free radicals within blood vessels, damaging the vascular endothelium and further increasing capillary permeability. Direct activation of the coagulation pathway combines with endothelial cell disruption to form clots within the damaged vessels. The

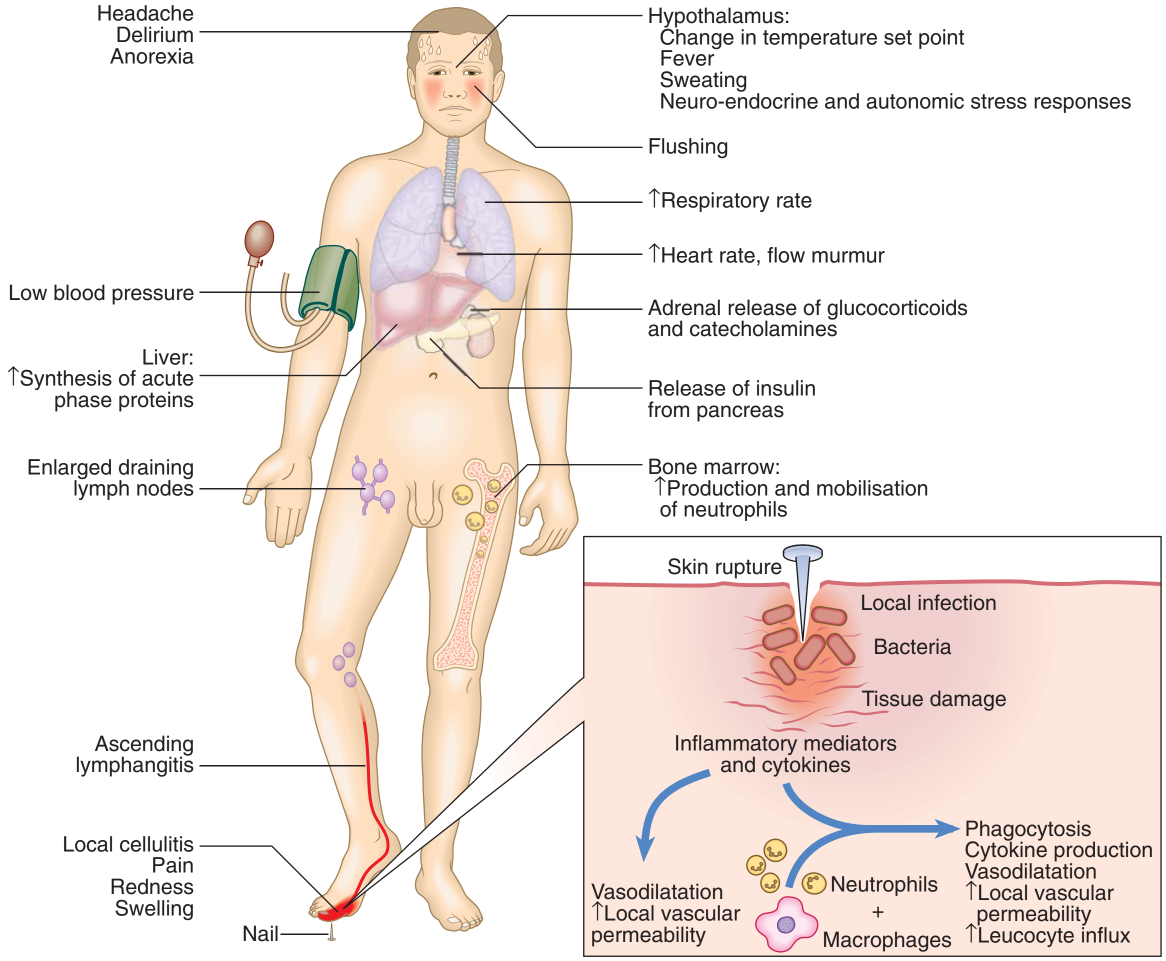

Fig. 4.8 Clinical features of acute inflammation. In this example, the response is to a penetrating injury and infection of the foot.

clinical consequences include cardiovascular collapse, acute respiratory distress syndrome, disseminated intravascular coagulation, multi-organ failure and often death. Septic shock most frequently results from infection with Gram-negative bacteria, because lipopolysaccharide produced by these organisms is particularly effective at activating the inflammatory cascade. Early recognition and appropriate early intervention can improve patient outcome (p. 196).

Resolution of inflammation

Resolution of an inflammatory response is crucial for normal healing. This involves active down-modulation of inflammatory stimuli and repair of bystander damage to local tissues. Extravasated neutrophils undergo apoptosis and are phagocytosed by macrophages, along with the remains of microorganisms. Macrophages also synthesise collagenase and elastase, which break down local connective tissue and aid in the removal of debris. Normal tissue homeostasis is also associated with reversion of parenchymal cells to a non-inflammatory phenotype. Macrophage-derived cytokines, including transforming growth factor-beta (TGF-β) and platelet-derived growth factor, stimulate fibroblasts and promote the synthesis of new collagen, while angiogenic factors stimulate new vessel formation.

Chronic inflammation

In most instances, the development of an active immune response results in clearance and control of the inflammatory stimulus and resolution of tissue damage. Failure of this process may result in chronic inflammation, with significant associated bystander damage, known as hypersensitivity responses. Persistence of microorganisms can result in ongoing accumulation of neutrophils, macrophages and activated T lymphocytes within the lesion. If this is associated with local deposition of fibrous tissue, a granuloma may form. Granulomas are characteristic of tuberculosis and leprosy (Hansen's disease), in which the microorganism is protected by a robust cell wall that shields it from killing, despite phagocytosis.

Laboratory features of inflammation

Inflammation is associated with changes in many laboratory investigations. Leucocytosis is common, and reflects the transit of activated neutrophils and monocytes to the site of infection. The platelet count may also be increased. The most widely used laboratory measure of acute inflammation is CRP. Circulating

levels of many other acute phase reactants, including fibrinogen, ferritin and complement components, are also increased in response to acute inflammation, while albumin levels are reduced. Chronic inflammation is frequently associated with a normocytic normochromic anaemia (p. 943).

C-reactive protein

C-reactive protein (CRP) is an acute phase reactant synthesised by the liver, which opsonises invading pathogens. Circulating concentrations of CRP increase within 6 hours of the start of an inflammatory stimulus. Serum concentrations of CRP provide a direct biomarker of acute inflammation and, because the serum half-life of CRP is 18 hours, levels fall promptly once the inflammatory stimulus is removed. Sequential measurements are useful in monitoring disease activity (Box 4.4). For reasons that remain unclear, some diseases are associated with only minor elevations of CRP despite unequivocal evidence of active inflammation. These include systemic lupus erythematosus (SLE), systemic sclerosis, ulcerative colitis and leukaemia. An important practical point is that if the CRP is raised in these conditions, it suggests intercurrent infection rather than disease activity. Since the CRP is a more sensitive early indicator of the acute phase response, it is generally used in preference to the erythrocyte sedimentation rate (ESR). If both ESR and CRP are used, any discrepancy should be resolved by assessing the individual determinants of the ESR, which are discussed below.

Erythrocyte sedimentation rate

The ESR is an indirect measure of inflammation. It measures how fast erythrocytes fall through plasma, which is determined by the composition of plasma proteins and the morphology of circulating erythrocytes. These factors govern the propensity of red cells to aggregate, the major determinant of the ESR. Erythrocytes are inherently negatively charged, which prevents them from clumping together in the blood stream. Since plasma proteins are positively charged, an increase in plasma protein concentrations neutralises the negative charge of erythrocytes, overcoming their inherent repulsive forces and causing them aggregate, resulting in rouleaux formation. Rouleaux have a higher mass-to-surface area ratio than single red cells, and therefore sediment faster. The most common reason for an increased ESR is an acute phase response, which causes an increase in the concentration of acute phase proteins, including CRP. However, other conditions that do not affect acute phase proteins may alter the composition and concentration of other plasma protein (Box 4.4). For example, immunoglobulins comprise a significant proportion of plasma proteins but do not participate in the acute phase response. Thus any condition that causes an increase in serum immunoglobulins will increase the ESR without a corresponding increase in CRP. In addition, abnormal red cell morphology can make rouleaux formation impossible. For these reasons, an inappropriately low ESR occurs in spherocytosis and sickle-cell anaemia.

Plasma viscosity

Plasma viscosity is another surrogate measure of plasma protein concentration. Like the ESR, it is affected by the concentration of large plasma proteins, including fibrinogen and immunoglobulins. It is not affected by properties of erythrocytes and is generally considered to be more reliable than the ESR as a marker of inflammation.

4.4 Conditions commonly associated with abnormal C-reactive protein (CRP) and/or erythrocyte sedimentation rate (ESR)

Condition	Consequence	Effect on CRP[1]	Effect on ESR[2]
Acute bacterial, fungal or viral infection	Stimulates acute phase response	Increased (range 50–150 mg/L; in severe infections may be >300 mg/L)	Increased
Necrotising bacterial infection	Stimulates profound acute inflammatory response	Greatly increased (may be >300 mg/L)	Increased
Chronic bacterial or fungal infection Localised abscess, bacterial endocarditis or tuberculosis	Stimulates acute and chronic inflammatory response with polyclonal increase in immunoglobulins, as well as increased acute phase proteins	Increased (range 50–150 mg/L)	Increased disproportionately to CRP
Acute inflammatory diseases Crohn's disease, polymyalgia rheumatica, inflammatory arthritis	Stimulates acute phase response	Increased (range 50–150 mg/L)	Increased
Systemic lupus erythematosus, Sjögren's syndrome, ulcerative colitis	Chronic inflammatory response	Normal	Increased
Multiple myeloma	Monoclonal increase in serum immunoglobulin without acute inflammation	Normal	Increased
Pregnancy, old age, end-stage renal disease	Increased fibrinogen	Normal	Moderately increased

[1]Reference range <10 mg/L. [2]Reference range: adult males <10 mm/hr, adult females <20 mm/hr.

4

Presenting problems in immune disorders

Recurrent infections

Infections can occur in otherwise healthy individuals but recurrent infection raises suspicion of an immune deficiency. Depending on the component of the immune system affected, the infections may involve bacteria, viruses, fungi or protozoa, as summarised in Box 4.5. T-cell deficiencies can involve pathogens from all groups.

Aetiology

Infections secondary to immune deficiency occur because of defects in the number or function of phagocytes, B cells, T cells or complement, as described later in this chapter.

Clinical assessment

Clinical features that may indicate immune deficiency are listed in Box 4.6. Frequent or severe infections, or ones caused by unusual organisms or at unusual sites are typical of immune deficiency.

Investigations

Initial investigations should include full blood count and white cell differential, CRP, renal and liver function tests, urine dipstick, serum immunoglobulins with protein electrophoresis, and HIV testing. Additional microbiological tests, virology and imaging are required to identify the causal organism and localise the site of infection, as outlined in Box 4.7. If primary immune deficiency is suspected on the basis of initial investigations, more specialised tests should be considered, as summarised in Box 4.8.

Management

If an immune deficiency is suspected but has not yet been formally characterised, patients should not receive live vaccines because of the risk of vaccine-induced disease. Further management depends on the underlying cause and details are provided later.

i 4.6 Warning signs of primary immune deficiency*

In children	In adults
≥4 new ear infections within 1 year	≥2 new ear infections within 1 year
≥2 serious sinus infections within 1 year	≥2 new sinus infections within 1 year, in the absence of allergy
≥2 months on antibiotics with little effect	Recurrent viral infections
≥2 pneumonias within 1 year	≥1 pneumonia per year for more than 1 year
Failure of an infant to gain weight or grow normally	Chronic diarrhoea with weight loss
Recurrent deep skin or organ abscesses	Recurrent deep skin or organ abscesses
Persistent thrush in mouth or elsewhere on skin after infancy	Persistent thrush or fungal infection on skin or elsewhere
Need for intravenous antibiotics to clear infections	Recurrent need for intravenous antibiotics to clear infections
≥2 deep-seated infections such as sepsis, meningitis or cellulitis	Infection with atypical mycobacteria
A family history of primary immune deficiency	A family history of primary immune deficiency

*The presence of two or more of the above features may indicate the presence of an underlying primary immunodeficiency.

i 4.5 Immune deficiencies and common patterns of infection

Phagocyte deficiency	Complement deficiency	Antibody deficiency	T-lymphocyte deficiency
Bacteria *Staphylococcus aureus* *Pseudomonas aeruginosa* *Serratia marcescens* *Burkholderia cenocepacia* *Nocardia* *Mycobacterium tuberculosis* Atypical mycobacteria	*Neisseria meningitidis* *Neisseria gonorrhoeae* *Haemophilus influenzae* *Streptococcus pneumoniae*	*Haemophilus influenzae* *Streptococcus pneumoniae* *Staphylococcus aureus*	*Mycobacterium tuberculosis* Atypical mycobacteria
Fungi *Candida* spp. *Aspergillus* spp.	–	–	*Candida* spp. *Aspergillus* spp. *Pneumocystis jirovecii*
Viruses	–	–	Cytomegalovirus (CMV) Enteroviruses Epstein–Barr virus (EBV) Herpes zoster virus Human papillomavirus Human herpesvirus 8
Protozoa	–	*Giardia lamblia*	*Toxoplasma gondii* *Cryptosporidia*

i 4.7 Initial investigations in suspected immune deficiency

Test	Value	Comment
Full blood count	Full white cell differential	May define pathway for further investigation
Acute phase reactants	Help determine presence of active infection	
Serum immunoglobulins	Detection of antibody deficiency	
Serum protein electrophoresis	Detection of paraprotein	May be the cause of immune paresis; paraprotein should be excluded prior to diagnosis of primary antibody deficiency
Serum free light chains/Bence Jones proteins	Detection of paraprotein	
Human immunodeficiency virus (HIV) test	To exclude HIV as cause of secondary immune deficiency	
Imaging according to history and examination findings	Detection of active infection/end-organ damage	May support treatment decisions, e.g. if there is evidence of bronchiectasis

i 4.8 Specialist investigations in suspected immune deficiency

Test	Value	Comment
Complement (C3/C4/CH50/AP50)	Investigation of recurrent pyogenic bacterial infection	Inherited complement deficiency likely to give low/absent results on functional assays
Test vaccination	Determination of functional humoral immune response	Helpful in patients with borderline low or normal immunoglobulins but confirmed recurrent infection
Neutrophil function	Investigation of recurrent invasive bacterial and fungal infection, especially with catalase-positive organisms Investigation of leucocyte adhesion deficiency	Respiratory burst low/absent in chronic granulomatous disease Leucocytosis with absent CD11a, b, c expression
Lymphocyte immunophenotyping (by flow cytometry)	Determination of specific lymphocyte subsets, T cell, B cell, NK cell	May define specific primary immune deficiency, e.g. absent B cells in X-linked agammaglobulinaemia
Lymphocyte proliferation	Determination of lymphocyte proliferation in response to mitogenic stimulation	Poor responses seen in certain T-cell immune deficiencies
Cytokine production	To determine T-cell immune function in response to antigen stimulation; limited availability, not routine	Can be helpful, for example, in investigation of atypical mycobacterial infection
Genetic testing	Under specialist supervision when specific primary immune deficiency suspected	May confirm genetic cause, with implications for family members and future antenatal testing

(NK = natural killer)

Intermittent fever

Intermittent fever has a wide differential diagnosis, including recurrent infection, malignancy and certain rheumatic disorders, such as Still's disease, vasculitis and SLE (pp. 1040 and 1034), but a familial fever syndrome is a potential cause.

Aetiology

Familial fever syndromes are genetic disorders caused by mutations in genes responsible for regulating the inflammatory response. The symptoms are caused by activation of intracellular signalling pathways involved in the regulation of inflammation, with over-production of pro-inflammatory cytokines such as IL-1.

Clinical assessment

A full clinical history and physical examination should be performed, paying attention to the patient's ethnic background and any family history of a similar disorder. If this assessment shows no evidence of underlying infection, malignancy or a rheumatic disorder and there is a positive family history and early age at onset, then the likelihood of a familial fever syndrome is increased.

Investigations

Blood should be taken for a full blood count, measurement of ESR and CRP, and assessment of renal and liver function. Serum ferritin should be checked, as very high levels support the diagnosis of Still's disease. Blood and urine cultures should also be performed, along with an autoimmune screen that includes measurement of antinuclear antibodies and consideration of antineutrophil cytoplasmic antibodies to check for evidence of SLE or vasculitis, respectively. Imaging may be required to exclude occult infection. If these investigations provide no evidence of infection or another cause, then genetic analysis should be considered to confirm the diagnosis of a familial fever syndrome (p. 81). Negative genetic testing does not, however, entirely exclude a periodic fever syndrome.

Management

Symptomatic management with non-steroidal anti-inflammatory drugs (NSAIDs) should be initiated, pending the results of investigations. If the response to NSAIDs is inadequate, glucocorticoids can be tried, provided that infection has been excluded. If a familial fever syndrome is confirmed, then definitive therapy should be initiated, depending on the underlying diagnosis (p. 81).

Anaphylaxis

Anaphylaxis is a potentially life-threatening, systemic allergic reaction characterised by circulatory collapse, bronchospasm, laryngeal stridor, often associated with angioedema, and urticaria. The risk of death is increased in patients with pre-existing asthma, particularly if this is poorly controlled, and in situations where treatment with adrenaline (epinephrine) is delayed.

Aetiology

Anaphylaxis occurs when an allergen binds to and cross-links membrane-bound IgE on mast cells in a susceptible individual, causing release of histamine, tryptase and other vasoactive mediators from mast cells. These mediators have a variety of effects, including vasodilatation, increased capillary permeability leading to hypotension, and bronchoconstriction, as summarised in Box 4.9. It can be difficult to distinguish IgE-mediated anaphylaxis clinically from non-specific degranulation of mast cells on exposure to drugs, chemicals or other triggers where IgE is not involved, previously known as anaphylactoid reactions. Common triggers are shown in Box 4.10.

Clinical assessment

The clinical features of anaphylaxis and 'anaphylactoid' reactions are indistinguishable and are summarised in Figure 4.9. Several other conditions can mimic anaphylaxis and these are listed in Box 4.11.

It is important to assess the severity of the reaction, and the time between allergen exposure and onset of symptoms provides

4.9 Clinical features of mast cell degranulation

Mediator	Biological effects
Pre-formed and stored within granules	
Histamine	Vasodilatation, chemotaxis, bronchoconstriction, increased capillary permeability and increased mucus secretion
Tryptase	Bronchoconstriction, activates complement C3
Eosinophil chemotactic factor	Eosinophil chemotaxis
Neutrophil chemotactic factor	Neutrophil chemotaxis
Synthesised on activation of mast cells	
Leukotrienes	Increase vascular permeability, chemotaxis, mucus secretion and smooth muscle contraction
Prostaglandins	Bronchoconstriction, platelet aggregation and vasodilatation
Thromboxanes	Bronchoconstriction
Platelet-activating factor	Bronchoconstriction, chemotaxis of eosinophils and neutrophils

4.10 Common causes of systemic allergic reactions

Anaphylaxis: IgE-mediated mast cell degranulation

Foods
- Peanuts
- Tree nuts
- Fish and shellfish
- Milk
- Eggs
- Soy products

Insect stings
- Bee venom
- Wasp venom

Chemicals, drugs and other foreign proteins
- Intravenous anaesthetic agents (suxamethonium)
- Penicillin and other antibiotics
- Latex

Anaphylactoid: non-IgE-mediated mast cell degranulation

Drugs
- Aspirin and non-steroidal anti-inflammatory drugs (NSAIDs)
- Opiates
- Radiocontrast media

Physical
- Exercise
- Cold

Idiopathic
- No cause is identified in 20% of patients with anaphylaxis

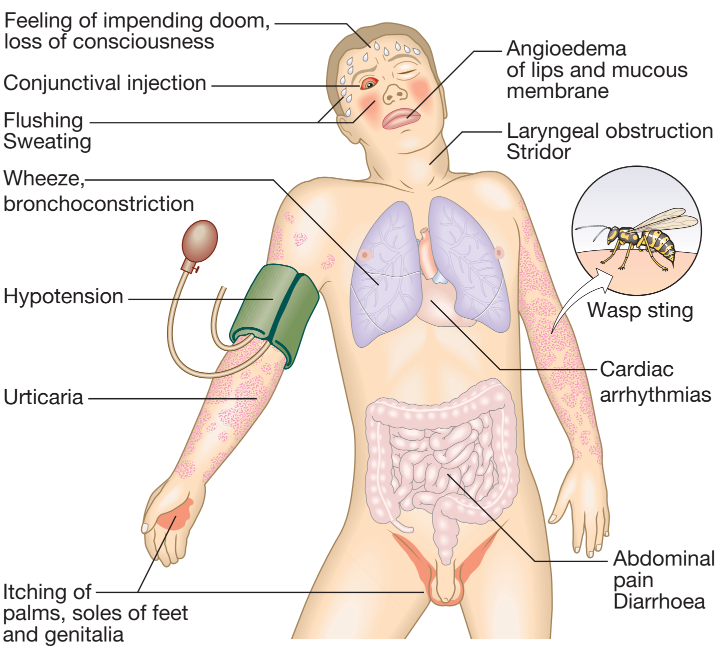

Fig. 4.9 Clinical manifestations of anaphylaxis. In this example, the response is to an insect sting containing venom to which the patient is allergic. This causes release of histamine and other vasoactive mediators, which cause the characteristic features of anaphylaxis that are illustrated.

4.11 Differential diagnosis of anaphylaxis

Causes of hypotension
- Vasovagal syncope
- Cardiac arrhythmia
- Cardiogenic shock

Causes of respiratory distress
- Status asthmaticus
- Pulmonary embolus

Causes of laryngeal obstruction
- C1 inhibitor deficiency
- Idiopathic angioedema

Causes of generalised flushing
- Systemic mastocytosis
- Carcinoid syndrome
- Phaeochromocytoma

4.12 Emergency management of anaphylaxis

Treatment	Comment
Prevent further contact with allergen	Prevents ongoing mast cell activation
Ensure airway patency	Prevents hypoxia
Administer adrenaline (epinephrine) promptly: 0.3–1.0 mL 1 : 1000 solution IM in adults Repeat at 5–10-min intervals if initial response is inadequate	Intramuscular route important because of peripheral vasoconstriction Acts within minutes Increases blood pressure Reverses bronchospasm
Administer antihistamines: Chlorphenamine 10 mg IM or slow IV injection	Blocks effect of histamine on target cells
Administer glucocorticoids: Hydrocortisone 200 mg IV	Reduces cytokine release Prevents rebound symptoms in severe cases
Provide supportive treatment: Nebulised β_2-agonists IV fluids Oxygen	Reverses bronchospasm Restores plasma volume Reverses hypoxia

(IM = intramuscular; IV = intravenous)

a guide. Enquiry should be made about potential triggers. If none is immediately obvious, a detailed history of the previous 24 hours may be helpful. The most common triggers of anaphylaxis are foods, latex, insect venom and drugs (see Box 4.10). A history of previous local allergic responses to the offending agent is common. The route of allergen exposure may influence the principal clinical features of a reaction; for example, if an allergen is inhaled, the major symptom is frequently wheezing. Features of anaphylaxis may overlap with the direct toxic effects of drugs and venoms (Chs 7 and 8). Potentiating factors, such as exercise or alcohol, can lower the threshold for an anaphylactic event. It is important to identify precipitating factors so that appropriate avoidance measures may be taken in the longer term.

Investigations

Measurement of serum mast cell tryptase concentrations is useful to confirm the diagnosis but cannot distinguish between anaphylaxis and non-IgE-mediated anaphylactoid reactions. Specific IgE tests may be useful in confirming hypersensitivity and may be preferable to skin-prick tests when investigating patients with a history of anaphylaxis.

4.13 How to prescribe self-injectable adrenaline (epinephrine)

Prescription (normally initiated by an immunologist or allergist)
- Specify the brand of autoinjector, as they have different triggering mechanisms
- Prescribe two devices

Indications
- Anaphylaxis to allergens that are difficult to avoid:
  - Insect venom
  - Foods
- Idiopathic anaphylactic reactions
- History of severe localised reactions with high risk of future anaphylaxis:
  - Reaction to trace allergen
  - Likely repeated exposure to allergen
- History of severe localised reactions with high risk of adverse outcome:
  - Poorly controlled asthma
  - Lack of access to emergency care

Patient and family education
- Know when and how to use the device
- Carry the device at all times
- Seek medical assistance immediately after use
- Wear an alert bracelet or necklace
- Include the school in education for young patients (see 'Further information')

Other considerations
- Caution with β-blockers in anaphylactic patients as they may increase the severity of an anaphylactic reaction and reduce the response to adrenaline (epinephrine)

4.14 Allergy in adolescence

- **Resolution of childhood allergy**: most children affected by allergy to milk, egg, soybean or wheat will grow out of their food allergies by adolescence but allergies to peanuts, tree nuts, fish and shellfish are frequently life-long.
- **Risk-taking behaviour and fatal anaphylaxis**: serious allergy is increasingly common in adolescents and this is the highest risk group for fatal, food-induced anaphylaxis. This is associated with increased risk-taking behaviour, and food-allergic teenagers are more likely than adults to eat unsafe foods, deny reaction symptoms and delay emergency treatment.
- **Emotional impact of food allergies**: some adolescents may neglect to carry a prescribed adrenalin autoinjector because of the associated nuisance and/or stigma. Surveys of food-allergic teens reveal that many take risks because they feel socially isolated by their allergy.

Management

The principles of management of the acute event are summarised in Box 4.12. Individuals who have recovered from an anaphylactic event should be referred for specialist assessment. The aim is to identify the trigger factor, to educate the patient regarding avoidance and management of subsequent episodes, and to establish whether specific treatment, such as immunotherapy, is indicated. If the trigger factor cannot be identified or avoided, recurrence is common. Patients who have previously experienced an anaphylactic event should be prescribed self-injectable adrenaline (epinephrine) and they and their families or carers should be instructed in its use (Box 4.13). The use of a MedicAlert (or similar) bracelet will increase the likelihood of the injector being administered in an emergency. Allergy in adolescence requires additional consideration and management, as set out in Box 4.14.

Immune deficiency

The consequences of immune deficiency include recurrent infection, autoimmunity as a result of immune dysregulation, and increased susceptibility to malignancy, especially malignancy driven by viral infections such as Epstein–Barr virus. Immune deficiency may arise through intrinsic defects in immune function but is much more commonly due to secondary causes, including infection, drug therapy, malignancy and ageing. This section gives an overview of primary immune deficiencies. More than a hundred such deficiencies have been described, most of which are genetically determined and present in childhood or adolescence. The presentation of immune deficiency depends on the component of the immune system that is defective (see Box 4.5). There is considerable overlap and redundancy in the immune network, however, and some diseases do not fall easily into this classification.

Primary phagocyte deficiencies

Primary phagocyte deficiencies typically present with recurrent bacterial and fungal infections, which may involve unusual sites. Affected patients require aggressive management of infections, including intravenous antibiotics and surgical drainage of abscesses, and long-term prophylaxis with antibacterial and antifungal agents. The most important examples are illustrated in Figure 4.10 and discussed below.

Chronic granulomatous disease

This is caused by mutations in genes that encode NADPH oxidase enzymes, which results in failure of oxidative killing. The defect leads to susceptibility to catalase-positive organisms such as *Staphylococcus aureus*, *Burkholderia cenocepacia* and *Aspergillus*. Intracellular killing of mycobacteria in macrophages is also impaired. Infections most commonly involve the lungs, lymph nodes, soft tissues, bone, skin and urinary tract, and are characterised histologically by granuloma formation. Most cases are X-linked (p. 48).

Leucocyte adhesion deficiencies

These very rare disorders of phagocyte migration occur because of failure to express adhesion molecules on the surface of leucocytes, resulting in their inability to exit the blood stream. The most common cause is loss-of-function mutations affecting the *ITGB2* gene, which encodes the integrin β-2 chain, a component of the adhesion molecule LFA1. They are characterised by recurrent bacterial infections but sites of infection lack evidence of neutrophil infiltration, such as pus formation. Peripheral blood neutrophil counts may be very high during acute infection because of the failure of mobilised neutrophils to exit blood vessels. Specialised tests show reduced or absent expression of adhesion molecules on neutrophils.

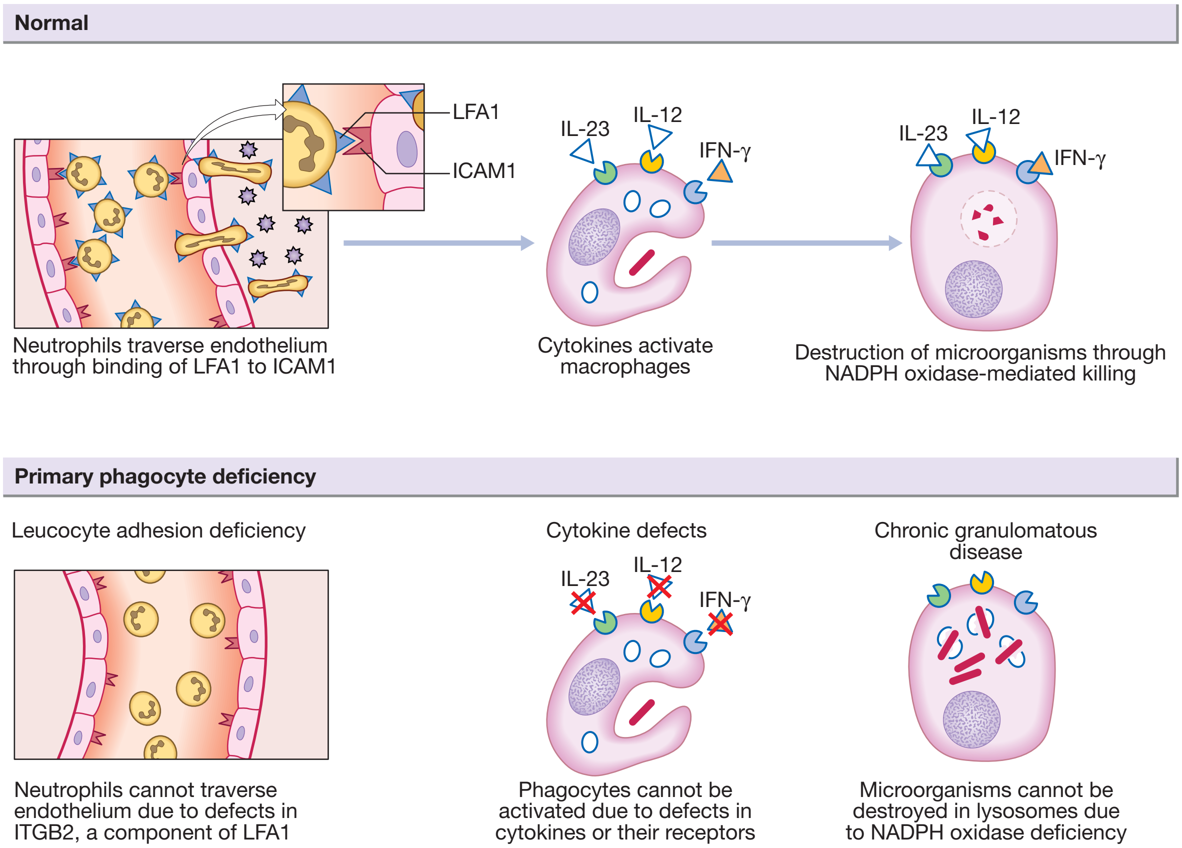

Fig. 4.10 Normal phagocyte function and mechanisms of primary phagocyte deficiency. Under normal circumstances, neutrophils traverse the endothelium to enter tissues by the cell surface molecule lymphocyte function-associated antigen 1 (LFA1), which binds to intercellular adhesion molecule 1 (ICAM1) on endothelium. In order for macrophages to engulf and kill microorganisms, they need to be activated by cytokines and also require nicotinamide adenine dinucleotide phosphate (NADPH) oxidase to generate free radicals. Primary phagocyte deficiencies can occur as the result of leucocytes being unable to traverse endothelium due to defects in LFA1, because of mutations in cytokines or their receptors, or because of defects in NADPH oxidase. (IFN-γ = interferon-gamma; IL = interleukin)

Defects in cytokines and cytokine receptors

Mutations of the genes encoding cytokines such as IFN-γ, IL-12, IL-23 or their receptors result in failure of intracellular killing by macrophages, and affected individuals are particularly susceptible to mycobacterial infections.

Complement pathway deficiencies

Loss-of-function mutations have been identified in almost all the complement pathway proteins (see Fig. 4.4). While most complement deficiencies are rare, mannose-binding lectin deficiency is common and affects about 5% of the northern European population, many of whom are asymptomatic (see below).

Clinical features

Patients with deficiency in complement proteins can present in different ways. In some cases, the presenting feature is recurrent infection with encapsulated bacteria, particularly *Neisseria* spp., reflecting the importance of the membrane attack complex in defence against these organisms. However, genetic deficiencies of the classical complement pathway (C1, C2 and C4) also present with an increased risk of autoimmune disease, particularly SLE (p. 1034). Individuals with mannose-binding lectin deficiency have an increased incidence of bacterial infections if subjected to an additional cause of immune compromise, such as premature birth or chemotherapy. The significance of this condition has been debated, however, since population studies have shown no overall increase in infectious disease or mortality in patients with this disorder. Deficiency of the regulatory protein Cl inhibitor is not associated with recurrent infection but causes recurrent angioedema (p. 87).

Investigations

Screening for complement deficiencies usually involves specialised functional tests of complement-mediated haemolysis. These are known as the CH50 (classical haemolytic pathway 50) and AP50 (alternative pathway 50) tests. If abnormal, haemolytic tests are followed by measurement of individual complement components.

Management

Patients with complement deficiencies should be vaccinated with meningococcal, pneumococcal and *H. influenzae* B vaccines to boost their adaptive immune responses. Lifelong prophylactic penicillin to prevent meningococcal infection is recommended, as is early access to acute medical assessment in the event of infection. Patients should also carry a MedicAlert or similar. At-risk family members should be screened for complement deficiencies with functional complement assays. The management of C1 esterase deficiency is discussed elsewhere.

Primary antibody deficiencies

Primary antibody deficiencies occur as the result of abnormalities in B-cell function, as summarised in Figure 4.11. They are characterised by recurrent bacterial infections, particularly of the respiratory and gastrointestinal tract. The most common causative organisms are encapsulated bacteria such as *Streptococcus pneumoniae* and *H. influenzae.* These disorders usually present in infancy, when the protective benefit of placental transfer of maternal immunoglobulin has waned. The most important causes are discussed in more detail below.

X-linked agammaglobulinaemia

This rare X-linked disorder (p. 48) is caused by mutations in the *BTK* gene, which encodes Bruton tyrosine kinase, a signalling protein that is required for B-cell development. Affected males present with severe bacterial infections during infancy. There is a marked reduction in B-cell numbers and immunoglobulin levels are low or undetectable. Management is with immunoglobulin replacement therapy and antibiotics to treat infections.

Selective IgA deficiency

This is the most common primary antibody deficiency, affecting 1 : 600 northern Europeans. Although IgA deficiency is usually asymptomatic with no clinical sequelae, about 30% of individuals experience recurrent mild respiratory and gastrointestinal infections. The diagnosis can be confirmed by measurement of IgA levels, which are low or undetectable (<0.05 g/L). In some

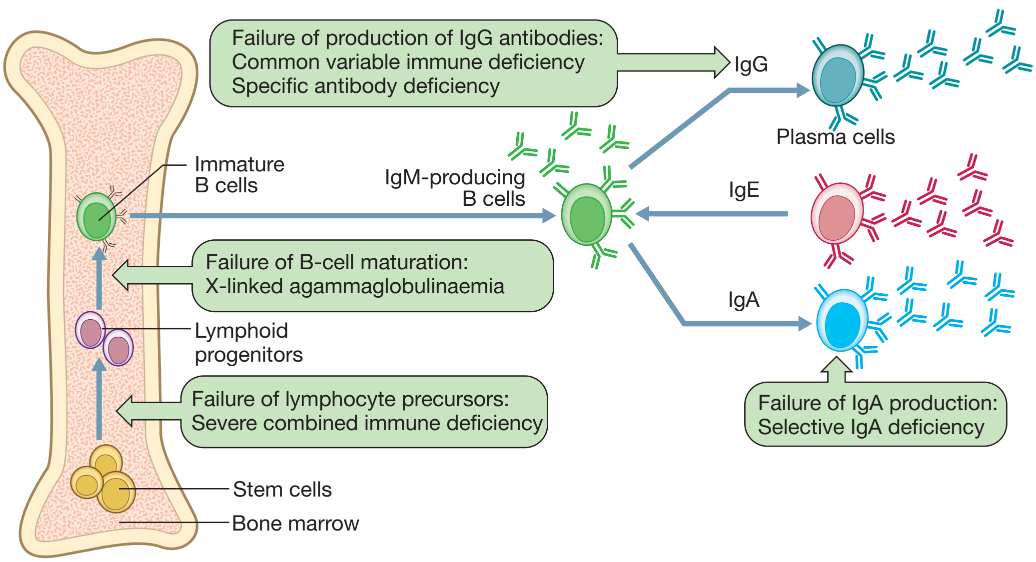

Fig. 4.11 B lymphocytes and primary antibody deficiencies (green boxes). (Ig = immunoglobulin)

i 4.15 Investigation of primary antibody deficiencies

	Serum immunoglobulin (Ig) concentrations				Circulating lymphocyte numbers		
	IgM	IgG	IgA	IgE	B cells	T cells	Test immunisation
Selective IgA deficiency	Normal	Often elevated	Absent	Normal	Normal	Normal	Not applicable*
Common variable immune deficiency	Normal or low	Low	Low or absent	Low or absent	Variable	Variable	No antibody response
Specific antibody deficiency	Normal	Normal	Normal	Normal	Normal	Normal	No antibody response to polysaccharide antigens

*Test immunisation is not usually performed in IgA deficiency but some patients may have impaired responses.

patients, there is a compensatory increase in serum IgG levels. Specific treatment is generally not required.

Common variable immune deficiency

Common variable immune deficiency (CVID) is characterised by low serum IgG levels and failure to make antibody responses to exogenous pathogens. It is a heterogeneous adult-onset primary immune deficiency of unknown cause. The presentation is with recurrent infections, and bronchiectasis is a recognised complication. Paradoxically, antibody-mediated autoimmune diseases, such as idiopathic thrombocytopenic purpura and autoimmune haemolytic anaemia, are common in CVID. It is also associated with an increased risk of malignancy, particularly lymphoproliferative disease.

Functional IgG antibody deficiency

This is a poorly characterised condition resulting in defective antibody responses to polysaccharide antigens. Some patients are also deficient in the antibody subclasses IgG2 and IgG4, and this condition was previously called IgG subclass deficiency. There is overlap between specific antibody deficiency, IgA deficiency and CVID, and some patients may progress to a more global antibody deficiency over time.

Investigations

Serum immunoglobulins (Box 4.15) should be measured in conjunction with protein and urine electrophoresis to exclude secondary causes of hypogammaglobulinaemia, and B- and T-lymphocyte subsets should be measured. Specific antibody responses to known pathogens should be assessed by measuring IgG antibodies against tetanus, *H. influenzae* and *S. pneumoniae* (most patients will have been exposed to these antigens through infection or immunisation). If specific antibody levels are low, immunisation with the appropriate killed vaccine should be followed by repeat antibody measurement 6–8 weeks later; failure to mount a response indicates a significant defect in antibody production. These functional tests have generally superseded IgG subclass quantitation.

Management

Patients with antibody deficiencies generally require aggressive treatment of infections and prophylactic antibiotics may be indicated. An exception is deficiency of IgA, which usually does not require treatment. The mainstay of treatment in most patients with antibody deficiency is immunoglobulin replacement therapy. This is derived from plasma from hundreds of donors and contains IgG antibodies to a wide variety of common organisms. Replacement immunoglobulin may be administered either intravenously or subcutaneously, with the aim of maintaining trough IgG levels (the IgG level just prior to an infusion) within the normal range. This has been shown to minimise progression of end-organ damage and improve clinical outcome. Treatment may be self-administered and is life-long. Benefits of immunisation are limited because of the defect in IgG antibody production, and as with all primary immune deficiencies, live vaccines should be avoided.

Primary T-lymphocyte deficiencies

These are a group of diseases characterised by recurrent viral, protozoal and fungal infections (see Box 4.5). Many T-cell deficiencies are also associated with defective antibody production because of the importance of T cells in providing help for B cells. These disorders generally present in childhood. Several causes of T-cell deficiency are recognised. These are summarised in Figure 4.12 and discussed in more detail below.

DiGeorge syndrome

This results from failure of development of the third and fourth pharyngeal pouches, and is usually caused by a deletion of chromosome 22q11. The immune deficiency is accounted for by failure of thymic development; however, the immune deficiency can be very heterogeneous. Affected patients tend to have very low numbers of circulating T cells despite normal development in the bone marrow. It is associated with multiple developmental anomalies, including congenital heart disease, hypoparathyroidism, tracheo-oesophageal fistulae, cleft lip and palate.

Bare lymphocyte syndromes

These rare disorders are caused by mutations in a variety of genes that regulate expression of HLA molecules or their transport to the cell surface. If HLA class I molecules are affected, $CD8^+$ lymphocytes fail to develop normally, while absent expression of HLA class II molecules affects $CD4^+$ lymphocyte maturation. In addition to recurrent infections, failure to express HLA class I is associated with systemic vasculitis caused by uncontrolled activation of NK cells.

Severe combined immune deficiency

Severe combined immune deficiency (SCID) results from mutations in a number of genes that regulate lymphocyte development, with failure of T-cell maturation, with or without accompanying B- and NK-cell maturation. The most common cause is X-linked SCID, resulting from loss-of-function mutations in the interleukin-2 receptor gamma (*IL2RG*) gene. The gene product is a component of several interleukin receptors, including those for IL-2, IL-7 and IL-15, which are absolutely required for T-cell and NK development. This results in T-cell-negative, NK-cell-negative,

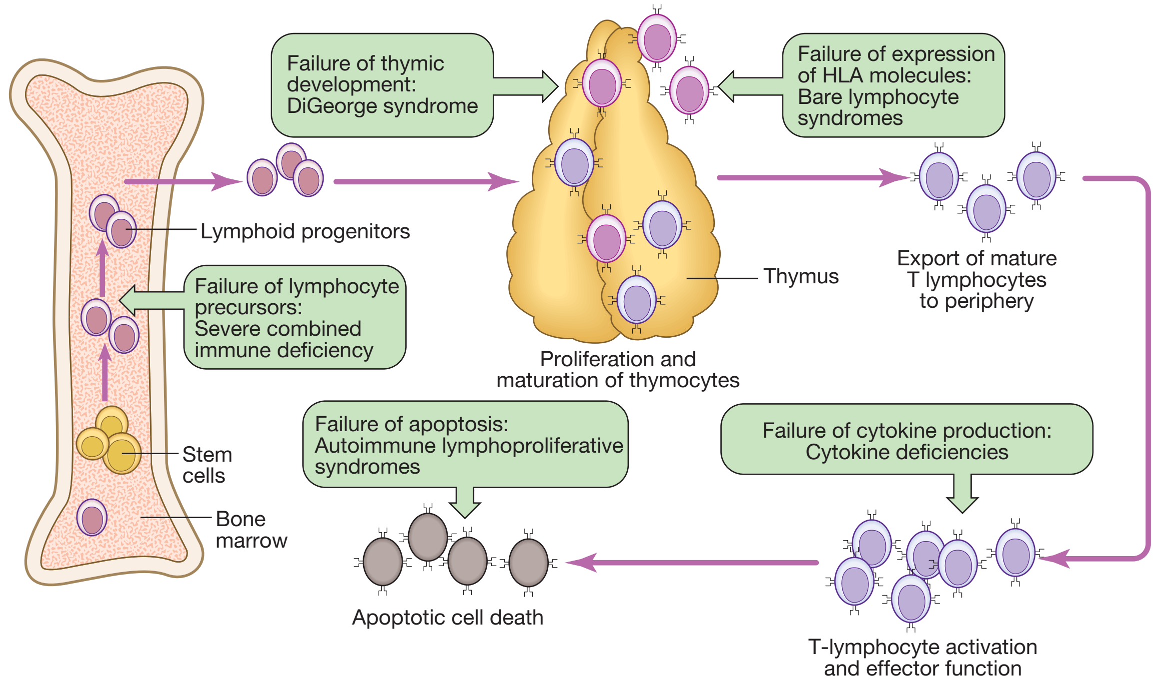

Fig. 4.12 T-lymphocyte function and dysfunction (green boxes). (HLA = human leucocyte antigen)

B-cell-positive SCID. Another cause is deficiency of the enzyme adenosine deaminase (ADA), which causes lymphocyte death due to accumulation of toxic purine metabolites intracellularly, resulting in T-cell-negative, B-cell-negative and NK-cell-negative SCID.

The absence of an effective adaptive immune response causes recurrent bacterial, fungal and viral infections soon after birth. Bone marrow transplantation (BMT; p. 936) is the treatment option of first choice. Gene therapy has been approved for treatment of ADA deficiency when there is no suitable donor for BMT and is under investigation for a number of other causes of SCID.

Investigations

The principal tests for T-lymphocyte deficiencies are a total lymphocyte count and quantitation of individual lymphocyte subpopulations. Serum immunoglobulins should also be measured. Second-line, functional tests of T-cell activation and proliferation may be indicated. Patients in whom T-lymphocyte deficiencies are suspected should be tested for HIV infection (p. 310).

Management

Patients with T-cell deficiencies should be considered for anti-*Pneumocystis* and antifungal prophylaxis, and require aggressive management of infections when they occur. Immunoglobulin replacement is indicated for associated defective antibody production. Stem cell transplantation (p. 936) or gene therapy may be appropriate in some disorders. Where a family history is known and antenatal testing confirms a specific defect, stem cell therapy prior to recurrent invasive infection can improve outcome.

Autoimmune lymphoproliferative syndrome

This rare disorder is caused by failure of normal lymphocyte apoptosis, most commonly due to mutations in the *FAS* gene, which encodes Fas, a signalling protein that regulates programmed cell death in lymphocytes. This results in massive accumulation of autoreactive T cells, which cause autoimmune-mediated anaemia, thrombocytopenia and neutropenia. Other features include lymphadenopathy, splenomegaly and a variety of other autoimmune diseases. Susceptibility to infection is increased because of the neutropenia.

Secondary immune deficiencies

Secondary immune deficiencies are much more common than primary immune deficiencies and occur when the immune system is compromised by external factors (Box 4.16). Common causes include infections, such as HIV and measles, and cytotoxic

4.16 Causes of secondary immune deficiency

Physiological	
• Ageing • Prematurity	• Pregnancy
Infection	
• HIV infection • Measles	• Mycobacterial infection
Iatrogenic	
• Immunosuppressive therapy • Antineoplastic agents • Glucocorticoids	• Stem cell transplantation • Radiation injury • Antiepileptic agents
Malignancy	
• B-cell malignancies including leukaemia, lymphoma and myeloma	• Solid tumours • Thymoma
Biochemical and nutritional disorders	
• Malnutrition • Renal insufficiency/dialysis • Diabetes mellitus	• Specific mineral deficiencies (iron, zinc)
Other conditions	
• Burns	• Asplenia/hyposplenism

4.17 Immune senescence

- **T-cell responses**: decline, with reduced delayed-type hypersensitivity responses.
- **Antibody production**: decreased for many exogenous antigens. Although autoantibodies are frequently detected, autoimmune disease is less common.
- **Response to vaccination**: reduced; 30% of healthy older people may not develop protective immunity after influenza vaccination.
- **Allergic disorders and transplant rejection**: less common.
- **Susceptibility to infection**: increased; community-acquired pneumonia by threefold and urinary tract infection by 20-fold. Latent infections, including tuberculosis and herpes zoster, may be reactivated.
- **Manifestations of inflammation**: may be absent, with lack of pyrexia or leucocytosis.
- **Secondary immune deficiency**: common.

and immunosuppressive drugs, particularly those used in the management of transplantation, autoimmunity and cancer. Physiological immune deficiency occurs at the extremes of life; the decline of the immune response in the elderly is known as immune senescence (Box 4.17). Management of secondary immune deficiency is described in the relevant chapters on infectious diseases (Ch. 11), HIV (Ch. 12), haematological disorders (Ch. 23) and oncology (Ch. 33).

Periodic fever syndromes

These rare disorders are characterised by recurrent episodes of fever and organ inflammation, associated with an elevated acute phase response (p. 74).

Familial Mediterranean fever

Familial Mediterranean fever (FMF) is the most common of the familial periodic fevers, predominantly affecting Mediterranean people, including Arabs, Turks, Sephardic Jews and Armenians. It results from mutations of the *MEFV* gene, which encodes a protein called pyrin that regulates neutrophil-mediated inflammation by indirectly suppressing the production of IL-1. FMF is characterised by recurrent painful attacks of fever associated with peritonitis, pleuritis and arthritis, which last for a few hours to 4 days and are associated with markedly increased CRP levels. Symptoms resolve completely between episodes. Most individuals have their first attack before the age of 20. The major complication of FMF is AA amyloidosis (see below). Colchicine significantly reduces the number of febrile episodes in 90% of patients but is ineffective during acute attacks.

Mevalonic aciduria (mevalonate kinase deficiency)

Mevalonate kinase deficiency, previously known as hyper-IgD syndrome, is an autosomal recessive disorder that causes recurrent attacks of fever, abdominal pain, diarrhoea, lymphadenopathy, arthralgia, skin lesions and aphthous ulceration. Most patients are from Western Europe, particularly the Netherlands and northern France. It is caused by loss-of-function mutations in the gene encoding mevalonate kinase, which is involved in the metabolism of cholesterol. It remains unclear why this causes an inflammatory periodic fever. Serum IgD and IgA levels may be persistently elevated, and CRP levels are increased during acute attacks. Standard anti-inflammatory drugs, including colchicine and glucocorticoids, are ineffective in suppressing the attacks but IL-1 inhibitors, such as anakinra, and TNF inhibitors, such as etanercept, may improve symptoms and can induce complete remission in some patients.

TNF receptor-associated periodic syndrome

TNF receptor-associated periodic syndrome (TRAPS) also known as Hibernian fever, is an autosomal dominant syndrome caused by mutations in the *TNFRSF1A* gene. The presentation is with recurrent attacks of fever, arthralgia, myalgia, serositis and rashes. Attacks may be prolonged for 1 week or more. During a typical attack, laboratory findings include neutrophilia, increased CRP and elevated IgA levels. The diagnosis can be confirmed by low serum levels of the soluble type 1 TNF receptor and by mutation screening of the *TNFRSF1A* gene. As in FMF, the major complication is amyloidosis, and regular screening for proteinuria is advised. Acute episodes respond to systemic glucocorticoids. Therapy with IL-1 inhibitors, such as anakinra, can be effective in preventing attacks.

Amyloidosis

Amyloidosis is the name given to a group of acquired and hereditary disorders characterised by the extracellular deposition of insoluble proteins.

Pathophysiology

Amyloidosis is caused by deposits consisting of fibrils of the specific protein involved, linked to glycosaminoglycans, proteoglycans and serum amyloid P. Protein accumulation may be localised or systemic, and the clinical manifestations depend on the organ(s) affected. Amyloid diseases are classified by the aetiology and type of protein deposited (Box 4.18).

Clinical features

The clinical presentation may be with nephrotic syndrome (p. 395), cardiomyopathy (p. 538) or peripheral neuropathy (p. 1138). Amyloidosis should always be considered as a potential diagnosis in patients with these disorders when the cause is unclear.

Investigations

The diagnosis is established by biopsy, which may be of an affected organ, rectum or subcutaneous fat. The pathognomonic histological feature is apple-green birefringence of amyloid deposits when stained with Congo red dye and viewed under polarised light. Immunohistochemical staining can identify the type of amyloid fibril present. Quantitative scintigraphy with radiolabelled serum amyloid P is a valuable tool in determining the overall load and distribution of amyloid deposits.

Management

The aims of treatment are to support the function of affected organs and, in acquired amyloidosis, to prevent further amyloid deposition through treatment of the primary cause. When the latter is possible, regression of existing amyloid deposits may occur.

Autoimmune disease

Autoimmunity can be defined as the presence of immune responses against self-tissue. This may be a harmless phenomenon, identified

4.18 Causes of amyloidosis

Disorder	Pathological basis	Predisposing conditions	Other features
Acquired systemic amyloidosis			
Reactive (AA) amyloidosis (p. 81)	Increased production of serum amyloid A as part of prolonged or recurrent acute inflammatory response	Chronic infection (tuberculosis, bronchiectasis, chronic abscess, osteomyelitis) Chronic inflammatory diseases (untreated rheumatoid arthritis, familial Mediterranean fever)	90% of patients present with non-selective proteinuria or nephrotic syndrome
Light chain amyloidosis (AL)	Increased production of monoclonal light chain	Monoclonal gammopathies, including myeloma, benign gammopathies and plasmacytoma	Restrictive cardiomyopathy, peripheral and autonomic neuropathy, carpal tunnel syndrome, proteinuria, spontaneous purpura, amyloid nodules and plaques Macroglossia occurs rarely but is pathognomonic Prognosis is poor
Dialysis-associated ($A\beta_2M$) amyloidosis	Accumulation of circulating β_2-microglobulin due to failure of renal catabolism in kidney failure	Renal dialysis	Carpal tunnel syndrome, chronic arthropathy and pathological fractures secondary to amyloid bone cyst formation Manifestations occur 5–10 years after the start of dialysis
Senile systemic amyloidosis	Normal transthyretin protein deposited in tissues	Age >70 years	Feature of normal ageing (affects >90% of 90-year-olds) Usually asymptomatic
Hereditary systemic amyloidosis			
>20 forms of hereditary systemic amyloidosis	Production of protein with an abnormal structure that predisposes to amyloid fibril formation. Most commonly due to mutations in *transthyretin* gene	Autosomal dominant inheritance	Peripheral and autonomic neuropathy, cardiomyopathy Renal involvement unusual 10% of gene carriers are asymptomatic throughout life

only by the presence of low-titre autoantibodies or autoreactive T cells. However, if these responses cause significant organ damage, autoimmune diseases occur. These are a major cause of chronic morbidity and disability, affecting up to 1 in 30 adults at some point during life.

Pathophysiology

Autoimmune diseases result from the failure of immune tolerance, the process by which the immune system recognises and accepts self-tissue. Central immune tolerance occurs during lymphocyte development, when T and B lymphocytes that recognise self-antigens are eliminated before they develop into fully immunocompetent cells. This process is most active in fetal life but continues throughout life as immature lymphocytes are generated. Some autoreactive cells inevitably evade deletion and escape into the circulation, however, and are controlled through peripheral tolerance mechanisms. Peripheral immune tolerance mechanisms include the suppression of autoreactive cells by regulatory T cells; the generation of functional hyporesponsiveness (anergy) in lymphocytes that encounter antigen in the absence of the co-stimulatory signals that accompany inflammation; and cell death by apoptosis. Autoimmune diseases develop when self-reactive lymphocytes escape from these tolerance mechanisms.

Multiple genetic and environmental factors contribute to the development of autoimmune disease. Autoimmune diseases are much more common in women than in men, for reasons that remain unclear. Many are associated with genetic variations in the HLA loci, reflecting the importance of HLA genes in shaping lymphocyte responses. Other important susceptibility genes include those determining cytokine activity, co-stimulation (the expression of second signals required for full T-cell activation; see Fig. 4.7) and cell death. Many of the same gene variants underlie multiple autoimmune disorders, reflecting their common pathogenesis (Box 4.19). Even though some of these associations are the strongest that have been identified in complex genetic diseases,

4.19 Association of specific gene polymorphisms with autoimmune diseases

Gene	Function	Diseases
HLA complex	Key determinants of antigen presentation to T cells	Most autoimmune diseases
PTPN22	Regulation of T- and B-cell receptor signalling	Rheumatoid arthritis, type 1 diabetes, systemic lupus erythematosus
CTLA4	Important co-stimulatory molecule that transmits inhibitory signals to T cells	Rheumatoid arthritis, type 1 diabetes
IL23R	Cytokine-mediated control of T cells	Inflammatory bowel disease, psoriasis, ankylosing spondylitis
TNFRSF1A	Control of tumour necrosis factor network	Multiple sclerosis
ATG5	Autophagy	Systemic lupus erythematosus

they have very limited predictive value and are generally not useful in determining management of individual patients. Several environmental factors may be associated with autoimmunity in genetically predisposed individuals, including infection, cigarette smoking and hormone levels. The most widely studied of these is infection, as occurs in acute rheumatic fever following streptococcal infection or reactive arthritis following bacterial infection. Several mechanisms have been invoked to explain the autoimmunity that occurs after an infectious trigger. These include cross-reactivity between proteins expressed by the pathogen and the host (molecular mimicry), such as Guillain–Barré syndrome and *Campylobacter* infection (p. 1140); release of sequestered antigens from tissues that are damaged during infections that are not usually visible to the immune system; and production of inflammatory cytokines that overwhelm the normal control mechanisms that prevent bystander damage. Occasionally, autoimmune disease may be an adverse effect of drug treatment. For example, metabolic products of the anaesthetic agent halothane can bind to liver enzymes, resulting in a structurally novel protein that is recognised as a foreign antigen by the immune system. This can provoke the development of autoantibodies and activated T cells, which can cause hepatic necrosis.

Clinical features

The clinical presentation of autoimmune disease is highly variable. Autoimmune diseases can be classified by organ involvement or by the predominant mechanism responsible for tissue damage. The Gell and Coombs classification of hypersensitivity is the most widely used, and distinguishes four types of immune response that result in tissue damage (Box 4.20).

- *Type I hypersensitivity* is relevant in allergy but is not associated with autoimmune disease.
- *Type II hypersensitivity* causes injury to a single tissue or organ and is mediated by specific autoantibodies.
- *Type III hypersensitivity* results from deposition of immune complexes, which initiates activation of the classical complement cascade, as well as recruitment and activation of phagocytes and $CD4^+$ lymphocytes. The site of immune complex deposition is determined by the relative amount of antibody, size of the immune complexes, nature of the antigen and local haemodynamics. Generalised deposition of immune complexes gives rise to systemic diseases such as SLE.
- *Type IV hypersensitivity* is mediated by activated T cells and macrophages, which together cause tissue damage.

Investigations

Autoantibodies

Many autoantibodies have been identified and are used in the diagnosis and monitoring of autoimmune diseases, as discussed elsewhere in this book. Antibodies can be quantified either by titre (the maximum dilution of the serum at which the antibody can be detected) or by concentration in standardised units using an enzyme-linked immunosorbent assay (ELISA) in which the antigen is used to coat microtitre plates to which the patient's serum is added (Fig. 4.13A). Qualitative tests are also employed for antinuclear antibodies in which the pattern of nuclear staining is recorded (Fig. 4.13B).

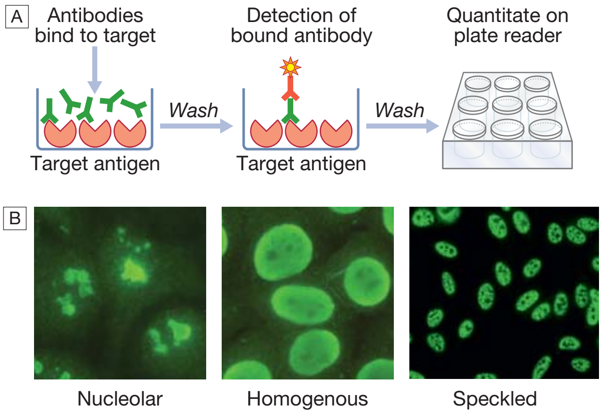

Fig. 4.13 Autoantibody testing. **A** Measurement of antibody levels by enzyme-linked immunosorbent assay (ELISA). The antigen of interest is used to coat microtitre plates to which patient serum is added. If autoantibodies are present, these bind to the target antigen on the microtitre plate. The amount of bound antibody is quantitated by adding a secondary antibody linked to an enzyme that converts a colourless substrate to a coloured one, which can be detected by a plate reader. **B** Qualitative analysis of autoantibodies by patterns of nuclear staining. In this assay, patient serum is added to cultured cells and a secondary antibody is added with a fluorescent label to detect any bound antibody. If antinuclear antibodies are present, they are detected as bright green staining. Different antinuclear antibody patterns may be seen in different types of connective tissue disease (Ch. 24). *B (Nucleolar and Homogenous), Courtesy of Juliet Dunphy, Biomedical Scientist, Royal United Hospital Bath, previously of Bath Institute of Rheumatic Diseases, UK; (Speckled), Courtesy of Mr Richard Brown, Clinical Scientist in Immunology, Southwest Pathology Services, UK.*

4.20 Gell and Coombs classification of hypersensitivity diseases

Type	Mechanism	Example of disease in response to exogenous agent	Example of autoimmune disease
Type I Immediate hypersensitivity	IgE-mediated mast cell degranulation	Allergic disease	None described
Type II Antibody-mediated	Binding of cytotoxic IgG or IgM antibodies to antigens on cell surface causes cell killing	ABO blood transfusion reaction Hyperacute transplant rejection	Autoimmune haemolytic anaemia Idiopathic thrombocytopenic purpura Goodpasture's disease
Type III Immune complex-mediated	IgG or IgM antibodies bind soluble antigen to form immune complexes that trigger classical complement pathway activation	Serum sickness Farmer's lung	Systemic lupus erythematosus Cryoglobulinaemia
Type IV Delayed type	Activated T cells, and phagocytes	Acute cellular transplant rejection Nickel hypersensitivity	Type 1 diabetes Hashimoto's thyroiditis

4.21 Classification of cryoglobulins

	Type I	Type II	Type III
Immunoglobulin (Ig) isotype and specificity	Isolated monoclonal IgM paraprotein with no particular specificity	Immune complexes formed by monoclonal IgM paraprotein directed towards constant region of IgG	Immune complexes formed by polyclonal IgM or IgG directed towards constant region of IgG
Prevalence	25%	25%	50%
Disease association	Lymphoproliferative disease, especially Waldenström macroglobulinaemia (p. 966)	Infection, particularly hepatitis C; lymphoproliferative disease	Infection, particularly hepatitis C; autoimmune disease, including rheumatoid arthritis and systemic lupus erythematosus
Symptoms	*Hyperviscosity:* Raynaud's phenomenon Acrocyanosis Retinal vessel occlusion Arterial and venous thrombosis	*Small-vessel vasculitis:* Purpuric rash Arthralgia Neuropathy Cutaneous ulceration, hepatosplenomegaly, glomerulonephritis, Raynaud's phenomenon	*Small-vessel vasculitis:* Purpuric rash, arthralgia Cutaneous ulceration Hepatosplenomegaly, glomerulonephritis Raynaud's phenomenon
Protein electrophoresis	Monoclonal IgM paraprotein	Monoclonal IgM paraprotein	No monoclonal paraprotein
Rheumatoid factor	Negative	Strongly positive	Strongly positive
Complement	Usually normal	Decreased C4	Decreased C4
Serum viscosity	Raised	Normal	Normal

Complement

Measurement of complement components can be useful in the evaluation of immune complex-mediated diseases. Classical complement pathway activation leads to a decrease in circulating C4 levels and is often also associated with decreased C3 levels. Serial measurement of C3 and C4 is a useful surrogate measure of disease activity in conditions such as SLE.

Cryoglobulins

Cryoglobulins are antibodies directed against other immunoglobulins, forming immune complexes that precipitate in the cold. They can lead to type III hypersensitivity reactions, with typical clinical manifestations including purpuric rash, often of the lower extremities, arthralgia and peripheral neuropathy. Cryoglobulins are classified into three types, depending on the properties of the immunoglobulin involved (Box 4.21). Testing for cryoglobulins requires the transport of a serum specimen to the laboratory at 37°C. Cryoglobulins should not be confused with cold agglutinins; the latter are autoantibodies specifically directed against the I/i antigen on the surface of red cells, which can cause intravascular haemolysis in the cold (p. 950).

Management

The management of autoimmune disease depends on the organ system involved and further details are provided elsewhere in this book. In general, treatment of autoimmune diseases involves the use of glucocorticoids and immunosuppressive agents, which are increasingly used in combination with biologic agents targeting disease-specific cytokines and their receptors. Not all conditions require immune suppression, however. For example, the management of coeliac disease involves dietary gluten withdrawal, while autoimmune hypothyroidism requires appropriate thyroxine supplementation.

Allergy

Allergic diseases are a common and increasing cause of illness, affecting between 15% and 20% of the population at some time. They comprise a range of disorders from mild to life-threatening and affect many organs. Atopy is the tendency to produce an exaggerated IgE immune response to otherwise harmless environmental substances, while an allergic disease can be defined as the clinical manifestation of this inappropriate IgE immune response.

Pathophysiology

The immune system does not normally respond to the many environmental substances to which it is exposed on a daily basis. In allergic individuals, however, an initial exposure to a normally harmless exogenous substance (known as an allergen) triggers the production of specific IgE antibodies by activated B cells. These bind to high-affinity IgE receptors on the surface of mast cells, a step that is not itself associated with clinical sequelae. However, re-exposure to the allergen binds to and cross-links membrane-bound IgE, which activates the mast cells, releasing a variety of vasoactive mediators (the early phase response; Fig. 4.14 and see Box 4.9). This type I hypersensitivity reaction forms the basis of an allergic reaction, which can range from sneezing and rhinorrhoea to anaphylaxis (Box 4.22). In some individuals, the early phase response is followed by persistent activation of mast cells, manifest by ongoing swelling and local inflammation. This is known as the late phase reaction and is mediated by mast cell metabolites, basophils, eosinophils and macrophages. Long-standing or recurrent allergic inflammation may give rise to a chronic inflammatory response characterised by a complex infiltrate of macrophages, eosinophils and T lymphocytes, in addition to mast cells and basophils. Once this has been established, inhibition of mast cell mediators with antihistamines is clinically ineffective in isolation. Mast cell activation may also be non-specifically triggered through other signals, such as neuropeptides, anaphylotoxins and bacterial peptides.

The increasing incidence of allergic diseases is largely unexplained but one widely held theory is the 'hygiene hypothesis'. This proposes that infections in early life are critically important in maturation of the immune response and bias the immune system against the development of allergies; the high prevalence

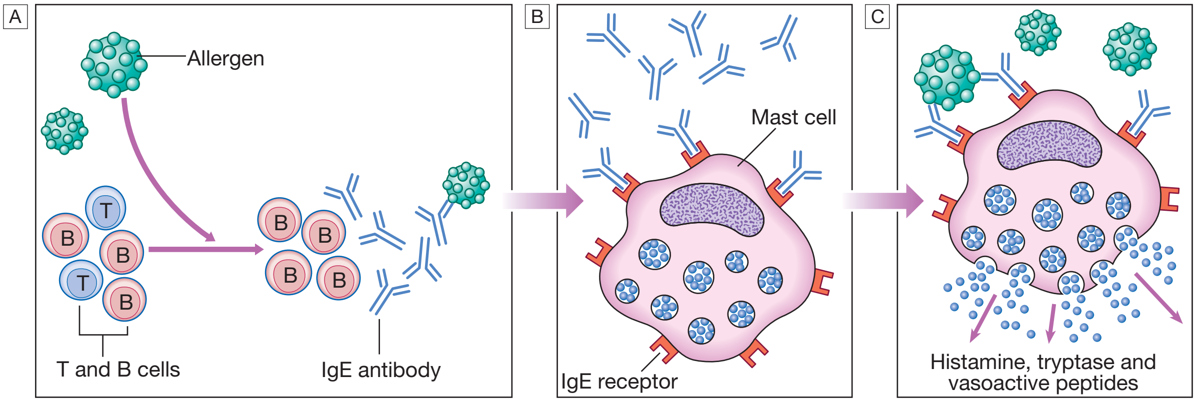

Fig. 4.14 Type I (immediate) hypersensitivity response. A After an encounter with allergen, B cells produce immunoglobulin E (IgE) antibody against the allergen. B Specific IgE antibodies bind to circulating mast cells via high-affinity IgE cell surface receptors. C On re-encounter with allergen, the allergen binds to the IgE antibody-coated mast cells. This cross-linking of the IgE triggers mast cell activation with release of vasoactive mediators (see Box 4.9).

i 4.22 Clinical manifestations of allergy

Dermatological	
• Urticaria • Atopic eczema if chronic	• Allergic contact eczema • Angioedema

• Anaphylaxis • Drug allergy	• Allergy to insect venom

of allergic disease is the penalty for the decreased exposure to infection that has resulted from improvements in sanitation and health care. Genetic factors also contribute strongly to the development of allergic diseases. A positive family history is common in patients with allergy, and genetic association studies have identified a wide variety of predisposing variants in genes controlling innate immune responses, cytokine production, IgE levels and the ability of the epithelial barrier to protect against environmental agents. The expression of a genetic predisposition is complex; it is governed by environmental factors, such as pollutants and cigarette smoke, and the incidence of bacterial and viral infection.

Clinical features

Common presentations of allergic disease are shown in Box 4.22. Those that affect the respiratory system and skin are discussed in more detail in Chapters 17 and 29, respectively. Here we focus on general principles of the approach to the allergic patient, some specific allergies and anaphylaxis.

Insect venom allergy

Local non-IgE-mediated reactions to insect stings are common and may cause extensive swelling around the site lasting up to 7 days. These usually do not require specific treatment. Toxic reactions to venom after multiple (50–100) simultaneous stings may mimic anaphylaxis. In addition, exposure to large amounts of insect venom frequently stimulates the production of IgE antibodies, and thus may be followed by allergic reactions to single stings. Allergic IgE-mediated reactions vary from mild to life-threatening. Antigen-specific immunotherapy (desensitisation; see below) with bee or wasp venom can reduce the incidence of recurrent anaphylaxis from 50–60% to approximately 10% but requires up to 5 years of treatment.

Peanut allergy

Peanut allergy is the most common food-related allergy. More than 50% of patients present before the age of 3 years and some individuals react to their first known exposure to peanuts, thought to result from sensitisation to arachis oil in topical creams. Peanuts are ubiquitous in the Western diet, and every year up to 25% of peanut-allergic individuals experience a reaction as a result of inadvertent exposure.

Birch oral allergy syndrome

This syndrome is characterised by the combination of birch pollen hay fever and local oral symptoms, including itch and angioedema, after contact with certain raw fruits, raw vegetables and nuts. Cooked fruits and vegetables are tolerated without difficulty. It is due to shared or cross-reactive allergens that are destroyed by cooking or digestion, and can be confirmed by skin prick testing using fresh fruit. Severe allergic reactions are unusual.

Diagnosis

When assessing a patient with a complaint of allergy, it is important to identify what the patient means by the term, as up to 20% of the UK population describe themselves as having a food allergy; in fact, less than 1% have true allergy, as defined by an IgE-mediated hypersensitivity reaction confirmed on double-blind challenge. The nature of the symptoms should be established and specific triggers identified, along with the predictability of a reaction, and the time lag between exposure to a potential allergen and onset of symptoms. An allergic reaction usually occurs within minutes of exposure and provokes predictable, reproducible symptoms such as angioedema, urticaria and wheezing. Specific enquiry should be made about other allergic symptoms, past and present, and about a family history of allergic disease. Potential allergens in the home and workplace should be identified. A detailed drug history should always be taken, including details of adherence to medication, possible adverse effects and the use of over-the-counter or complementary therapies.

Investigations

Skin-prick tests

Skin-prick testing is a key investigation in the assessment of patients suspected of having allergy. A droplet of diluted standardised allergen is placed on the forearm and the skin is superficially punctured through the droplet with a sterile lancet. Positive and negative control material must be included in the assessment. After 15 minutes, a positive response is indicated by a local weal and flare response 2 mm or more larger than the negative control. A major advantage of skin-prick testing is that patient can clearly see the results, which may be useful in gaining adherence to avoidance measures. Disadvantages include the remote risk of a severe allergic reaction, so resuscitation facilities should be available. Results are unreliable in patients with extensive skin disease. Antihistamines inhibit the magnitude of the response and should be discontinued for at least 3 days before testing; low-dose glucocorticoids do not influence test results. A number of other prescribed medicines can also lead to false-negative results, including amitriptyline and risperidone.

Specific IgE tests

An alternative to skin-prick testing is the quantitation of IgE directed against the suspected allergen. The sensitivity and specificity of specific IgE tests (previously known as radioallergosorbent tests, RAST) are lower than those of skin-prick tests. However, IgE tests may be very useful if skin testing is inappropriate, such as in patients taking antihistamines or those with severe skin disease or dermatographism. They can also be used to test for cross-reactivity – for example, with multiple insect venoms, where component-resolved diagnostics, using recombinant allergens, is increasingly used rather than crude allergen extract. Specific IgE tests can also be used post-mortem to identify allergens responsible for lethal anaphylaxis.

Supervised exposure to allergen

Tests involving supervised exposure to an allergen (allergen challenge) are usually performed in specialist centres on carefully selected patients, and include bronchial provocation testing, nasal challenge, and food or drug challenge. These may be particularly useful in the investigation of occupational asthma or food allergy. Patients can be considered for challenge testing when skin tests and/or IgE tests are negative, as they can be helpful in ruling out allergic disease.

Mast cell tryptase

Measurement of serum mast cell tryptase is extremely useful in investigating a possible anaphylactic event. Ideally, measurements should be made at the time of the reaction following appropriate resuscitation, and 3 hours and 24 hours later. The basis of the test is the fact that circulating levels of mast cell degranulation products rise dramatically to peak 1–2 hours after a systemic allergic reaction. Tryptase is the most stable of these and is easily measured in serum.

Serum total IgE

Serum total IgE measurements are not routinely indicated in the investigation of allergic disease, other than to aid in the interpretation of specific IgE results, as false-positive specific IgEs are common in patients with atopy, who often have a high total IgE level. Although atopy is the most common cause of an elevated total IgE in developed countries, there are many other causes, including parasitic and helminth infections (pp. 299 and 288), lymphoma (p. 961), drug reactions and eosinophilic granulomatosis with polyangiitis (previously known as Churg–Strauss vasculitis; p. 1043). Normal total IgE levels do not exclude allergic disease.

Eosinophilia

Peripheral blood eosinophilia is common in atopic individuals but lacks specificity. Eosinophilia of more than 20% or an absolute eosinophil count over 1.5×10^9/L should initiate a search for a non-atopic cause, such as eosinophilic granulomatosis with polyangiitis or parasitic infection (p. 928).

Management

Several approaches can be deployed in the management of allergic individuals, as discussed below.

Avoidance of the allergen

This is indicated in all cases and should be rigorously attempted, with the advice of specialist dietitians and occupational physicians if necessary.

Antihistamines

Antihistamines are useful in the management of allergy as they inhibit the effects of histamine on tissue H_1 receptors. Long-acting, non-sedating preparations are particularly useful for prophylaxis.

Glucocorticoids

These are highly effective in allergic disease, and if used topically, adverse effects can be minimised.

Sodium cromoglicate

Sodium cromoglicate stabilises the mast cell membrane, inhibiting release of vasoactive mediators. It is effective as a prophylactic agent in asthma and allergic rhinitis but has no role in management of acute attacks. It is poorly absorbed and therefore ineffective in the management of food allergies.

Antigen-specific immunotherapy

This involves the sequential administration of increasing doses of allergen extract over a prolonged period of time. The mechanism of action is not fully understood but it is highly effective in the prevention of insect venom anaphylaxis and of allergic rhinitis secondary to grass pollen. The traditional route of administration is by subcutaneous injection, which carries a risk of anaphylaxis and should be performed only in specialised centres. Sublingual immunotherapy is also increasingly used. Clinical studies to date do not support the use of allergen immunotherapy for food hypersensitivity, although this is an area of active investigation.

Omalizumab

Omalizumab is a monoclonal antibody directed against IgE; it inhibits the binding of IgE to mast cells and basophils. It is licensed for treatment of refractory chronic spontaneous urticaria and also for severe persistent allergic asthma that has failed to respond to standard therapy (p. 572). The dose and frequency are determined by baseline IgE (measured before the start of treatment) and body weight. It is under investigation for allergic rhinitis but not yet approved for this indication.

Adrenaline (epinephrine)

Adrenaline given by injection in the form of a pre-loaded self-injectable device can be life-saving in the acute management of anaphylaxis (see Box 4.12).

4

Angioedema

Angioedema is an episodic, localised, non-pitting swelling of submucous or subcutaneous tissues.

Pathophysiology

The causes of angioedema are summarised in Box 4.23. It may be a manifestation of allergy or non-allergic degranulation of mast cells in response to drugs and toxins. In these conditions the main cause is mast cell degranulation with release of histamine and other vasoactive mediators. In hereditary angioedema, the cause is C1 inhibitor deficiency, which causes increased local release of bradykinin. Angiotensin-converting enzyme (ACE) inhibitor-induced angioedema also occurs as the result of increased bradykinin levels due to inhibition of its breakdown.

Clinical features

Angioedema is characterised by soft-tissue swelling that most frequently affects the face (Fig. 4.15) but can also affect the extremities and genitalia. Involvement of the larynx or tongue may cause life-threatening respiratory tract obstruction, and oedema of the intestinal mucosa may cause abdominal pain and distension.

Investigations

Differentiating the mechanism of angioedema is important in determining the most appropriate treatment. A clinical history of allergy or drug exposure can give clues to the underlying diagnosis. If no obvious trigger can be identified, measurement of complement C4 is useful in differentiating hereditary and acquired angioedema from other causes. If C4 levels are low, further investigations should be initiated to look for evidence of C1 inhibitor deficiency.

Management

Management depends on the underlying cause. Angioedema associated with allergen exposure generally responds to antihistamines and glucocorticoids. Following acute management of angioedema secondary to drug therapy, drug withdrawal

A B

Fig. 4.15 Angioedema. This young man has hereditary angioedema. **A** Normal appearance. **B** During an acute attack. *From Helbert M. Flesh and bones of immunology. Edinburgh: Churchill Livingstone, Elsevier Ltd; 2006.*

i 4.23 Types of angioedema

	Allergic reaction to specific trigger	Idiopathic angioedema	Hereditary angioedema	ACE-inhibitor associated angioedema
Pathogenesis	IgE-mediated degradation of mast cells	Non-IgE-mediated degranulation of mast cells	C1 inhibitor deficiency, with resulting increased local bradykinin concentration	Inhibition of breakdown of bradykinin
Key mediator	Histamine	Histamine	Bradykinin	Bradykinin
Prevalence	Common	Common	Rare autosomal dominant disorder	0.1–0.2% of patients treated with ACE inhibitors
Clinical features	Usually associated with urticaria History of other allergies common Follows exposure to specific allergen, in food, animal dander or insect venom	Usually associated with urticaria May be triggered by physical stimuli such as heat, pressure or exercise Dermatographism common Occasionally associated with underlying infection or thyroid disease	Not associated with urticaria or other features of allergy Does not cause anaphylaxis May cause life-threatening respiratory tract obstruction Can cause severe abdominal pain	Not associated with urticaria Does not cause anaphylaxis Usually affects the head and neck, and may cause life-threatening respiratory tract obstruction Can occur years after the start of treatment
Investigations	Specific IgE tests or skin-prick tests	Specific IgE tests and skin-prick tests often negative Hypothyroidism should be excluded	Complement C4 (invariably low in acute attacks) C1 inhibitor levels	No specific investigations
Treatment	Allergen avoidance Antihistamines	Antihistamines are mainstay of treatment and prophylaxis	Unresponsive to antihistamines Anabolic steroids C1 inhibitor concentrate or icatibant for acute attacks	ACE inhibitor should be discontinued ARBs should be avoided if possible unless there is a strong indication
Associated drug reactions	Specific drug allergies	NSAIDs Opioids, radiocontrast media		ACE inhibitors, ARBs

(ACE = angiotensin-converting enzyme; ARBs = angiotensin II receptor blockers; NSAIDs = non-steroidal anti-inflammatory drugs)

should prevent further attacks, although ACE inhibitor-induced angioedema can continue for a limited period post drug withdrawal. Management of angioedema associated with C1 inhibitor deficiency is discussed below.

Hereditary angioedema

Hereditary angioedema (HAE), also known as inherited C1 inhibitor deficiency, is an autosomal dominant disorder caused by decreased production or activity of C1 inhibitor protein. This complement regulatory protein inhibits spontaneous activation of the classical complement pathway (see Fig. 4.4). It also acts as an inhibitor of the kinin cascade, activation of which increases local bradykinin levels, giving rise to local pain and swelling.

Clinical features

The angioedema in HAE may be spontaneous or triggered by local trauma or infection. Multiple parts of the body may be involved, especially the face, extremities, upper airway and gastrointestinal tract. Oedema of the intestinal wall causes severe abdominal pain and many patients with undiagnosed HAE undergo exploratory laparotomy. The most important complication is laryngeal obstruction, often associated with minor dental procedures, which can be fatal. Episodes of angioedema are self-limiting and usually resolve within 48 hours. Patients with HAE generally present in adolescence but may go undiagnosed for many years. A family history can be identified in 80% of cases. HAE is not associated with allergic diseases and is specifically not associated with urticaria.

Investigations

Acute episodes are accompanied by low C4 levels; a low C4 during an episode of angioedema should therefore trigger further investigation. The diagnosis can be confirmed by measurement of C1 inhibitor levels and function.

Management

Severe acute attacks should be treated with purified C1 inhibitor concentrate or the bradykinin receptor antagonist icatibant. Anabolic steroids, such as danazol, can be used to prevent attacks and act by increasing endogenous production of complement proteins. Tranexamic acid can be helpful as prophylaxis in some patients. Patients can be taught to self-administer therapy and should be advised to carry a MedicAlert or similar.

Acquired C1 inhibitor deficiency

This rare disorder is clinically indistinguishable from HAE but presents in late adulthood. It is associated with autoimmune and lymphoproliferative diseases. Most cases are due to the development of autoantibodies to C1 inhibitor, but the condition can also be caused by autoantibodies that activate C1. Treatment of the underlying disorder may induce remission of angioedema. As with HAE, a low C4 is seen during acute episodes.

4.24 Immunological diseases in pregnancy

Allergic disease

- **Maternal dietary restrictions during pregnancy or lactation**: current evidence does not support these for prevention of allergic disease.
- **Breastfeeding for at least 4 months**: prevents or delays the occurrence of atopic dermatitis, cow's milk allergy and wheezing in early childhood, as compared with feeding formula milk containing intact cow's milk protein.

Autoimmune disease

- **Suppressed T-cell-mediated immune responses in pregnancy**: may suddenly reactivate post-partum. Some autoimmune diseases may improve during pregnancy but flare immediately after delivery. Systemic lupus erythematosus (SLE) is an exception, however, as it is prone to exacerbation in pregnancy or the puerperium.
- **Passive transfer of maternal antibodies**: can mediate autoimmune disease in the fetus and newborn, including SLE, Graves' disease and myasthenia gravis.
- **Antiphospholipid syndrome** (p. 977): an important cause of fetal loss, intrauterine growth restriction and pre-eclampsia.
- **HIV in pregnancy**: see p. 326.

Transplantation and graft rejection

Transplantation provides the opportunity for definitive treatment of end-stage organ disease. The major complications are graft rejection, drug toxicity and infection consequent to immunosuppression. Transplant survival continues to improve, as a result of the introduction of less toxic immunosuppressive agents and increased understanding of the processes of transplant rejection. Stem cell transplantation and its complications are discussed on page 936.

Transplant rejection

Solid organ transplantation inevitably stimulates an aggressive immune response by the recipient, unless the transplant is between monozygotic twins. The type and severity of the rejection response is determined by the genetic disparity between the donor and recipient, the immune status of the host and the nature of the tissue transplanted (Box 4.25). The most important genetic determinant

4.25 Classification of transplant rejection

Type	Time	Pathological findings	Mechanism	Treatment
Hyperacute rejection	Minutes to hours	Thrombosis, necrosis	Pre-formed antibody to donor antigens results in complement activation (type II hypersensitivity)	None – irreversible graft loss
Acute cellular rejection	5–30 days	Cellular infiltration	$CD4^+$ and $CD8^+$ T cells (type IV hypersensitivity)	Increase immunosuppression
Acute vascular rejection	5–30 days	Vasculitis	Antibody and complement activation	Increase immunosuppression
Chronic allograft failure	>30 days	Fibrosis, scarring	Immune and non-immune mechanisms	Minimise drug toxicity, control hypertension and hyperlipidaemia

is the difference between donor and recipient HLA proteins (p. 67). The extensive polymorphism of these proteins means that donor HLA antigens are almost invariably recognised as foreign by the recipient immune system, unless an active attempt has been made to minimise incompatibility.

- *Hyperacute rejection* results in rapid and irreversible destruction of the graft (Box 4.25). It is mediated by pre-existing recipient antibodies against donor HLA antigens, which arise as a result of previous exposure through transplantation, blood transfusion or pregnancy. It is very rarely seen in clinical practice, as the use of screening for anti-HLA antibodies and pre-transplant cross-matching ensures the prior identification of recipient–donor incompatibility.
- *Acute cellular rejection* is the most common form of graft rejection. It is mediated by activated T lymphocytes and results in deterioration in graft function. If allowed to progress, it may cause fever, pain and tenderness over the graft. It is usually amenable to increased immunosuppressive therapy.
- *Acute vascular rejection* is mediated by antibody formed de novo after transplantation. It is more curtailed than the hyperacute response because of the use of intercurrent immunosuppression but it is also associated with reduced graft survival. Aggressive immunosuppressive therapy is indicated and physical removal of antibody through plasmapheresis may be indicated in severe causes. Not all post-transplant anti-donor antibodies cause graft damage; their consequences are determined by specificity and ability to trigger other immune components, such as the complement cascade.
- *Chronic allograft failure*, also known as chronic rejection, is a major cause of graft loss. It is associated with proliferation of transplant vascular smooth muscle, interstitial fibrosis and scarring. The pathogenesis is poorly understood but contributing factors include immunological damage caused by subacute rejection, hypertension, hyperlipidaemia and chronic drug toxicity.

Investigations

Pre-transplantation testing

HLA typing determines an individual's HLA polymorphisms and facilitates donor–recipient matching. Potential transplant recipients are also screened for the presence of anti-HLA antibodies. The recipient is excluded from receiving a transplant that carries these alleles.

Donor–recipient cross-matching is a functional assay that directly tests whether serum from a recipient (which potentially contains anti-donor antibodies) is able to bind and/or kill donor lymphocytes. It is specific to a prospective donor–recipient pair and is done immediately prior to transplantation. A positive cross-match is a contraindication to transplantation because of the risk of hyperacute rejection.

Post-transplant biopsy: C4d staining

C4d is a fragment of the complement protein C4 (see Fig. 4.4). Deposition of C4d in graft capillaries indicates local activation of the classical complement pathway and provides evidence of antibody-mediated damage. This is useful in the early diagnosis of vascular rejection.

Complications of transplant immunosuppression

Transplant recipients require indefinite treatment with immunosuppressive agents. In general, two or more immunosuppressive drugs are used in synergistic combination in order to minimise adverse effects (Box 4.26). The major complications of long-term immunosuppression are infection and malignancy. The risk of some opportunistic infections may be minimised through the use of prophylactic medication, such as ganciclovir for cytomegalovirus prophylaxis and trimethoprim–sulfamethoxazole for *Pneumocystis* prophylaxis. Immunisation with killed vaccines is appropriate, although the immune response may be curtailed. Live vaccines should not be given.

4.26 Immunosuppressive drugs used in transplantation

Drug	Mechanism of action	Major adverse effects
Anti-proliferative agents Azathioprine, mycophenolate mofetil	Inhibit lymphocyte proliferation by blocking DNA synthesis May be directly cytotoxic at high doses	Increased susceptibility to infection Leucopenia Hepatotoxicity
Calcineurin inhibitors Ciclosporin, tacrolimus	Inhibit T-cell signalling; prevent lymphocyte activation; block cytokine transcription	Increased susceptibility to infection Hypertension Nephrotoxicity Diabetogenic (especially tacrolimus) Gingival hypertrophy, hirsutism (ciclosporin)
Glucocorticoids	Decrease phagocytosis and release of proteolytic enzymes; decrease lymphocyte activation and proliferation; decrease cytokine production; decrease antibody production	Increased susceptibility to infection Multiple other complications (p. 670)
Anti-thymocyte globulin (ATG)	Antibodies to cell surface proteins deplete or block T cells	Profound non-specific immunosuppression Increased susceptibility to infection
Basiliximab	Monoclonal antibody directed against CD25 (IL-2Rα chain), expressed on activated T cells	Increased susceptibility to infection Gastrointestinal side-effects
Belatacept	Selectively inhibits T-cell activation through blockade of CTLA4	Increased susceptibility to infection and malignancy Gastrointestinal side-effects Hypertension Anaemia/leucopenia

The increased risk of malignancy arises because T-cell suppression results in failure to control viral infections associated with malignant transformation. Virus-associated tumours include lymphoma (associated with Epstein–Barr virus), Kaposi's sarcoma (associated with human herpesvirus 8) and skin tumours (associated with human papillomavirus). Immunosuppression is also linked with a small increase in the incidence of common cancers not associated with viral infection (such as lung, breast and colon cancer), reflecting the importance of T cells in anti-cancer surveillance.

Organ donation

The major problem in transplantation is the shortage of organ donors. Cadaveric organ donors are usually previously healthy individuals who experience brainstem death (p. 211), frequently as a result of road traffic accidents or cerebrovascular events. Even if organs were obtained from all potential cadaveric donors, though, their numbers would be insufficient to meet current needs. An alternative is the use of living donors. Altruistic living donation, usually from close relatives, is widely used in renal transplantation. Living organ donation is inevitably associated with some risk to the donor and it is highly regulated to ensure appropriate appreciation of the risks involved. Because of concerns about coercion and exploitation, non-altruistic organ donation (the sale of organs) is illegal in most countries.

Tumour immunology

Surveillance by the immune system is critically important in monitoring and removing damaged and mutated cells as they arise. The ability of the immune system to kill cancer cells effectively is influenced by tumour immunogenicity and specificity. Many cancer antigens are poorly expressed and specific antigens can mutate, either spontaneously or in response to treatment, which can result in evasion of immune responses. In addition, the inhibitory pathways that are used to maintain self-tolerance and limit collateral tissue damage during antimicrobial immune responses can be co-opted by cancerous cells to evade immune destruction. Recognition and understanding of these immune checkpoint pathways has led to the development of a number of new treatments for cancers that are otherwise refractory to treatment. For example, antibodies to CTLA4, a co-stimulatory molecule normally involved in down-regulation of immune responses, have been licensed for refractory melanoma, and antibodies to PD1 (programmed cell death protein 1) are used in melanoma, non-small-cell lung cancer and renal cell carcinoma. Potential risks include the development of autoimmunity, reflecting the importance of these pathways in the control of self-tolerance.

Population health and epidemiology

The UK Faculty of Public Health defines public health as 'the science and art of promoting and protecting health and well-being, preventing ill-health and prolonging life through the organised efforts of society'. This definition recognises that there is a collective responsibility for the health of the population that requires partnerships between government, health services and others to promote and protect health and prevent disease. Population health has been defined as 'the health outcomes of a group of individuals, including the distribution of such outcomes within the group'. Medical doctors can play a role in all these efforts to improve health both through their clinical work and through their support of broader actions to improve public health.

Global burden of disease and underlying risk factors

The Global Burden of Disease (GBD) exercise was initiated by the World Bank in 1992, with first estimates appearing in 1993. Regular updated figures have been published since, together with projections of future disease burden. The aim was to produce reliable and internally consistent estimates of disease burden for all diseases and injuries, and to assess their physiological, behavioural and social risk factors, so that this information could be made available to health workers, researchers and policy-makers.

The GBD exercise adopted the metric 'disability adjusted life year' (DALY) to describe population health. This combines information about premature mortality in a population (measured as Years of Life Lost from an 'expected' life expectancy) and years of life lived with disability (Years of Life lived with Disability, which is weighted by a severity factor). The International Classification of Disease (ICD) rules, which assign one cause to each death, are followed. All estimates are presented by age and sex groups and by regions of the world. Many countries now also report their own national burden of disease data.

Life expectancy

Global life expectancy at birth increased from 61.7 years in 1980 to 71.8 years in 2015, an increase of 0.29 years per calendar year. This change is due to a substantial fall in child mortality (mainly caused by common infections), partly offset by rises in mortality from adult conditions such as diabetes and chronic kidney disease. Some areas have not shown these increases in life expectancy in men, often due to war and interpersonal violence.

Global causes of death and disability

Box 5.1 shows a ranked list of the major causes of global premature deaths in 2015. Communicable, maternal, neonatal and nutritional causes accounted for about one-quarter of deaths worldwide, down from about one-third in 1990. In contrast, deaths from non-communicable diseases are increasing in importance and now account for about two-thirds of all deaths globally, including about 13 million from ischaemic heart disease and stroke, and about 8 million from cancer. The age-standardised death rates for most diseases globally are falling. However, despite this, the numbers of deaths from many diseases are rising due to global population growth and the change in age structure of the population to older ages, and this is placing an increasing burden on health systems. For a few conditions (e.g. HIV/AIDS, diabetes mellitus and chronic kidney disease), age-standardised death rates continue to rise. Within this overall pattern, significant regional variations exist: for example, communicable, maternal, neonatal and nutritional causes still account for about two-thirds of premature mortality in sub-Saharan Africa.

GBD also provides estimates of disability from disease (Box 5.2). This has raised awareness of the importance of conditions like depression, low back and neck pain, and asthma, which account for a relatively large disease burden but relatively few deaths. This, in turn, has resulted in greater health policy priority being given to these conditions. Since the policy focus in national health systems is increasingly on keeping people healthy rather than only on reducing premature deaths, it is important to have measures of these health outcomes.

It is also essential to recognise that, although these estimates represent the best overall picture of burden of disease, they are based on imperfect data. Nevertheless, the quality of data underlying the estimates and the modelling processes are

14. Unsafe water (2)
15. Low glomerular filtration rate (21)

[1]By percentage of burden of disease they cause. [2]Rank in 1990 is shown in brackets. [3]All dietary risk factors and physical inactivity combined accounted for 10% of global burden of disease. Low physical activity was ranked 21, iron deficiency 16 and suboptimal breastfeeding 22 in 2015.

improving over time and provide an increasingly robust basis for evidence-based health planning and priority setting.

Risk factors underlying disease

Box 5.3 shows a ranked list of the main risk factors that underlay GBD in 2015 and how this ranking has changed in recent years.

Social determinants of health

Health emerges from a highly complex interaction between a person's genetic background and environmental factors (aspects of the physical, biological (microbes), built and social environments, and also distant influences such as the global ecosystem; Fig. 5.1).

The hierarchy of systems – from molecules to ecologies

Influences on health exist at many levels and extend beyond the individual to include the family, community, population and ecology. Box 5.4 shows an example of this for determinants of coronary heart disease and demonstrates the importance of considering not only the disease process in a patient but also its context. Health care is not the only determinant – and is usually not the major determinant – of health status in the population. The concept of 'global health' recognises the global dimension of health problems, whether these be emerging or pandemic infections or global economic influences on health.

The life course

The determinants of health operate over the whole lifespan. Values and behaviours acquired during childhood and adolescence have a profound influence on educational outcomes, job prospects and risk of disease. These can have a strong influence, for example, on whether a young person takes up damaging behaviour like smoking, risky sexual activity and drug misuse. Influences on health can operate even before birth. Low birth weight can lead to higher risk of hypertension and type 2 diabetes in young adults, and of cardiovascular disease in middle age. It has been suggested that under-nutrition during middle to late gestation permanently 'programs' cardiovascular and metabolic responses. This 'life course' perspective highlights the cumulative effect on health of exposures to illness, adverse environmental conditions and behaviours that damage health.

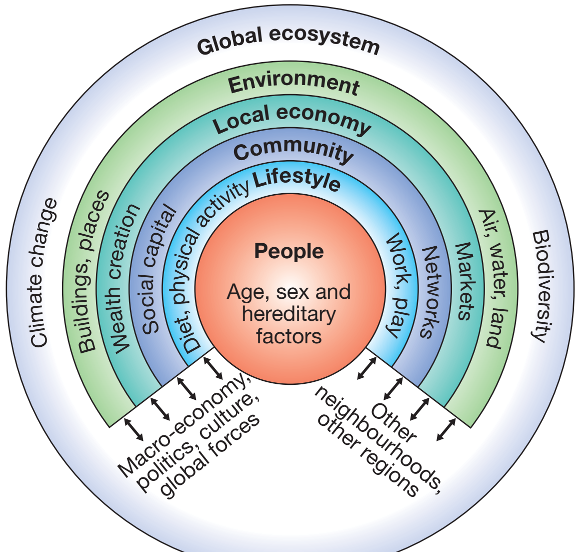

Fig. 5.1 **Hierarchy of systems that influence population health.** *Adapted from an original model by Whitehead M, Dahlgren G. What can be done about inequalities in health? Lancet 1991; 338:1059–1063.*

i 5.4 'Hierarchy of systems' applied to ischaemic heart disease

Level in the hierarchy	Example of effect
Molecular	ApoB mutation causing hypercholesterolaemia
Cellular	Macrophage foam cells accumulate in vessel wall
Tissue	Atheroma and thrombosis of coronary artery
Organ	Ischaemia and infarction of myocardium
System	Cardiac failure
Person	Limited exercise capacity, impact on employment
Family	Passive smoking, diet
Community	Shops and leisure opportunities
Population	Prevalence of obesity
Society	Policies on smoking, screening for risk factors
Ecology	Agriculture influencing fat content in diet

Preventive medicine

The complexity of interactions between physical, social and economic determinants of health means successful prevention is often difficult. Moreover, the life-course perspective illustrates that it may be necessary to intervene early in life or even before birth, to prevent important disease later. Successful prevention is likely to require many interventions across the life course and at several levels in the hierarchy of systems. The examples below illustrate this.

Alcohol

Alcohol use is an increasingly important risk factor underlying GBD (see Box 5.3). Reasons for increasing rates of alcohol-related harm vary by place and time but include the falling price of alcohol (in real terms), increased availability and cultural change fostering higher levels of consumption. Public, professional and governmental concern has now led to a minimum price being charged for a unit of alcohol, tightening of licensing regulations and curtailment of some promotional activity in many countries. However, even more aggressive public health measures will be needed to reverse the levels of harm in the population. The approach for individual patients suffering adverse effects of alcohol is described elsewhere (e.g. pp. 1184 and 880).

Smoking

Smoking is one of the top three risk factors underlying GBD (see Box 5.3). It is responsible for a substantial majority of cases of chronic obstructive pulmonary disease (COPD) and lung cancer (pp. 573 and 598), and most smokers die either from these or from ischaemic heart disease. Smoking also causes cancers of the upper respiratory and gastrointestinal tracts, pancreas, bladder and kidney, and increases risks of peripheral vascular disease, stroke and peptic ulceration. Maternal smoking is an important cause of fetal growth retardation. Moreover, there is evidence that passive ('second-hand') smoking has adverse effects on cardiovascular and respiratory health.

The decline in smoking in many high-income countries has been achieved not only by warning people of the health risks but also by increasing taxation of tobacco, banning advertising, legislating against smoking in public places and giving support for smoking cessation to maintain this decline. However, smoking rates remain high in many poorer areas and are increasing among young women. In many developing countries, tobacco companies have found new markets and rates are rising.

A complex hierarchy of systems interacts to cause smokers to initiate and maintain their habit. At the molecular and cellular levels, nicotine acts on the nervous system to create dependence and maintain the smoking habit. There are also strong influences at the personal and social level, such as young female smokers being motivated to 'stay thin' or 'look cool' and peer pressure. Other important influences include cigarette advertising, with the advertising budget of the tobacco industry being much greater than that of health services. Strategies to help individuals stop smoking (such as nicotine replacement therapy, anti-smoking advice and behavioural support) are cost-effective and form an important part of the overall strategy.

Obesity

Obesity is an increasingly important risk factor underlying GBD (see Box 5.3). The weight distribution of almost the whole population is shifting upwards: the slim are becoming less slim while the fat are getting fatter (p. 698). In the UK, this translates into a 1 kg increase in weight per adult per year (on average over the adult population). The current obesity epidemic cannot be explained simply by individual behaviour and poor choice but also requires an understanding of the obesogenic environment that encourages people to eat more and exercise less. This includes the availability of cheap and heavily marketed energy-rich foods, the increase in labour-saving devices (e.g. lifts and remote controls) and the rise in passive transport (cars as opposed to walking, cycling, or walking to public transport hubs). To combat the health impact of obesity, therefore, we not only need to help those who are already obese but also develop strategies that impact on the whole population and reverse the obesogenic environment.

Poverty and affluence

The adverse health and social consequences of poverty are well documented: high birth rates, high death rates and short life expectancy. Typically, with industrialisation, the pattern changes: low birth rates, low death rates and longer life expectancy. Instead of infections, chronic conditions such as heart disease dominate in an older population. Adverse health consequences of excessive affluence are also becoming apparent. Despite experiencing sustained economic growth for the last 50 years, people in many industrialised countries are not growing any happier and the litany of socioeconomic problems – crime, congestion, inequality – persists.

Many countries are now experiencing a 'double burden'. They have large populations still living in poverty who are suffering from problems such as diarrhoea and malnutrition, alongside affluent populations (often in cities) who suffer from chronic illness such as diabetes and heart disease.

Atmospheric pollution

Emissions from industry, power plants and motor vehicles of sulphur oxides, nitrogen oxides, respirable particles and metals are severely polluting cities and towns in Asia, Africa, Latin America and Eastern Europe. Burning of fossil and biomass fuels, with production of short-lived carbon pollutants (SLCPs – methane, ozone, black carbon and hydrofluorocarbons), contributes to increased death rates from respiratory and cardiovascular disease in vulnerable adults, such as those with established respiratory disease and the elderly, while children experience an increase in bronchitic symptoms. Developing countries also suffer high rates of respiratory disease as a result of indoor pollution caused mainly by heating and cooking using solid biomass fuels.

Climate change and global warming

Climate change is arguably the world's most important environmental health issue. A combination of habitat destruction and increased production of carbon dioxide and SLCPs, caused primarily by human activity, seems to be the main cause. The temperature of the globe is rising, and if current trends continue, warming by 4°C is predicted by 2050. The climate is being affected, putting millions of people at risk of rising sea levels, flooding, droughts and failed crops These have already claimed millions of lives during the past 20 years and have adversely affected the lives of many more. The economic costs of property damage and the impact on agriculture, food supplies and prosperity have also been substantial. Global warming will also include changes in the geographical range of some vector-borne infectious diseases. Currently, politicians cannot agree an effective framework of actions to tackle the problem, but reducing emissions of CO_2 and SLCPs is essential.

Principles of screening

Screening is the application of a test to a large number of asymptomatic people with the aim of reducing morbidity or mortality from a disease. The World Health Organisation (WHO)

has identified a set of ('Wilson and Jungner') criteria to guide health systems in deciding when it is appropriate to implement screening programmes. The essential criteria are:

- Is the disease an important public health problem?
- Is there a suitable screening test available?
- Is there a recognisable latent or early stage?
- Is there effective treatment for the disease at this stage that improves prognosis?

A suitable screening test is one that is cheap, acceptable, easy to perform and safe, and gives a valid result in terms of sensitivity and specificity (p. 4). Screening programmes should always be evaluated in trials so that robust evidence is provided in favour of their adoption. These evaluations are prone to several biases – self-selection bias, lead-time bias and length bias – and these need to be accounted for in the analysis. Examples of large-scale programmes in the UK include breast, colorectal and cervical cancer national screening programmes and a number of screening tests carried out in pregnancy and in the newborn, such as the:

- diabetic eye screening programme
- fetal anomaly screening programme
- infectious diseases in pregnancy screening programme
- newborn and infant physical examination screening programme
- newborn blood spot screening programme
- newborn hearing screening programme
- sickle-cell and thalassaemia screening programme.

These are illustrated in Figure 5.2.

Problems with screening include:

- over-diagnosis (of a disease that would not have come to attention on its own or would not have led to death)
- false reassurance
- diversion of resources from investments that could control the disease more cost-effectively.

An example of these problems is the use of prostate-specific antigen (PSA) testing as a screening test for the diagnosis of prostate cancer (p. 438).

Epidemiology

Epidemiologists study disease in free-living humans, seeking to describe patterns of health and disease and to understand how different exposures cause or prevent disease (Box 5.5).

Chronic diseases and risk factors (e.g. smoking, obesity etc.) are often described in terms of their prevalence. A prevalence is simply a proportion: e.g. the prevalence of diabetes in people aged 80 and older in developed countries is around 10%.

Events such as deaths, hospitalisations and first occurrences of a disease are described using incidence rates: e.g. if there are 100 new cases of a disease in a single year in a population of 1000, the incidence rate is 105 per 1000 person-years, not 100, because of the effect of 'person-time'. Person-time is the sum of the total 'exposed' time for the population and in this example is 950 person-years. The reason person-time is less than 1000 is that 100 people experienced the event. These 100 people are assumed to have had an event, on average, halfway through the time period, removing 100×0.5 person-years from the exposure time (as it is not possible to have a first occurrence of a disease twice). Hence, the incidence per 1000 person-years is 105, not 100.

5.5 Calculation of risk using descriptive epidemiology

Prevalence

- The ratio of the number of people with a longer-term disease or condition, at a specified time, to the number of people in the population

Incidence

- The number of events (new cases or episodes) occurring in the population at risk during a defined period of time

Attributable risk

- The difference between the risk (or incidence) of disease in exposed and non-exposed populations

Attributable fraction

- The ratio of the attributable risk to the incidence

Relative risk

- The ratio of the risk (or incidence) in the exposed population to the risk (or incidence) in the non-exposed population

A similar measure is the cumulative incidence or risk, which is the number of new cases as a proportion of the total people at risk at the beginning of the exposure time. If, in the example above, the same 1000 people were observed for a year (i.e. with no one joining or leaving the group), then the 1-year risk is 10% (100/1000). The time period should always be specified.

These rates and proportions are used to describe how diseases (and risk factors) vary according to time, person and place. Temporal variation may occur seasonally (e.g. malaria occurs in the wet season but not the dry) or as longer-term 'secular' trends (e.g. malaria may re-emerge due to drug resistance). Person comparisons include age, sex, socioeconomic status, employment, and lifestyle characteristics. Place comparisons include the local environment (e.g. urban versus rural) and international comparisons.

Understanding causes and effect

Epidemiological research complements that based on animal, cell and tissue models, the findings of which do not always translate to humans. For example, only a minority of drug discoveries from laboratory research are effective when tested in people.

However, differentiating causes from mere non-causal associations is a considerable challenge for epidemiology. This is because while laboratory researchers can directly manipulate conditions to isolate and understand causes, such approaches are impossible in free-living populations. Epidemiologists have developed a different approach, based around a number of study designs (Box 5.6). Of these, the clinical trial is closest to the laboratory experiment. An early example of a clinical trial is shown in Figure 5.3, along with 'effect measures', which are used to quantify the difference in rates and risks.

In clinical trials, patients are usually allocated randomly to treatments so that, on average, groups are similar, apart from the intervention of interest. Nevertheless, for any particular trial, especially a small trial, the laws of probability mean that differences can and do occur by chance. Poorly designed or executed trials can also limit comparability between groups. Allocation may not be truly random (e.g. because of inadequate concealment of the randomisation sequence), and there may

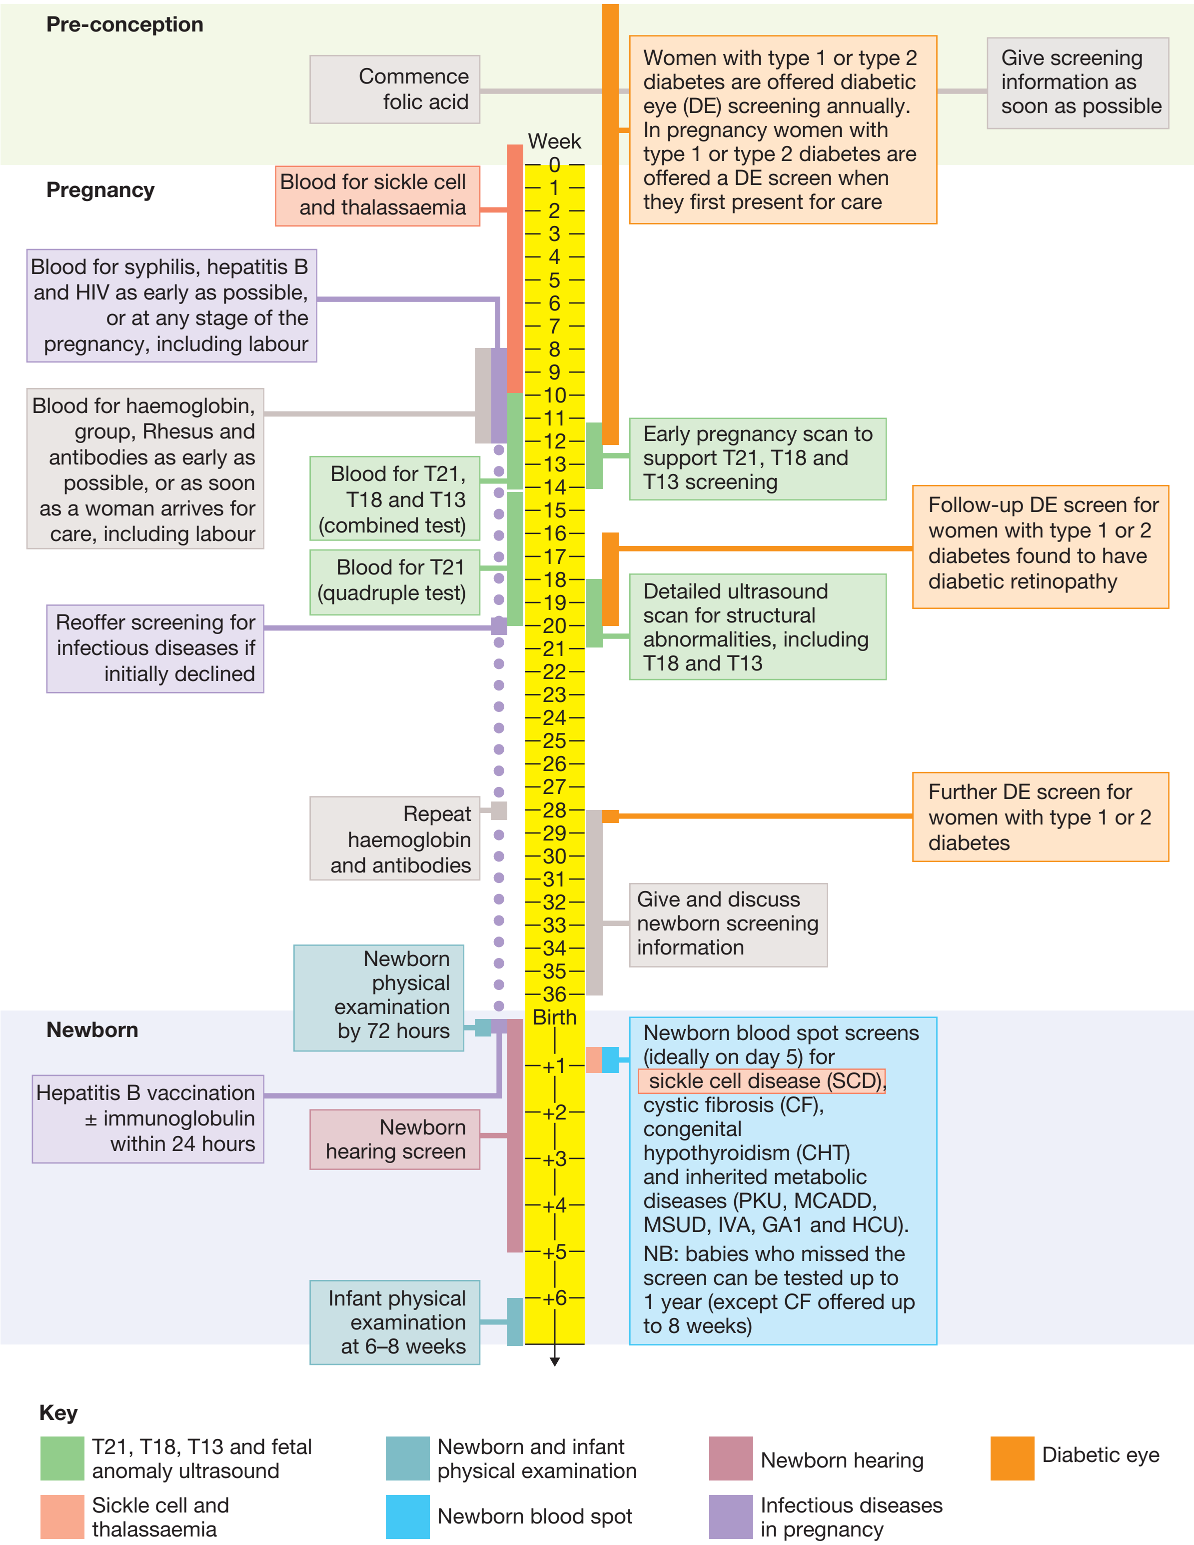

Fig. 5.2 UK NHS Pregnancy and Newborn Screening Programmes: optimum times for testing. i 5.6 Epidemiological study designs

Design	Description	Example
Clinical trial	Enrols a sample from a population and compares outcomes after randomly allocating patients to an intervention	Medical Research Council (MRC) Streptomycin Trial – demonstrated effectiveness of streptomycin in tuberculosis
Cohort	Enrols a sample from a population and compares outcomes according to exposures	Framingham Study – identified risk factors for cardiovascular disease
Case–control	Enrols cases with an outcome of interest and controls without that outcome and compares exposures between the groups	Doll R, Hill AB. Smoking and carcinoma of the lung. British Medical Journal 1950 – demonstrated that smoking caused lung cancer
Cross-sectional	Enrols a cross-section (sample) of people from the population of interest; obtains data on exposures and outcomes	World Health Organisation Demographic and Health Survey – captures risk factor data in a uniform way across many countries

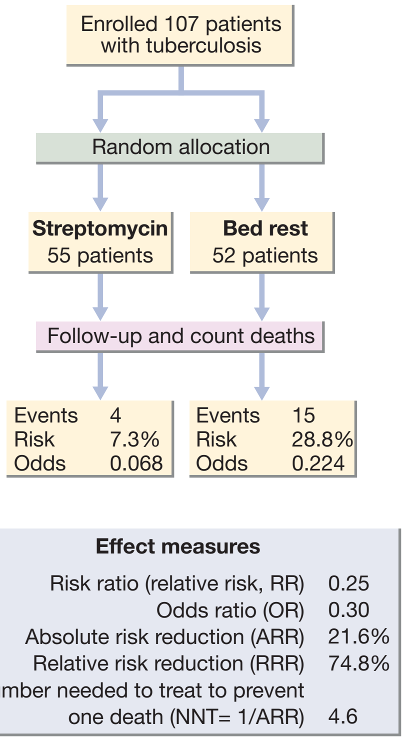

Fig. 5.3 An example of a clinical trial: streptomycin versus bed rest in tuberculosis. Both prevalences and risks are, in fact, proportions, and are therefore frequently expressed as odds. The reasons for doing so are beyond the scope of this text.

be systematic differences (biases) in the way people allocated to different groups are treated or studied.

Such biases also occur in observational epidemiological study designs, such as cohort, case–control and cross-sectional studies (Box 5.6). These designs are also much more subject to the problem of confounding than are randomised trials.

Confounding is where the relationship between an exposure and outcome of interest is confused by the presence of some other causal factor. For example, coffee consumption may be associated with lung cancer because smoking is more common among coffee-drinkers. Here, smoking is said to confound the association between coffee and lung cancer.

Despite these limitations, for most causes of diseases, randomised controlled trials are not feasible because of ethical, or more often practical, considerations. Epidemiologists therefore seek to minimise bias and confounding by good study analysis and design. They subsequently make causal inferences by balancing the probability that an observed association has been caused by chance, bias and/or confounding against the alternative probability that the relationship is causal. This weighing-up requires an understanding of the frequency and importance of different sources of bias and confounding, as well as the scientific rationale of the putative causal relationship. It was this approach, collectively and over a number of years, that settled the fact that smoking causes lung cancer and, subsequently, heart disease.

Health data/informatics

As patients pass through health and social care systems, data are recorded concerning their family background, lifestyle and disease states, which is of potential interest to health-care organisations seeking to deliver services, policy-makers concerned with improving health, scientific researchers trying to understand health, and also pharmaceutical and other commercial organisations aiming to identify markets.

There is a long tradition of maintaining health information systems. In most countries, registration of births and deaths is required by law, and in the majority, the cause of death is also recorded (Fig. 5.4). There are many challenges in ensuring such data are useful, especially for comparisons across time and place:

- A system of standard terminologies is needed, such as the WHO International Classification of Diseases (ICD-10), which provides a list of diagnostic codes attempting to cover every diagnostic entity.
- These terms must be understood to refer to the same, or at least similar, diseases in different places.
- Access to diagnostic skill and facilities is required.
- Standard protocols for assigning clinical diagnoses to ICD-10 codes are needed
- Robust quality control processes are needed to maintain some level of data completeness and accuracy.

Many countries employ similar systems for hospitalisations, to allow recovery of health-care utilisation costs or to manage and plan services. Similar data are rarely collected for community-based health care, nor are detailed data on health-care processes generally included in national data systems. Consequently, there has been considerable interest in using data from information technology systems used to deliver care, such as electronic

INTERNATIONAL FORM OF MEDICAL CERTIFICATE OF CAUSE OF DEATH

	Cause of death	Approximate interval between onset and death
I Disease or condition directly leading to death*	(a) Acute myocardial infarction I21.9	2 days
	due to (or as a consequence of)	
Antecedent causes Morbid conditions, if any, giving rise to the above cause, stating the underlying condition last	(b) Familial hypercholesterolaemia E78.0	30 years
	due to (or as a consequence of)	
	(c)	....
	due to (or as a consequence of)	
	(d)	....
II Other significant conditions contributing to the death, but not related to the disease or condition causing it	Brochiectasis J47	10 years
	....	....

**This does not mean the mode of dying, e.g. heart failure, respiratory failure. It means the disease, injury, or complication that caused death.*

Fig. 5.4 Completed death certificate. International Classification of Diseases 10 (ICD-10) codes are appended in red. *WHO ICD-10, vol. 2; 1990. Available at https://commons.m.wikimedia.org/wiki/File:International_form_of_medical_certificate_of_cause_of_death.png.*

patient records, drug-dispensing databases, radiological software and clinical laboratory information systems.

Data from such systems are, of course, much less structured than those obtained from vital registrations. Moreover, the completeness of such data depends greatly on local patterns of health-care utilisation, as well as how clinicians and others use information technology systems within different settings. As such, deriving useful, unbiased information from such data is a considerable challenge.

Much of the discipline of health informatics is concerned with addressing this challenge. One approach has been to develop comprehensive standard classification systems such as SNOMED-CT, 'a standardised, multilingual vocabulary of terms relating to the care of the individual', which has been designed for electronic health-care records.

An alternative has been to use statistical methods such as natural language processing to derive information automatically from free text (such as culling diagnoses from radiological reports), or to employ 'machine learning', in which software algorithms are applied to data in order to derive useful insights. Such approaches are suited to large, messy data where the costs of systematisation would be prohibitive. It is likely that such innovations will, over the coming years, provide useful information to complement that obtained from more traditional health information systems.

Principles of infectious disease

'Infection' in its strict sense describes the situation where microorganisms or other infectious agents become established in the host organism's cells or tissues, replicate, cause harm and induce a host response. If a microorganism survives and replicates on a mucosal surface without causing harm or illness, the host is said to be 'colonised' by that organism. If a microorganism survives and lies dormant after invading host cells or tissues, infection is said to be 'latent'. When the infectious agent, or the host response to it, is sufficient to cause illness or harm, then the process is termed an 'infectious disease'. Most pathogens (infectious agents that can cause disease) are microorganisms but some are multicellular organisms. The manifestations of disease may aid pathogen dissemination (e.g. diarrhoea).

The term 'infection' is often used interchangeably with 'infectious disease' but not all infections are 'infectious', i.e. transmissible from person to person. Infectious diseases transmitted between hosts are called communicable diseases, whereas those caused by organisms that are already colonising the host are described as endogenous. The distinction is blurred in some situations, including health care-associated infections such as meticillin-resistant *Staphylococcus aureus* (MRSA) or *Clostridium difficile* infection (CDI), in which colonisation precedes infection but the colonising bacteria may have been recently transmitted between patients. The chain of infection (Fig. 6.1) describes six essential elements for communicable disease transmission.

Despite dramatic advances in hygiene, immunisation and antimicrobial therapy, infectious agents still cause a massive burden of disease worldwide. Key challenges remain in tackling infection in resource-poor countries. Microorganisms are continually mutating and evolving; the emergence of new infectious agents and antimicrobial-resistant microorganisms is therefore inevitable. This chapter describes the biological and epidemiological principles of infectious diseases and the general approach to their prevention, diagnosis and treatment. Specific infectious diseases are described in Chapters 11–13 and many of the organ-based chapters.

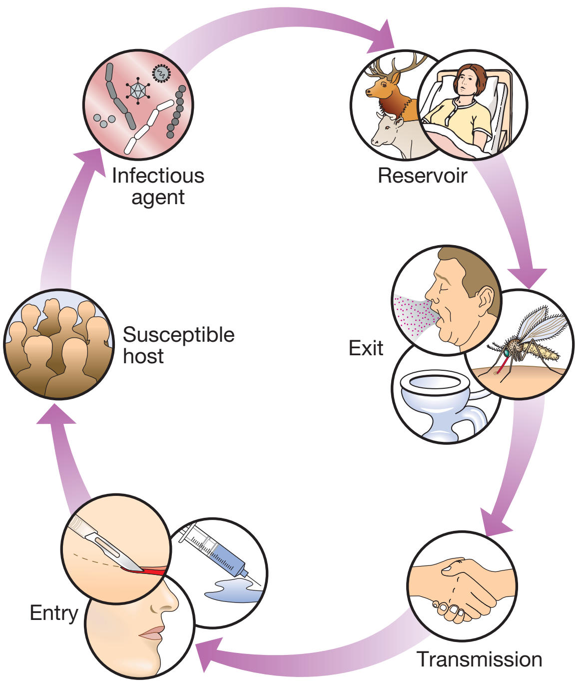

Fig. 6.1 Chain of infection. The infectious agent is the organism that causes the disease. The reservoir is the place where the population of an infectious agent is maintained. The portal of exit is the point from which the infectious agent leaves the reservoir. Transmission is the process by which the infectious agent is transferred from the reservoir to the human host, either directly or via a vector or fomite. The portal of entry is the body site that is first accessed by the infectious agent. Finally, in order for disease to ensue, the person to whom the infectious agent is transmitted must be a susceptible host.

Infectious agents

The concept of an infectious agent was established by Robert Koch in the 19th century (Box 6.1). Although fulfilment of 'Koch's postulates' became the standard for the definition of an infectious agent, they do not apply to uncultivable organisms (e.g. *Mycobacterium leprae*, *Tropheryma whipplei*) or members of the normal human flora (e.g. *Escherichia coli*, *Candida* spp.). The following groups of infectious agents are now recognised.

Viruses

Viruses are incapable of independent replication. Instead, they subvert host cellular processes to ensure synthesis of their nucleic acids and proteins. Viruses' genetic material (the genome) consists of single- or double-stranded DNA or RNA. Retroviruses transcribe their RNA into DNA in the host cell by reverse transcription. An antigenically unique protein coat (capsid) encloses the genome, and together these form the nucleocapsid. In many viruses, the nucleocapsid is packaged within a lipid envelope. Enveloped viruses are less able to survive in the environment and are spread by respiratory, sexual or blood-borne routes, including arthropod-based transmission. Non-enveloped viruses survive better in the environment and are predominantly transmitted by faecal–oral or, less often, respiratory routes. A generic virus life cycle is shown in Figure 6.2. A virus that infects a bacterium is a bacteriophage (phage).

Prokaryotes: bacteria (including mycobacteria and actinomycetes)

Prokaryotic cells are capable of synthesising their own proteins and nucleic acids, and are able to reproduce autonomously, although they lack a nucleus. The bacterial cell membrane is bounded by a peptidoglycan cell wall, which is thick (20–80 nm) in Gram-positive organisms and thin (5–10 nm) in Gram-negative ones. The Gram-negative cell wall is surrounded by an outer membrane containing lipopolysaccharide. Genetic information is contained within a chromosome but bacteria may also contain rings of extra-chromosomal DNA, known as plasmids, which can be transferred between organisms, without cells having to divide. Bacteria may be embedded in a polysaccharide capsule,

i 6.1 Definition of an infectious agent – Koch's postulates

1. The same organism must be present in every case of the disease
2. The organism must be isolated from the diseased host and grown in pure culture
3. The isolate must cause the disease, when inoculated into a healthy, susceptible animal
4. The organism must be re-isolated from the inoculated, diseased animal

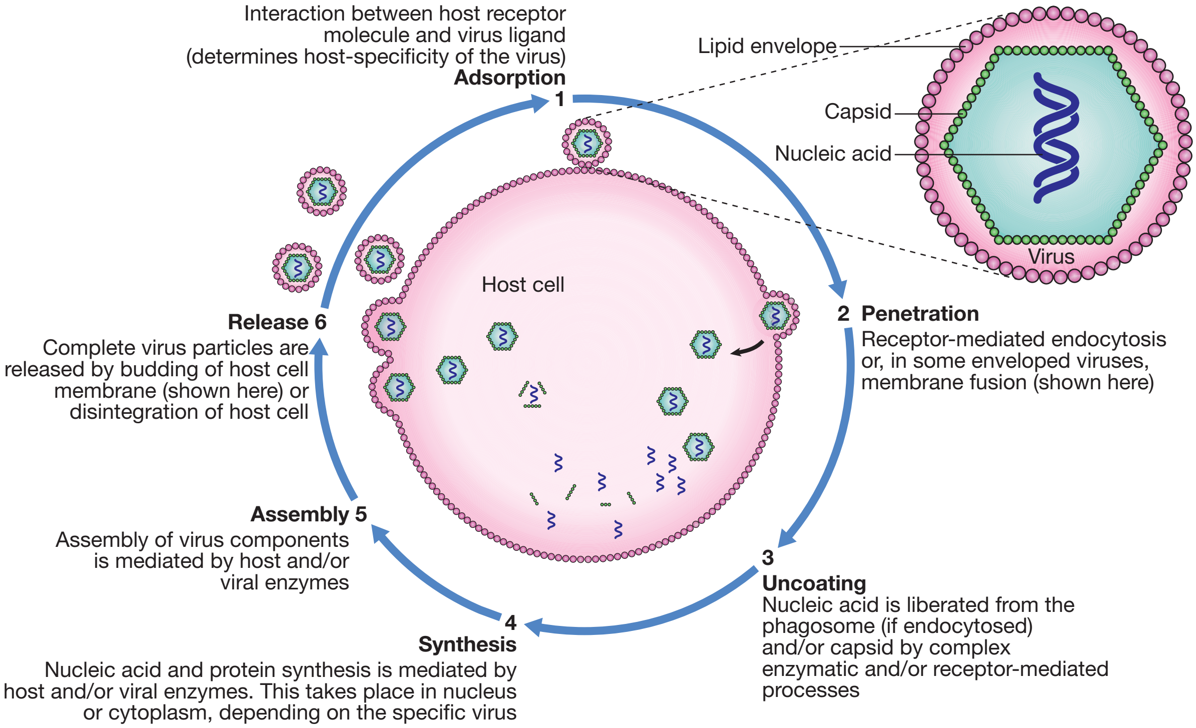

Fig. 6.2 A generic virus life cycle. Life cycle components common to most viruses are host cell attachment and penetration, virus uncoating, nucleic acid and protein synthesis, virus assembly and release. Virus release is achieved either by budding, as illustrated, or by lysis of the cell membrane. Life cycles vary between viruses.

i 6.2 How bacteria are identified

Gram stain reaction (see Fig. 6.3)	**Motility**
• Gram-positive (thick peptidoglycan layer), Gram-negative (thin peptidoglycan) or unstainable	• Motile or non-motile
Microscopic morphology	**Antibiotic susceptibility**
• Cocci (round cells) or bacilli (elongated cells) • Presence or absence of capsule	• Identifies organisms with invariable susceptibility (e.g. to optochin in *Streptococcus pneumoniae* or metronidazole in obligate anaerobes)
Cell association	**Matrix-assisted laser desorption/ionisation time-of-flight mass spectrometry (MALDI-TOF-MS)**
• Association in clusters, chains or pairs	• A rapid technique that identifies bacteria and some fungi from their specific molecular composition
Colonial characteristics	**Sequencing bacterial 16s ribosomal RNA gene**
• Colony size, shape or colour • Effect on culture media (e.g. β-haemolysis of blood agar in haemolytic streptococci; see Fig. 6.4)	• A highly specific test for identification of organisms in pure culture and in samples from normally sterile sites
Atmospheric requirements	**Whole-genome sequencing**
• Strictly aerobic (requires O_2), strictly anaerobic (requires absence of O_2), facultatively aerobic (grows with or without O_2) or micro-aerophilic (requires reduced O_2)	• Although not yet in routine use, whole-genome sequencing (WGS) offers the potential to provide rapid and simultaneous identification, sensitivity testing and typing of organisms from pure culture and/or directly from clinical samples. As such, WGS is likely to replace many of the technologies described above over the next few years (p. 58)
Biochemical reactions	
• Expression of enzymes (oxidase, catalase, coagulase) • Ability to ferment or hydrolyse various biochemical substrates	

and motile bacteria are equipped with flagella. Although many prokaryotes are capable of independent existence, some (e.g. *Chlamydia trachomatis*, *Coxiella burnetii*) are obligate intracellular organisms. Bacteria that can grow in artificial culture media are classified and identified using a range of characteristics (Box 6.2); examples are shown in Figures 6.3 and 6.4.

Eukaryotes: fungi, protozoa and helminths

Eukaryotic cells contain membrane-bound organelles, including nuclei, mitochondria and Golgi apparatus. Pathogenic eukaryotes are unicellular (e.g. fungi, protozoa) or complex multicellular organisms (e.g. nematodes, trematodes and cestodes, p. 288).

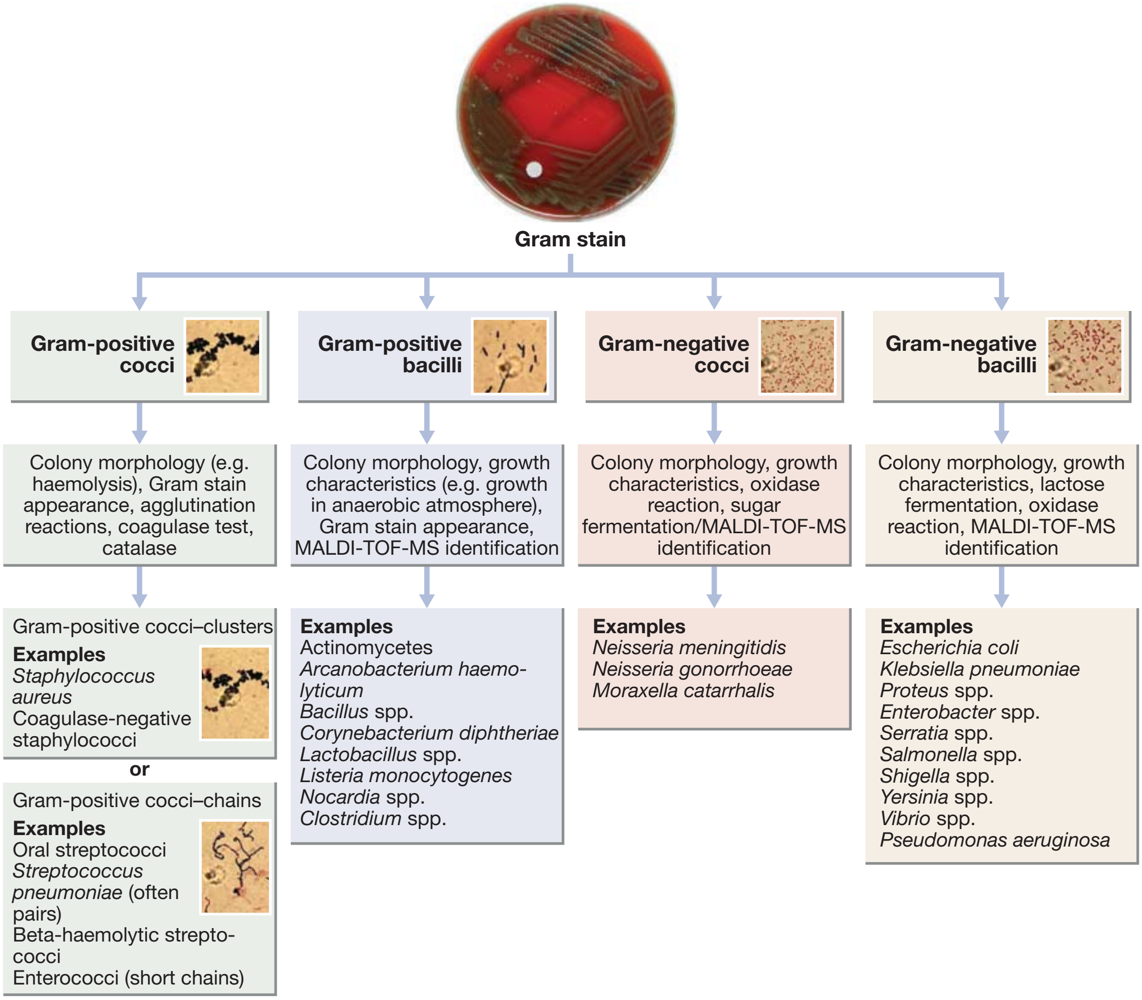

Fig. 6.3 Flow chart for bacterial identification, including Gram film appearances on light microscopy (×100). (MALDI-TOF-MS = matrix-assisted laser desorption/ionisation time-of-flight mass spectroscopy)

Fig. 6.4 Beta-haemolytic streptococci (A) and alpha-haemolytic streptococci (B) spread on each half of a blood agar plate (backlit). This image is half life size. ×0.5. Beta-haemolysis renders the agar transparent around the colonies (A) and alpha-haemolysis imparts a green tinge to the agar (B).

Fungi exist as either moulds (filamentous fungi) or yeasts. Dimorphic fungi exist in either form, depending on environmental conditions (see Fig. 11.59, p. 300). The fungal plasma membrane differs from the human cell membrane in that it contains the sterol, ergosterol. Fungi have a cell wall made up of polysaccharides, chitin and mannoproteins. In most fungi, the main structural component of the cell wall is β-1,3-D-glucan, a glucose polymer. These differences from mammalian cells are important because they offer useful therapeutic targets.

Protozoa and helminths are often referred to as parasites. Many parasites have complex multi-stage life cycles, which involve animal and/or plant hosts in addition to humans.

Prions

Although prions are transmissible and have some of the characteristics of infectious agents, they are not microorganisms and are not diagnosed in microbiology laboratories. Prions are covered on page 250.

Normal microbial flora

The human body is colonised by large numbers of microorganisms (collectively termed the human microbiota). These colonising

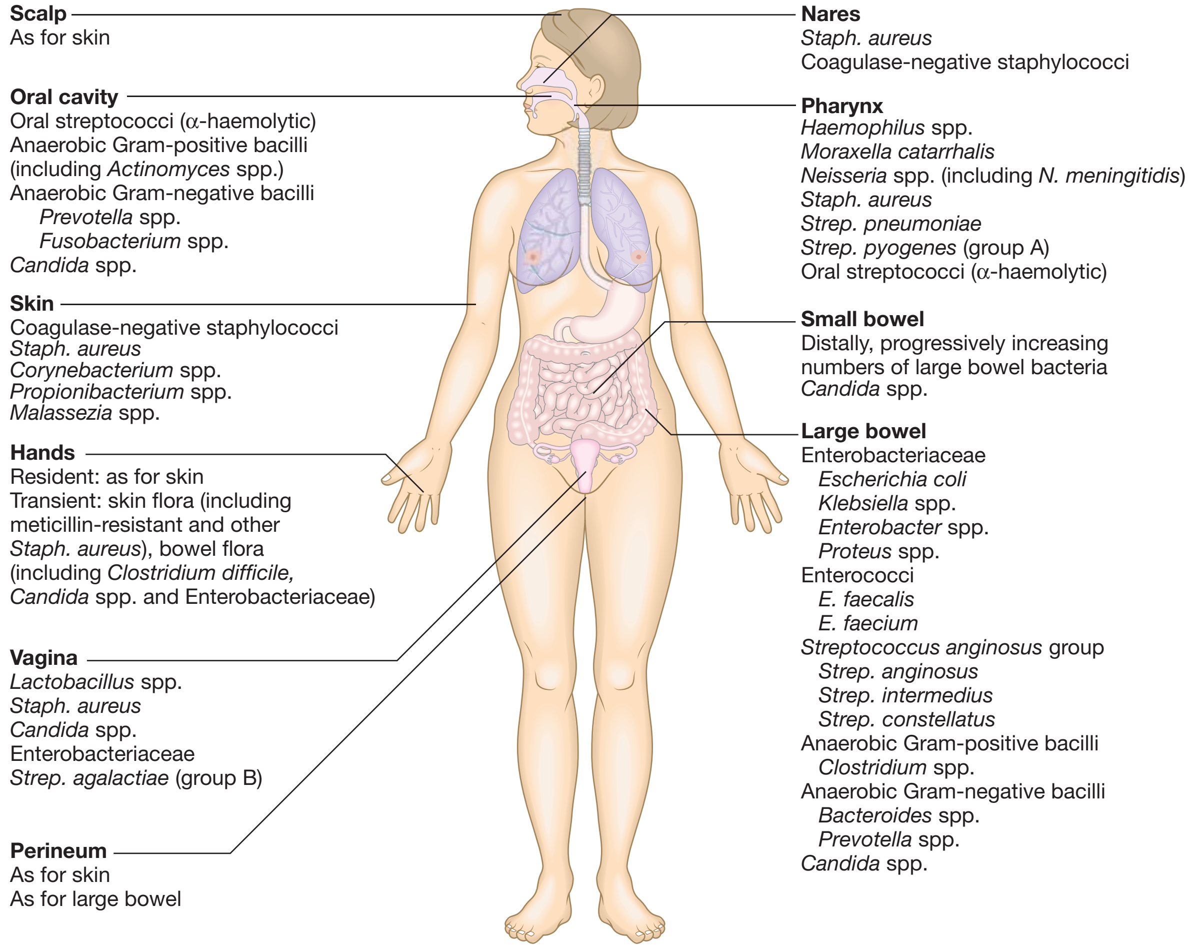

Fig. 6.5 **Human non-sterile sites and normal flora in health.**

bacteria, also referred to as the 'normal flora', are able to survive and replicate on skin and mucosal surfaces. The gastrointestinal tract and the mouth are the two most heavily colonised sites in the body and their microbiota are distinct, in both composition and function. Knowledge of non-sterile body sites and their normal flora is required to inform microbiological sampling strategies and interpret culture results (Fig. 6.5).

The microbiome is the total burden of microorganisms, their genes and their environmental interactions, and is now recognised to have a profound influence over human health and disease. Maintenance of the normal flora is beneficial to health. For example, lower gastrointestinal tract bacteria synthesise and excrete vitamins (e.g. vitamins K and B_{12}); colonisation with normal flora confers 'colonisation resistance' to infection with pathogenic organisms by altering the local environment (e.g. lowering pH), producing antibacterial agents (e.g. bacteriocins (small antimicrobial peptides/proteins), fatty acids and metabolic waste products), and inducing host antibodies that cross-react with pathogenic organisms.

Conversely, normally sterile body sites must be kept sterile. The mucociliary escalator transports environmental material deposited in the respiratory tract to the nasopharynx. The urethral sphincter prevents flow from the non-sterile urethra to the sterile bladder. Physical barriers, including the skin, lining of the gastrointestinal tract and other mucous membranes, maintain sterility of the submucosal tissues, blood stream and peritoneal and pleural cavities, for example.

The normal flora contribute to endogenous disease mainly by translocation to a sterile site but excessive growth at the 'normal' site (overgrowth) can also cause disease. Overgrowth is exemplified by dental caries, vaginal thrush and 'blind loop' syndrome (p. 808). Translocation results from spread along a surface or penetration though a colonised surface, e.g. urinary tract infection caused by perineal/enteric flora, and surgical site infections, particularly of prosthetic materials, caused by skin flora such as staphylococci. Normal flora also contribute to disease by cross-infection, in which organisms that are colonising one individual cause disease when transferred to another, more susceptible, individual.

The importance of limiting perturbations of the microbiota by antimicrobial therapy is increasingly recognised. Probiotics are microbes or mixtures of microbes that are given to a patient to prevent or treat infection and are intended to restore a beneficial profile of microbiota. Although probiotics have been used in a number of settings, whether they have demonstrable clinical benefits remains a subject of debate.

Host–pathogen interactions

'Pathogenicity' is the capability of an organism to cause disease and 'virulence' is the extent to which a pathogen is able to cause disease. Pathogens produce proteins and other factors, termed virulence factors, which contribute to disease.

- *Primary pathogens* cause disease in a proportion of individuals to whom they are exposed, regardless of the host's immunological status.
- *Opportunistic pathogens* cause disease only in individuals whose host defences are compromised, e.g. by an intravascular catheter, or when the immune system is compromised, by genetic susceptibility or immunosuppressive therapy.

Characteristics of successful pathogens

Successful pathogens have a number of attributes. They compete with host cells and colonising flora by various methods, including sequestration of nutrients and production of bacteriocins. Motility enables pathogens to reach their site of infection, often sterile sites that colonising bacteria do not reach, such as the distal airway. Many microorganisms, including viruses, use 'adhesins' to attach to host cells initially. Some pathogens can invade through tissues. Many bacterial and fungal infections form 'biofilms'. After initial adhesion to a host surface, bacteria multiply in biofilms to form complex three-dimensional structures surrounded by a matrix of host and bacterial products that afford protection to the colony and limit the effectiveness of antimicrobials. Biofilms forming on man-made medical devices such as vascular catheters or grafts can be particularly difficult to treat.

Pathogens may produce toxins, microbial molecules that cause adverse effects on host cells, either at the site of infection, or remotely following carriage through the blood stream. Endotoxin is the lipid component of Gram-negative bacterial outer membrane lipopolysaccharide. It is released when bacterial cells are damaged and has generalised inflammatory effects. Exotoxins are proteins released by living bacteria, which often have specific effects on target organs (Box 6.3).

Intracellular pathogens, including viruses, bacteria (e.g. *Salmonella* spp., *Listeria monocytogenes* and *Mycobacterium tuberculosis*), parasites (e.g. *Leishmania* spp.) and fungi (e.g. *Histoplasma capsulatum*), are able to survive in intracellular environments, including after phagocytosis by macrophages. Pathogenic bacteria express different genes, depending on environmental stress (pH, iron starvation, O_2 starvation etc.) and anatomical location.

Genetic diversity enhances the pathogenic capacity of bacteria. Some virulence factor genes are found on plasmids or in phages and are exchanged between different strains or species. The ability to acquire genes from the gene pool of all strains of the species (the 'bacterial supragenome') increases diversity and the potential for pathogenicity. Viruses exploit their rapid reproduction and potential to exchange nucleic acid with host cells to enhance diversity. Once a strain acquires a particularly effective combination of virulence genes, it may become an epidemic strain, accounting for a large subset of infections in a particular region. This phenomenon accounts for influenza pandemics (see Box 6.10).

i 6.3 Exotoxin-mediated bacterial diseases

Disease	Organism
Antibiotic-associated diarrhoea/ pseudomembranous colitis	*Clostridium difficile* (p. 230)
Botulism	*Clostridium botulinum* (p. 1126)
Cholera	*Vibrio cholerae* (p. 264)
Diphtheria	*Corynebacterium diphtheriae* (p. 265)
Haemolytic uraemic syndrome	Enterohaemorrhagic *Escherichia coli* (*E. coli* 0157 and other strains) (p. 263)
Necrotising pneumonia	*Staphylococcus aureus* (p. 250)
Tetanus	*Clostridium tetani* (p. 1125)
Toxic shock syndrome	*Staphylococcus aureus* (p. 252) *Streptococcus pyogenes* (p. 253)

The host response

Innate and adaptive immune and inflammatory responses, which humans use to control the normal flora and respond to pathogens, are reviewed in Chapter 4.

Pathogenesis of infectious disease

The harmful manifestations of infection are determined by a combination of the virulence of the organism and the host response to infection. Despite the obvious benefits of an intact host response, an excessive response is undesirable. Cytokines and antimicrobial factors contribute to tissue injury at the site of infection, and an excessive inflammatory response may lead to hypotension and organ dysfunction (p. 196). The contribution of the immune response to disease manifestations is exemplified by the immune reconstitution inflammatory syndrome (IRIS). This is seen, for example, in human immunodeficiency virus (HIV) infection, post-transplantation neutropenia or tuberculosis (which causes suppression of T-cell function): there is a paradoxical worsening of the clinical condition as the immune dysfunction is corrected, caused by an exuberant but dysregulated inflammatory response.

The febrile response

Thermoregulation is altered in infectious disease, which may cause both hyperthermia (fever) and hypothermia. Fever is mediated mainly by 'pyrogenic cytokines' (e.g. interleukins IL-1 and IL-6, and tumour necrosis factor alpha (TNF-α)), which are released in response to various immunological stimuli including activation of pattern recognition receptors (PRRs) by microbial pyrogens (e.g. lipopolysaccharide) and factors released by injured cells. Their ultimate effect is to induce the synthesis of prostaglandin E_2, which binds to specific receptors in the preoptic nucleus of the hypothalamus (thermoregulatory centre), causing the core temperature to rise.

Rigors are a clinical symptom (or sign if they are witnessed) characterised by feeling very cold ('chills') and uncontrollable shivering, usually followed by fever and sweating. Rigors occur when the thermoregulatory centre attempts to correct a core temperature to a higher level by stimulating skeletal muscle activity and shaking.

There are data to support the hypothesis that raised body temperature interferes with the replication and/or virulence of pathogens. The mechanisms and possible protective role of infection-driven hypothermia, however, are poorly understood, and require further study.

Investigation of infection

The aims of investigating a patient with suspected infection are to confirm the presence of infection, identify the specific pathogen(s) and identify its susceptibility to specific antimicrobial agents in order to optimise therapy. The presence of infection may be suggested by identifying proteins that are produced in response to pathogens as part of the innate immune and acute phase responses (p. 70). Pathogens may be detected directly (e.g. by culturing a normally sterile body site) or their presence may be inferred by identifying the host response to the organism, ('indirect detection', Box 6.4). Careful sampling increases the likelihood of diagnosis (Box 6.5). Culture results must be interpreted in the context of the normal flora at the sampled site (see Fig. 6.5). The extent to which a microbiological test result supports or excludes a particular diagnosis depends on its statistical performance (e.g. sensitivity, specificity, positive and negative predictive value, p. 4). Sensitivity and specificity vary according to the time between infection and testing, and positive and negative predictive values depend on the prevalence of the condition in the test population. The complexity of test interpretation is illustrated in Figure 6.8 below, which shows the 'windows of opportunity' afforded by various testing methods. Given this complexity, effective communication between the clinician and the microbiologist is vital to ensure accurate test interpretation.

Direct detection of pathogens

Some direct detection methods provide rapid results and enable detection of organisms that cannot be grown easily on artificial culture media, such as *Chlamydia* spp.; they can also provide information on antimicrobial sensitivity, e.g. *Mycobacterium tuberculosis*.

Detection of whole organisms

Whole organisms are detected by examination of biological fluids or tissue using a microscope.

- *Bright field microscopy* (in which the test sample is interposed between the light source and the objective lens) uses stains to enhance visual contrast between the organism and its background. Examples include Gram staining of bacteria and Ziehl–Neelsen or auramine staining of acid- and alcohol-fast bacilli (AAFB) in tuberculosis (the latter requires an ultraviolet light source). In histopathological examination of tissue samples, multiple stains are used to demonstrate not only the presence of microorganisms but also features of disease pathology.
- *Dark field microscopy* (in which light is scattered to make organisms appear bright on a dark background) is used, for example, to examine genital chancre fluid in suspected syphilis.
- *Electron microscopy* may be used to examine stool and vesicle fluid to detect enteric and herpesviruses, respectively, but its use has largely been supplanted by nucleic acid detection (see below).
- *Flow cytometry* can be used to analyse liquid samples (e.g. urine) for the presence of particles based on properties such as size, impedance and light scatter. This technique can detect bacteria but may misidentify other particles as bacteria too.

6.4 Tests used to diagnose infection

Non-specific markers of inflammation/infection
• e.g. White cell count in blood sample (WCC), plasma C-reactive protein (CRP), procalcitonin, serum lactate, cell counts in urine or cerebrospinal fluid (CSF), CSF protein and glucose
Direct detection of organisms or organism components
• Microscopy • Detection of organism components (e.g. antigen, toxin) • Nucleic acid amplification (e.g. polymerase chain reaction)
Culture of organisms
• ± Antimicrobial susceptibility testing
Tests of the host's specific immune response
• Antibody detection • Interferon-gamma release assays (IGRA)

6.5 How to provide samples for microbiological sampling

Communicate with the laboratory
• Discuss samples that require processing urgently or that may contain hazardous or unusual pathogens with laboratory staff *before* collection • Communication is key to optimising microbiological diagnosis. If there is doubt about any aspect of sampling, it is far better to discuss it with laboratory staff beforehand than to risk diagnostic delay by inappropriate sampling or sample handling
Take samples based on a clinical diagnosis
• Sampling in the absence of clinical evidence of infection is rarely appropriate (e.g. collecting urine, or sputum for culture)
Use the correct container
• Certain tests (e.g. nucleic acid and antigen detection tests) require proprietary sample collection equipment
Follow sample collection procedures
• Failure to follow sample collection instructions precisely can result in false-positive (e.g. contamination of blood culture samples) or false-negative (e.g. collection of insufficient blood for culture) results
Label sample and request form correctly
• Label sample containers and request forms according to local policies, with demographic identifiers, specimen type and time/date collected • Include clinical details on request forms • Identify samples carrying a high risk of infection (e.g. blood liable to contain a blood-borne virus) with a hazard label
Use appropriate packaging
• Close sample containers tightly and package securely (usually in sealed plastic bags) • Attach request forms to samples but not in the same compartment (to avoid contamination, should leakage occur)
Manage storage and transport
• Transport samples to the microbiology laboratory quickly • If pre-transport storage is required, conditions (e.g. refrigeration, incubation, storage at room temperature) vary with sample type • Notify the receiving laboratory prior to arrival of unusual or urgent samples, to ensure timely processing

Detection of components of organisms

Components of microorganisms detected for diagnostic purposes include nucleic acids, cell wall molecules, toxins and other antigens. Commonly used examples include *Legionella pneumophila* serogroup 1 antigen in urine and cryptococcal polysaccharide antigen in cerebrospinal fluid (CSF). Most antigen detection methods are based on in vitro binding of specific antigen/antibody and are described below. Other methods may be used, such as tissue culture cytotoxicity assay for *C. difficile* toxin. In toxin-mediated disease, detection of toxin may be of greater relevance than identification of the organism itself (e.g. stool *C. difficile* toxin).

Nucleic acid amplification tests

In a nucleic acid amplification test (NAAT), specific sequences of microbial DNA and RNA are identified using a nucleic acid primer that is amplified exponentially by enzymes to generate multiple copies of a target nucleotide sequence. The most commonly used amplification method is the polymerase chain reaction (PCR; see Fig. 3.11, p. 53). Reverse transcription (RT) PCR is used to detect RNA from RNA viruses (e.g. hepatitis C virus and HIV-1). The use of fluorescent labels in the reaction enables 'real-time' detection of amplified DNA; quantification is based on the principle that the time taken to reach the detection threshold is proportional to the initial number of copies of the target nucleic acid sequence. In multiplex PCR, multiple primer pairs are used to enable detection of several different organisms at once.

Determination of nucleotide sequences in a target gene(s) can be used to assign microorganisms to specific strains, which may be relevant to treatment and/or prognosis (e.g. in hepatitis C infection, p. 877). Genes that are relevant to pathogenicity (such as toxin genes) or antimicrobial resistance can also be detected; for example, the *mecA* gene is used to screen for MRSA.

NAATs are the most sensitive direct detection methods and are also relatively rapid. They are used widely in virology, where the possibility of false-positive results from colonising or contaminating organisms is remote, and are applied to blood, respiratory samples, stool and urine. In bacteriology, PCR is used to examine CSF, blood, tissue and genital samples, and multiplex PCR is being developed for use in faeces. PCR is particularly helpful for microorganisms that cannot be readily cultured, e.g. *Tropheryma whipplei*, and is being used increasingly in mycology and parasitology.

Culture

Microorganisms may be both detected and further characterised by culture from clinical samples (e.g. tissue, swabs and body fluids).

- *Ex vivo culture* (tissue or cell culture) was widely used in the isolation of viruses but has been largely supplanted by NAAT.
- *In vitro culture* (in artificial culture media) of bacteria and fungi is used to confirm the presence of pathogens, allow identification, test antimicrobial susceptibility and subtype the organism for epidemiological purposes.

Culture has its limitations: results are not immediate, even for organisms that are easy to grow, and negative cultures rarely exclude infection. Organisms such as *Mycobacterium tuberculosis* are slow-growing, typically taking at least 2 weeks, even in rapid-culture systems. Certain organisms, such as *Mycobacterium leprae* and *Tropheryma whipplei*, cannot be cultivated on artificial media, and others (e.g. *Chlamydia* spp. and viruses) grow only in culture systems, which are slow and labour-intensive.

Blood culture

The terms 'bacteraemia' and 'fungaemia' describe the presence of bacteria and fungi in the blood. 'Blood-stream infection' (p. 225) is the association of bacteraemia/fungaemia with clinical evidence of infection. The presence of bacteraemia/fungaemia can be determined by inoculating a liquid culture medium with freshly drawn blood, which is then incubated in a system that monitors it constantly for growth of microorganisms (e.g. by detecting products of microbial respiration using fluorescence; Fig. 6.6). If growth is detected, organisms are identified and sensitivity testing is performed. Traditionally, identification has been achieved by Gram stain appearance and biochemical reactions. However, matrix-assisted laser desorption/ionisation time-of-flight mass spectroscopy (MALDI-TOF-MS; see Box 6.2) is being used increasingly to identify organisms. MALDI-TOF-MS produces a profile of proteins of different sizes from the target microorganism and uses databases of such profiles to identify the organism (Fig. 6.7). It is rapid and accurate. Taking multiple blood samples for culture at different times allows differentiation of transient (one or two positive samples) and persistent (majority are positive) bacteraemia. This can be clinically important in the identification of the source of infection (p. 530).

Indirect detection of pathogens

Tests may be used to detect the host's immune (antibody) response to a specific microorganism, and can enable the diagnosis of infection with organisms that are difficult to detect by other methods or are no longer present in the host. The term 'serology' describes tests carried out on serum and includes both antigen (direct) and antibody (indirect) detection.

Antibody detection

Organism-specific antibody detection is applied mainly to blood (Fig. 6.8). Results are typically expressed as titres: that is, the reciprocal of the highest dilution of the serum at which antibody is detectable (for example, detection at serum dilution of 1 : 64 gives a titre of 64). 'Seroconversion' is defined as either a change from negative to positive detection or a fourfold rise in titre between acute and convalescent serum samples. An acute sample is usually taken during the first week of disease and the convalescent sample 2–4 weeks later. Earlier diagnosis can be achieved by detection of immunoglobulin M (IgM) antibodies, which are produced early in infection (p. 68). A limitation of these tests is that antibody production requires a fully functional host immune system, so there may be false-negative results in immunocompromised patients. Also, other than in chronic infections and with IgM detection, antibody tests usually provide a retrospective diagnosis.

Antibody detection methods are described below (antigen detection methods are also described here as they share similar methodology).

Enzyme-linked immunosorbent assay

The principles of the enzyme-linked immunosorbent assay (ELISA, EIA) are illustrated in Figure 6.9. These assays rely on linking

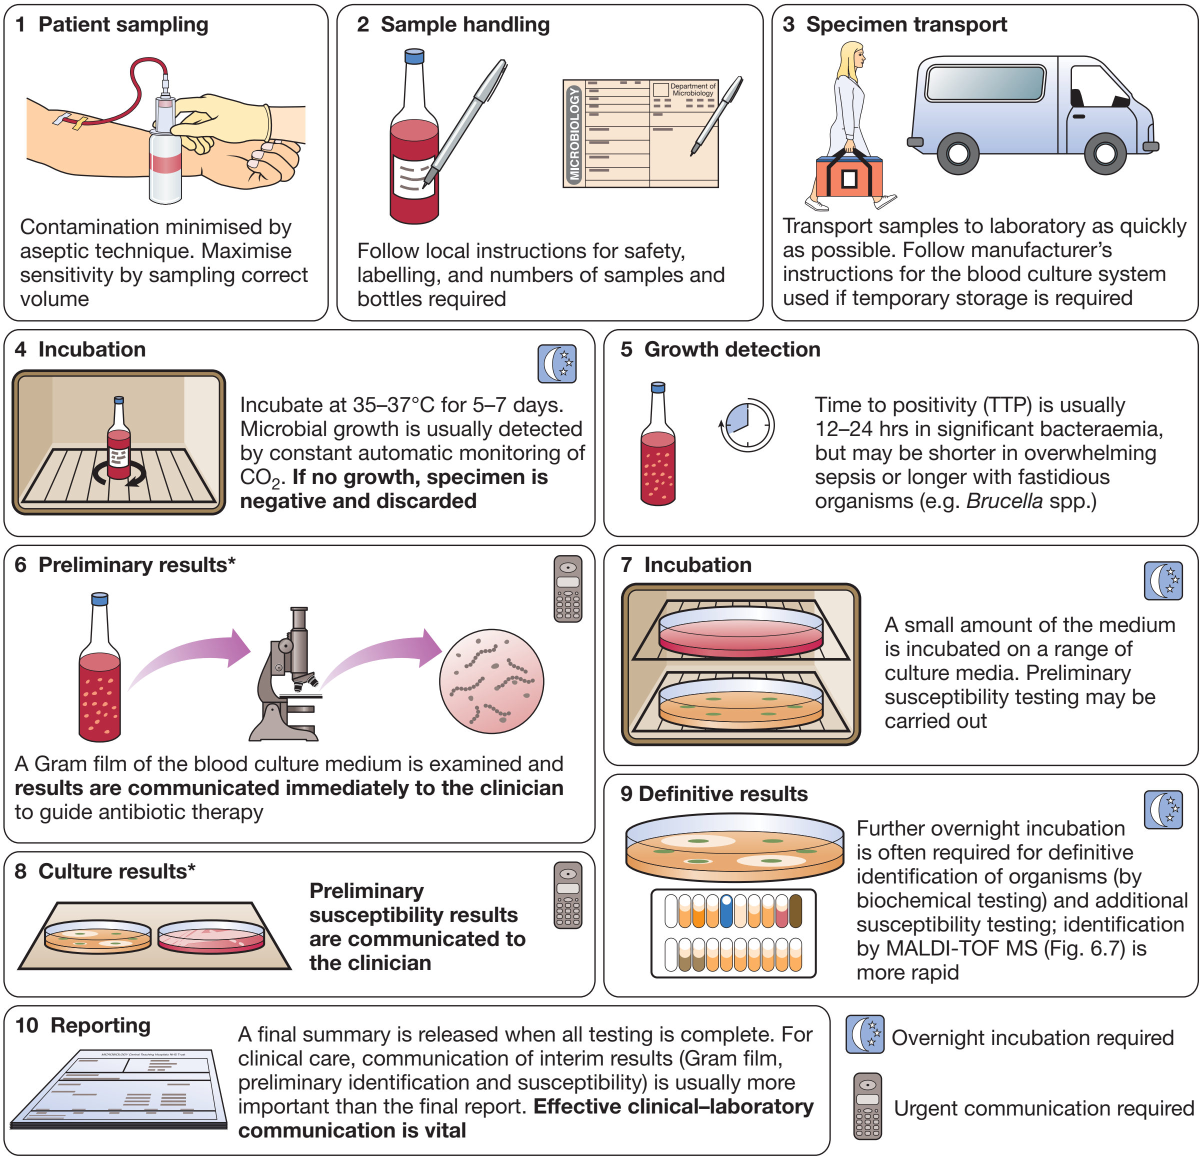

Fig. 6.6 An overview of the processing of blood cultures. *In laboratories equipped with MALDI-TOF-MS (p. 106), rapid definitive organism identification may be achieved at stage 6 and/or stage 8.

an antibody with an enzyme that generates a colour change on exposure to a chromogenic substrate. Various configurations allow detection of antigens or specific subclasses of immunoglobulin (e.g. IgG, IgM, IgA). ELISA may also be adapted to detect PCR products, using immobilised oligonucleotide hybridisation probes and various detection systems.

Immunoblot (Western blot)

Microbial proteins are separated according to molecular weight by polyacrylamide gel electrophoresis (PAGE) and transferred (blotted) on to a nitrocellulose membrane, which is incubated with patient serum. Binding of specific antibody is detected with an enzyme–anti-immunoglobulin conjugate similar to that used in ELISA, and specificity is confirmed by its location on the membrane. Immunoblotting is a highly specific test, which may be used to confirm the results of less specific tests such as ELISA (e.g. in Lyme disease, p. 255).

Immunofluorescence assays

Indirect immunofluorescence assays (IFAs) detect antibodies by incubating a serum sample with immobilised antigen (e.g. cells known to be infected with virus on a glass slide); any virus-specific antibody present in the serum binds to antigen and is then detected using a fluorescent-labelled anti-human immunoglobulin ('secondary' antibody). Fluorescence is visualised using a microscope. This method can also detect organisms in clinical samples (usually tissue or centrifuged cells) using a specific antibody in place of immobilised antigen to achieve capture.

Complement fixation test

In a complement fixation test (CFT), patient serum is heat-treated to inactivate complement and mixed with the test antigen. Any specific antibody in the serum will complex with the antigen. Complement is then added to the reaction. If antigen–antibody

complexes are present, the complement will be 'fixed' (consumed). Sheep erythrocytes, coated with an anti-erythrocyte antibody, are added. The degree of erythrocyte lysis reflects the remaining complement and is inversely proportional to the quantity of the specific antigen–antibody complex present.

Agglutination tests

When antigens are present on the surface of particles (e.g. cells, latex particles or microorganisms) and cross-linked with antibodies, visible clumping (or 'agglutination') occurs.

- In *direct agglutination*, patient serum is added to a suspension of organisms that express the test antigen. For example, in the Weil–Felix test, if a patient's serum contains antibodies to rickettsial species they cause agglutination when *Proteus* spp. surface (O) antigens are added because the antibodies cross-react with the *Proteus* antigens. The test lacks sensitivity and specificity but is still used to diagnose rickettsial infection in resource-limited settings. The Widal test reaction uses a suspension of *Salmonella typhi* and *S. paratyphi* 'A' and 'B', treated to retain only 'O' and 'H' antigens. These antigens are kept to detect corresponding antibodies in serum from a patient suspected of having typhoid fever. The test is not specific but is still used in some parts of the world.
- In *indirect (passive) agglutination*, specific antigen is attached to the surface of carrier particles, which agglutinate when incubated with patient samples that contain specific antibodies.
- In *reverse passive agglutination* (an antigen detection test), the carrier particle is coated with antibody rather than antigen.

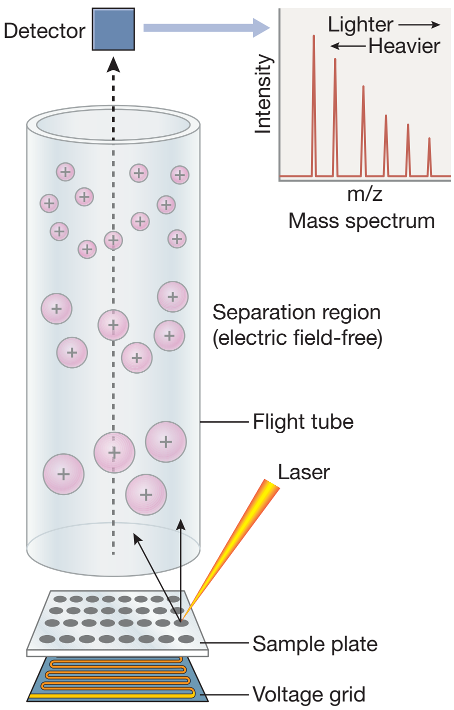

Fig. 6.7 The workings of matrix-assisted laser desorption/ionisation time-of-flight mass spectrometry (MALDI-TOF MS). *Adapted from Sobin K, Hameer D, Ruparel T. Digital genotyping using molecular affinity and mass spectrometry. Nature Rev Genet 2003; 4:1001–1008.*

Other tests

Immunodiffusion involves antibodies and antigen migrating through gels, with or without the assistance of electrophoresis, and forming insoluble complexes where they meet. The complexes are seen on staining as 'precipitin bands'. Immunodiffusion is used in the diagnosis of dimorphic fungi (p. 300) and some forms of aspergillosis (p. 596).

Immunochromatography is used to detect antigen. The system consists of a porous test strip (e.g. a nitrocellulose membrane), at one end of which there is target-specific antibody, complexed with coloured microparticles. Further specific antibody is immobilised in a transverse narrow line some distance along the strip. Test material (e.g. blood or urine) is added to the antibody–particle complexes, which then migrate along the strip by capillary action. If these are complexed with antigen, they will be immobilised by the specific antibody and visualised as a transverse line across the strip. If the test is negative, the antibody–particle complexes will bind to a line of immobilised anti-immunoglobulin antibody placed further along the strip, which acts as a negative control. Immunochromatographic tests are rapid and relatively cheap to perform, and are appropriate for point-of-care testing, e.g. in HIV 1 and malaria (p. 276).

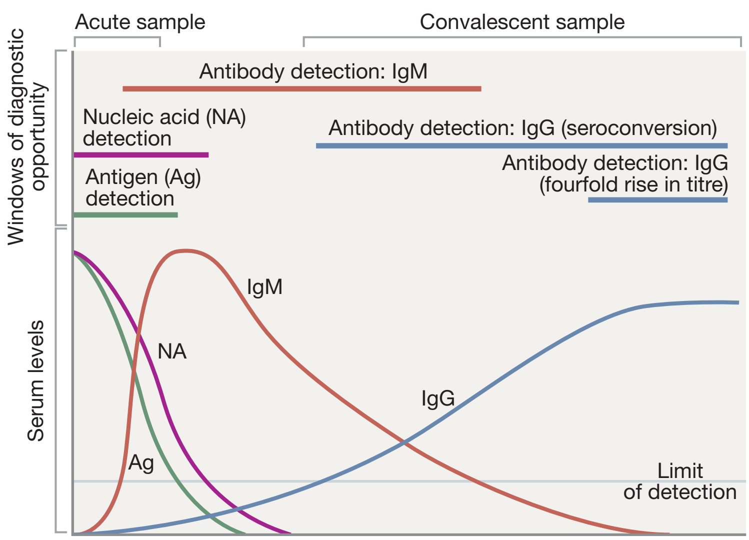

Fig. 6.8 Detection of antigen, nucleic acid and antibody in infectious disease. The acute sample is usually taken during the first week of illness, and the convalescent sample 2–4 weeks later. Detection limits and duration of detectability vary between tests and diseases, although in most diseases immunoglobulin M (IgM) is detectable within the first 1–2 weeks.

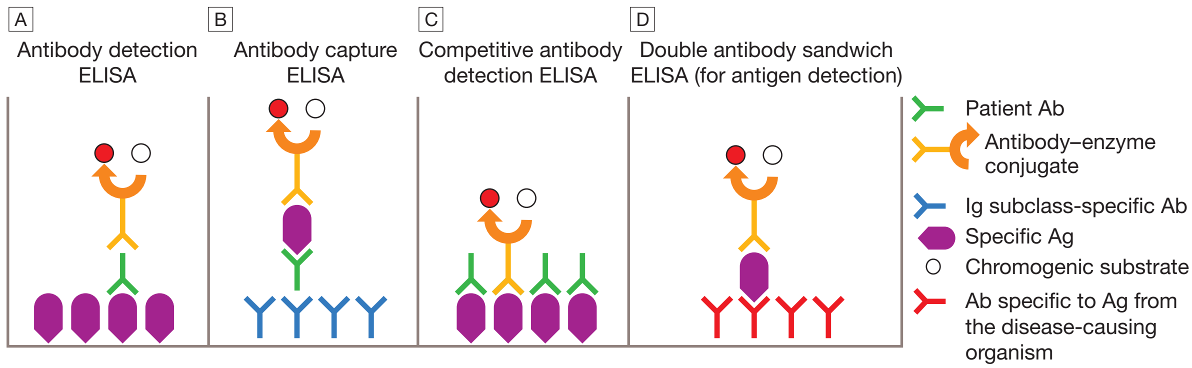

Fig. 6.9 Antibody (Ab) and antigen (Ag) detection by enzyme-linked immunosorbent assay (ELISA). This can be configured in various ways. **A** Patient Ab binds to immobilised specific Ag and is detected by addition of anti-immunoglobulin–enzyme conjugate and chromogenic substrate. **B** Patient Ab binds to immobilised Ig subclass-specific Ab and is detected by addition of specific Ag, followed by antibody–enzyme conjugate and chromogenic substrate. **C** Patient Ab and antibody–enzyme conjugate bind to immobilised specific Ag. Magnitude of colour change reaction is inversely proportional to concentration of patient Ab. **D** Patient Ag binds to immobilised Ab and is detected by addition of antibody–enzyme conjugate and chromogenic substrate. In A, the conjugate Ab is specific for human immunoglobulin. In B–D, it is specific for Ag from the disease-causing organism.

Antibody-independent specific immunological tests

The interferon-gamma release assay (IGRA) is being used increasingly to diagnose latent tuberculosis infection (LTBI). The principle behind IGRA is discussed on page 594. IGRA cannot distinguish between latent and active tuberculosis infection and is therefore appropriate for use only in countries where the background incidence of tuberculosis is low.

Antimicrobial susceptibility testing

If growth of microorganisms in culture is inhibited by the addition of an antimicrobial agent, the organism is considered to be susceptible to that antimicrobial. Bacteriostatic agents cause reversible inhibition of growth and bactericidal agents cause cell death; the terms fungistatic/fungicidal are equivalent for antifungal agents, and virustatic/virucidal for antiviral agents. The lowest concentration of antimicrobial agent at which growth is inhibited is the minimum inhibitory concentration (MIC), and the lowest concentration that causes cell death is the minimum bactericidal concentration (MBC). If the MIC is less than or equal to a predetermined breakpoint threshold, the organism is considered susceptible, and if the MIC is greater than the breakpoint, it is resistant.

Breakpoints are determined for each antimicrobial agent from a combination of pharmacokinetic (p. 17) and clinical data. The relationship between in vitro antimicrobial susceptibility and clinical response is complex, as response also depends on immune status, pharmacokinetic variability (p. 17), comorbidities that may influence pharmacokinetics or pharmacodynamics, and antibiotic dosing, as well as MIC/MBC. Thus, although treating a patient according to the results of susceptibility testing increases the likelihood of recovery, it does not guarantee therapeutic success.

Susceptibility testing is often carried out by disc diffusion (Fig. 6.10). Antibiotic-impregnated filter paper discs are placed on agar plates containing bacteria; antibiotic diffuses into the agar, resulting in a concentration gradient centred on the disc. Bacteria are unable to grow where the antibiotic concentration exceeds the MIC, which may therefore be inferred from the size of the zone of inhibition. The MIC is commonly measured in diagnostic laboratories using ‘diffusion strips’.

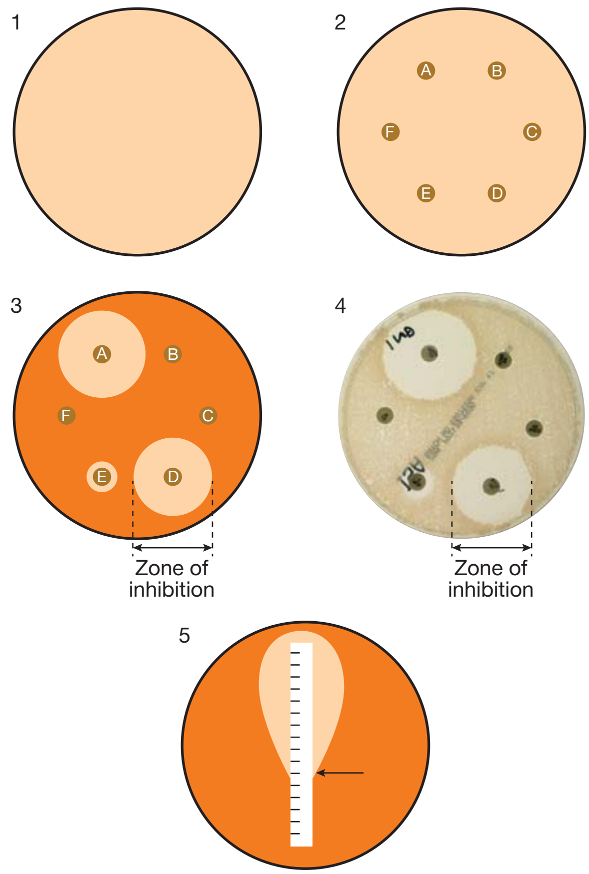

Fig. 6.10 Antimicrobial susceptibility testing by disc diffusion (panels 1-4) and minimum inhibitory concentration (MIC, panel 5). 1. The test organism is spread over the surface of an agar plate. 2. Antimicrobial-impregnated discs (A–F) are placed on the surface and the plate is incubated (e.g. overnight). 3–4. After incubation, zones of growth inhibition may be seen. The organism is considered susceptible if the diameter of the zone of inhibition exceeds a pre-determined threshold. 5. In a ‘diffusion strip’ test, the strip is impregnated with antimicrobial at a concentration gradient that decreases steadily from top to bottom. The system is designed so that the MIC value is the point at which the ellipse cuts a scale on the strip (arrow). *4, Kindly supplied by Charlotte Symes.*

Epidemiology of infection

The communicability of infectious disease means that, once a clinician has diagnosed an infectious disease, potential exposure of other patients must also be considered. The patient may require separation from other patients ('isolation'), or an outbreak of disease may need to be investigated in the community (Ch. 5). The approach will be specific to the microorganism involved (Chs 11–13) but the principles are outlined below.

Geographical and temporal patterns of infection

Endemic disease

Endemic disease has a constant presence within a given geographical area or population. The infectious agent may have a reservoir, vector or intermediate host that is geographically restricted, or may itself have restrictive environmental requirements (e.g. temperature range, humidity). The population affected may be geographically isolated or the disease may be limited to unvaccinated populations. Factors that alter geographical restriction include:

- expansion of an animal reservoir (e.g. Lyme disease from reforestation)
- vector escape (e.g. airport malaria)
- extension of host range (e.g. schistosomiasis from dam construction)
- human migration (e.g. carbapenemase-producing *Klebsiella pneumoniae*)
- public health service breakdown (e.g. diphtheria in unvaccinated areas)
- climate change (e.g. dengue virus and Rift Valley fever).

Emerging and re-emerging disease

An emerging infectious disease is one that has newly appeared in a population, or has been known for some time but is increasing in incidence or geographical range. If the disease was previously known and thought to have been controlled or eradicated, it is considered to be re-emerging. Many emerging diseases are caused by organisms that infect animals and have undergone adaptations that enable them to infect humans. This is exemplified by HIV-1, which is believed to have originated in higher primates in Africa. The geographical pattern of some recent emerging and re-emerging infections is shown in Figure 6.11.

Reservoirs of infection

The US Centers for Disease Control (CDC) define a reservoir of infection as any person, other living organism, environment or combination of these in which the infectious agent lives and replicates and on which the infectious agent is dependent for its survival. The infectious agent is transmitted from this reservoir to a susceptible host.

Human reservoirs

Both colonised individuals and those with infection can act as reservoirs, e.g. with *Staph. aureus* (including MRSA), *Strep. pyogenes* and *C. difficile.* For infected humans to act as reservoirs, the infections caused must be long-lasting in at least a proportion of those affected, to enable onward transmission (e.g. tuberculosis, sexually transmitted infections). Humans are the only reservoir for some infections (e.g. measles).

Animal reservoirs

The World Health Organization (WHO) defines a zoonosis as 'a disease or infection that is naturally transmissible from vertebrate animals to humans'. Infected animals may be asymptomatic. Zoonotic agents may be transmitted via any of the routes described below. Primary infection with zoonoses may be transmitted onward between humans, causing secondary disease (e.g. Q fever, brucellosis, Ebola).

Environmental reservoirs

Many infective pathogens are acquired from an environmental source. However, some of these are maintained in human or animal reservoirs, with the environment acting only as a conduit for infection.

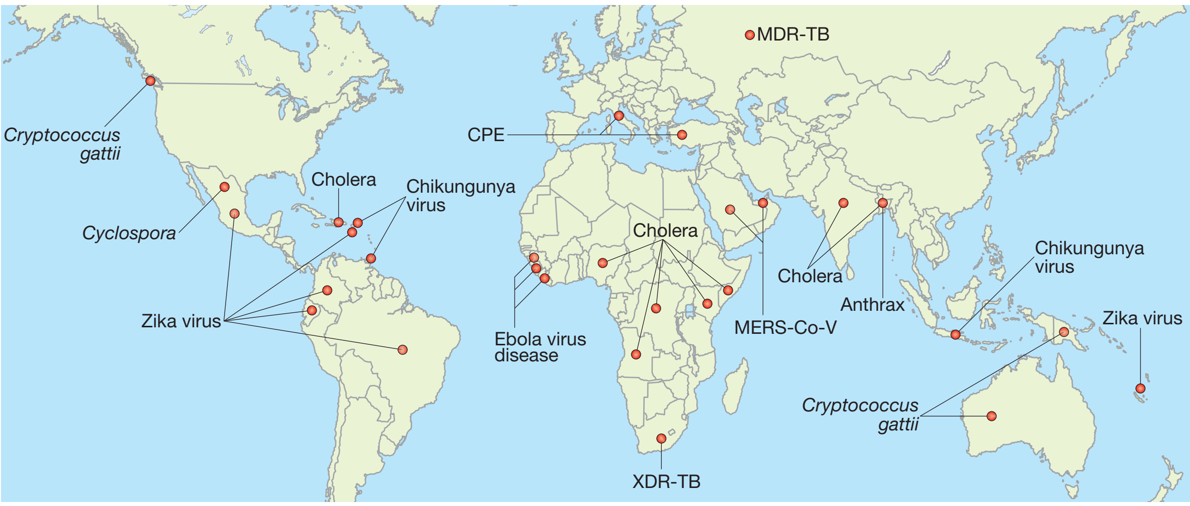

Fig. 6.11 Geographical locations of some infectious disease outbreaks, with examples of emerging and re-emerging diseases. (CPE = carbapenemase-producing Enterobacteriaceae; MDR-TB = multidrug-resistant tuberculosis; MERS-Co-V = Middle East respiratory syndrome coronavirus; XDR-TB = extensively drug-resistant tuberculosis)

6.6 Incubation periods of important infections[1]

Infection	Incubation period
Short incubation periods	
Anthrax, cutaneous[3]	9 hrs to 2 weeks
Anthrax, inhalational[3]	2 days[2]
Bacillary dysentery[5]	1–6 days
Cholera[3]	2 hrs to 5 days
Dengue haemorrhagic fever[6]	3–14 days
Diphtheria[6]	1–10 days
Gonorrhoea[4]	2–10 days
Influenza[5]	1–3 days
Meningococcaemia[3]	2–10 days
Norovirus[1]	1–3 days
SARS coronavirus[3]	2–7 days[2]
Scarlet fever[5]	2–4 days
Intermediate incubation periods	
Amoebiasis[6]	1–4 weeks
Brucellosis[4]	5–30 days
Chickenpox[5]	11–20 days
Lassa fever[3]	3–21 days
Malaria[3]	10–15 days
Measles[5]	6–19 days
Mumps[5]	15–24 days
Poliomyelitis[6]	3–35 days
Psittacosis[4]	1–4 weeks
Rubella[5]	15–20 days
Typhoid[5]	5–31 days
Whooping cough[5]	5–21 days
Long incubation periods	
Hepatitis A[5]	3–7 weeks
Hepatitis B[4]	6 weeks to 6 months
Leishmaniasis, cutaneous[6]	Weeks to months
Leishmaniasis, visceral[6]	Months to years
Leprosy (Hansen's disease)[3]	5–20 years
Rabies[4]	2–8 weeks[2]
Trypanosoma brucei gambiense infection[6]	Months to years
Tuberculosis[5]	1–12 months

[1]Incubation periods are approximate and may differ from local or national guidance. [2]Longer incubation periods have been reported. [3]WHO. [4]Health Protection Agency (now Health Protection England). [5]Richardson M, Elliman D, Maguire H, et al. Pediatr Infect Dis J 2001; 20:380–388. [6]Centers for Disease Control, USA.
(SARS = severe acute respiratory syndrome)

Transmission of infection

Communicable diseases may be transmitted by one or more of the following routes:

- *Respiratory route*: inhalation.
- *Faecal–oral route*: ingestion of material originating from faeces.
- *Sexually transmitted infections*: direct contact between mucous membranes.
- *Blood-borne infections*: direct inoculation of blood or body fluids.
- *Direct contact*: very few organisms are capable of causing infection by direct contact with intact skin. Most infection by this route requires contact with damaged skin (e.g. surgical wound).
- *Via a vector or fomite*: the vector/fomite bridges the gap between the infected host or reservoir and the uninfected host. Vectors are animate, and include mosquitoes in malaria, dengue and Zika virus infection, fleas in plague and humans in MRSA. Fomites are inanimate objects such as door handles, water taps and ultrasound probes, which are particularly associated with health care-associated infection (HCAI).

6.7 Periods of infectivity in common childhood infectious diseases

Disease	Infectious period
Chickenpox[1]	From 4 days before until 5 days after appearance of the rash (transmission before 48 hrs prior to the onset of rash is rare)[4]
Measles[2]	From 4 days before onset to 4 days after onset of the rash
Mumps[3]	From 2–3 days before to 5 days after disease onset[5]
Rubella[3]	From 10 days before until 15 days after the onset of the rash, but most infectious during prodromal illness[4]
Scarlet fever[1]	Unknown[6]
Whooping cough[1]	Unknown[6,7]

[1]From Richardson M, Elliman D, Maguire H, et al. Pediatr Infect Dis J 2001; 20:380–388. [2]Centers for Disease Control, USA; cdc.gov/measles/hcp/. [3]Bennett JE, Dolin R, Blaser MJ. Mandell, Douglas and Bennett's Principles and practice of infectious diseases, 8th edn. Philadelphia: Elsevier; 2015. [4–6]Exclude from contact with non-immune and immunocompromised people for 5 days from [4]onset of rash, [5]onset of parotitis, or [6]start of antibiotic treatment. [7]Exclude for 3 weeks if untreated.
Durations are approximate and vary between information sources, and these recommendations may differ from local or national guidance.

The likelihood of infection following transmission of a pathogen depends on organism factors (virulence, p. 104) and host susceptibility. The incubation period is the time between exposure and development of symptoms, and the period of infectivity is the period after exposure during which the patient is infectious to others. Knowledge of incubation periods and of periods of infectivity is important in controlling the spread of disease, although for many diseases these estimates are imprecise (Boxes 6.6 and 6.7).

Deliberate release

Deliberate release of pathogens with the intention of causing disease is known as biological warfare or bioterrorism, depending on the scale and context. Deliberate release incidents have included a 750-person outbreak of *Salmonella typhimurium* caused by contamination of salads in 1984 (Oregon, USA) and 22 cases of anthrax (five fatal) from the mailing of finely powdered (weaponised) anthrax spores in 2001 (New Jersey, USA). Diseases with high potential for deliberate release include anthrax, plague, tularaemia, smallpox and botulism (through toxin release).

Infection prevention and control

Infection prevention and control (IPC) describes the measures applied to populations with the aim of breaking the chain of infection (see Fig. 6.1, p. 100).

Health care-associated infection

The risk of developing infection following admission to a health-care facility (health care-associated infection, HCAI) in

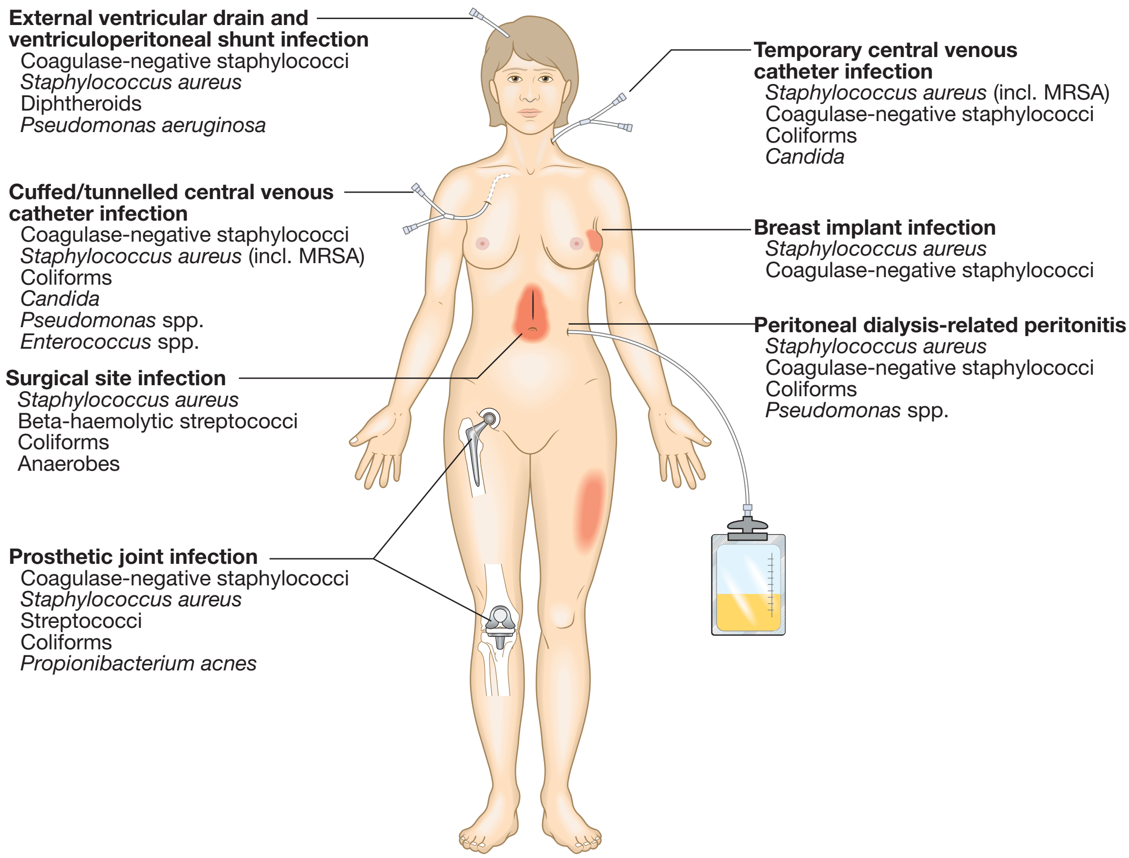

Fig. 6.12 Commonly encountered health care-associated infections (HCAIs) and the factors that predispose to them.

i 6.8 Measures used in infection prevention and control (IPC)

Institutions	Clinical practice
• Handling, storage and disposal of clinical waste • Containment and safe removal of spilled blood and body fluids • Cleanliness of environment and medical equipment • Specialised ventilation (e.g. laminar flow, air filtration, controlled pressure gradients) • Sterilisation and disinfection of instruments and equipment • Food hygiene • Laundry management	• Antibiotic stewardship (p. 115) • Aseptic technique • Perioperative antimicrobial prophylaxis • Screening patients for colonisation or infection (e.g. MRSA, GRE, CPE)
Health-care staff	**Response to infections**
• Education • Hand hygiene, including hand-washing (see Fig. 6.13) • Sharps management and disposal • Use of personal protective equipment (masks, sterile and non-sterile gloves, gowns and aprons) • Screening health workers for disease (e.g. tuberculosis, hepatitis B virus, MRSA) • Immunisation and post-exposure prophylaxis	• Surveillance to detect alert organism (see text) outbreaks and antimicrobial resistance • Antibiotic chemoprophylaxis in infectious disease contacts, if indicated (see Box 6.18) • Isolation (see Box 6.9) • Reservoir control • Vector control

(CPE = carbapenemase-producing Enterobacteriaceae; GRE = glycopeptide-resistant enterococci; MRSA = meticillin-resistant *Staphylococcus aureus*)

the developed world is about 10%. Many nosocomial bacterial infections are caused by organisms that are resistant to numerous antibiotics (multi-resistant bacteria), including MRSA, extended-spectrum β-lactamases (ESBLs) and carbapenemase-producing Enterobacteriaceae (CPE), and glycopeptide-resistant enterococci (GRE). Other infections of particular concern in hospitals include *C. difficile* (p. 264) and norovirus (p. 249). Some examples are shown in Figure 6.12.

IPC measures are described in Box 6.8. The most important is maintenance of good hand hygiene (Fig. 6.13). Hand

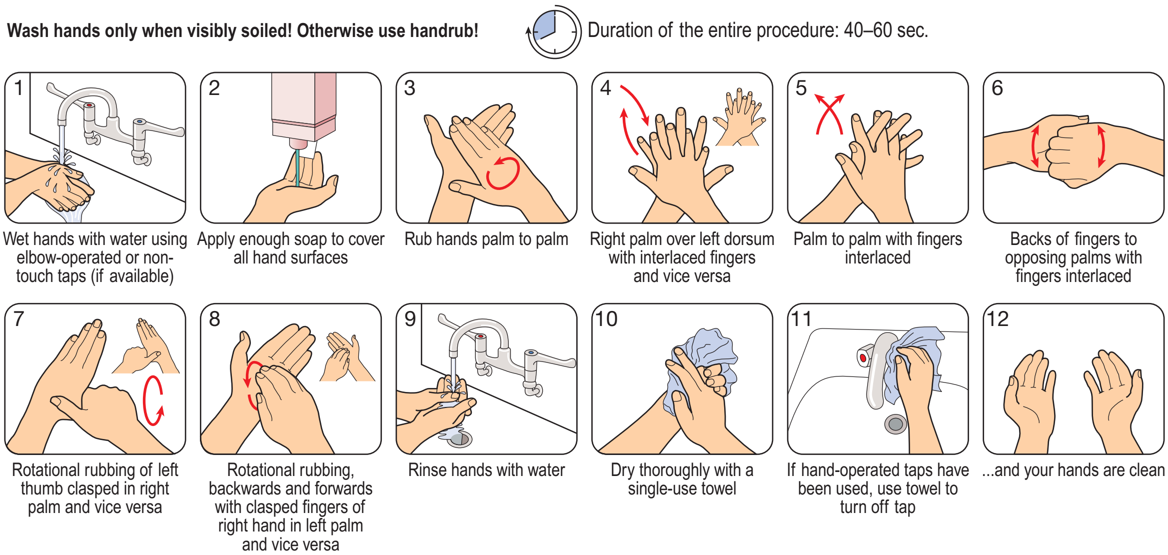

Fig. 6.13 Hand-washing. Good hand hygiene, whether with soap/water or alcohol handrub, includes areas that are often missed, such as fingertips, web spaces, palmar creases and the backs of hands. *Adapted from the 'How to Handwash' URL: who.int/gpsc/5may/How_To_Handwash_Poster.pdf © World Health Organization 2009. i 6.9 Types of isolation precaution[1]

Airborne transmission	Contact transmission	Droplet transmission
Precautions		
Negative pressure room with air exhausted externally or filtered N95 masks or personal respirations for staff; avoid using non-immune staff	Private room preferred (otherwise, inter-patient spacing ≥ 1 m) Gloves and gown for staff in contact with patient or contaminated areas	Private room preferred (otherwise, inter-patient spacing ≥ 1 m) Surgical masks for staff in close contact with patient
Infections managed with these precautions		
Measles Tuberculosis, pulmonary or laryngeal, confirmed or suspected	Enteroviral infections in young children (diapered or incontinent) Norovirus[2] *C. difficile* infection Multidrug-resistant organisms (e.g. MRSA, ESBL, GRE, VRSA, penicillin-resistant *Strep. pneumoniae*)[3] Parainfluenza in infants and young children Rotavirus RSV in infants, children and immunocompromised Viral conjunctivitis, acute	Diphtheria, pharyngeal *Haemophilus influenzae* type B infection Herpes simplex virus, disseminated or severe Influenza Meningococcal infection Mumps *Mycoplasma pneumoniae* Parvovirus (erythrovirus) B19 (erythema infectiosum, fifth disease) Pertussis Plague, pneumonic/bubonic Rubella *Strep. pyogenes* (group A), pharyngeal
Infections managed with multiple precautions		
← Smallpox, monkeypox, VZV (chickenpox or disseminated disease)[4]	→	
	← Adenovirus pneumonia	→
←	SARS, viral haemorrhagic fever[2]	→

[1]Recommendations based on 2007 CDC guideline for isolation precautions. May differ from local or national recommendations. [2]Not a CDC recommendation. [3]Subject to local risk assessment. [4]Or in any immunocompromised patient until possibility of disseminated infection excluded. (ESBL = extended-spectrum β-lactamase; GRE = glycopeptide-resistant enterococci; MRSA = meticillin-resistant *Staph. aureus*; RSV = respiratory syncytial virus; SARS = severe acute respiratory syndrome; VRSA = vancomycin-resistant *Staph. aureus*; VZV = varicella zoster virus)

decontamination (e.g. using alcohol gel or washing) is mandatory before and after every patient contact. Decontamination with alcohol gel is usually adequate but hand-washing (with hot water, liquid soap and complete drying) is required after any procedure that involves more than casual physical contact, or if hands are visibly soiled. In situations where the prevalence of *C. difficile* is high (e.g. a local outbreak), alcohol gel decontamination between patient contacts is inadequate as it does not kill *C. difficile* spores, and hands must be washed.

Some infections necessitate additional measures to prevent cross-infection (Box 6.9). To minimise risk of infection, invasive procedures must be performed using strict aseptic technique.

Outbreaks of infection

Descriptive terms are defined in Box 6.10. Confirmation of an infectious disease outbreak usually requires evidence from 'typing' that the causal organisms have identical phenotypic and/or genotypic characteristics. If this is found not to be the case, the term pseudo-outbreak is used. When an outbreak of infection is suspected, a case definition is agreed. The number of cases that meet the case definition is then assessed by case-finding, using methods ranging from administration of questionnaires to national reporting systems. Case-finding usually includes microbiological testing, at least in the early stages of an outbreak. Temporal changes in cases are noted in order to plot an outbreak curve, and demographic details are collected to identify possible sources of infection. A case–control study, in which recent activities (potential exposures) of affected 'cases' are compared to those of unaffected 'controls', may be undertaken to establish the outbreak source, and measures are taken to manage the outbreak and control its spread. Good communication between relevant personnel during and after the outbreak is important to inform practice in future outbreaks.

Surveillance ensures that disease outbreaks are either prevented or identified early. In hospitals, staff are made aware of the isolation of alert organisms, which have the propensity to cause outbreaks, and alert conditions, which are likely to be caused by such organisms. Analogous systems are used nationally; many countries publish lists of organisms and diseases, which, if detected (or suspected), must be reported to public health authorities (reportable or notifiable diseases). Reasons for a disease to be classified as reportable are shown in Box 6.11.

6.10 Terminology in outbreaks of infection

Term	Definition
Classification of related cases of infectious disease*	
Cluster	An aggregation of cases of a disease that are closely grouped in time and place, and may or may not exceed the expected number
Epidemic	The occurrence of more cases of disease than expected in a given area or among a specific group of people over a particular period of time
Outbreak	Synonymous with epidemic. Alternatively, a localised, as opposed to generalised, epidemic
Pandemic	An epidemic occurring over a very wide area (several countries or continents) and usually affecting a large proportion of the population
Classification of affected patients (cases)	
Index case	The first case identified in an outbreak
Primary cases	Cases acquired from a specific source of infection
Secondary cases	Cases acquired from primary cases
Types of outbreak	
Common source outbreak	Exposure to a common source of infection (e.g. water-cooling tower, medical staff member shedding MRSA). New primary cases will arise until the source is no longer present
Point source outbreak	Exposure to a single source of infection at a specific point in time (e.g. contaminated food at a party). Primary cases will develop disease synchronously
Person-to-person spread	Outbreak with both primary and secondary cases. May complicate point source or common source outbreak

*Adapted from cdc.gov. (MRSA = meticillin-resistant *Staphylococcus aureus*)

6.11 Reasons for including an infectious disease on a regional/national list of reportable diseases*

Reason for inclusion	Examples
Endemic/local disease with the potential to spread and/or cause outbreaks	Influenza, *Salmonella*, tuberculosis
Imported disease with the propensity to spread and/or cause outbreaks	Typhoid, cholera (depending on local epidemiology)
Evidence of a possible breakdown in health protection/public health functions	*Legionella*, *Cryptosporidium*
Evidence of a possible breakdown in food safety practices	Botulism, verotoxigenic *E. coli*
Evidence of a possible failure of a vaccination programme	Measles, poliomyelitis, pertussis
Disease with the potential to be a novel or increasing threat to human health	SARS, MERS-CoV, multi-resistant bacteria
Evidence of expansion of the range of a reservoir/vector	Lyme disease, rabies, West Nile encephalitis
Evidence of possible deliberate release	Anthrax, tularaemia, plague, smallpox, botulism

*Given the different geographical ranges of individual diseases and wide national variations in public health services, vaccination programmes and availability of resources, reporting regulations vary between regions, states and countries. Many diseases are reportable for more than one reason. (MERS-CoV = Middle East respiratory syndrome coronavirus; SARS = severe acute respiratory syndrome)

Immunisation

Immunisation may be passive or active. Passive immunisation is achieved by administering antibodies targeting a specific pathogen. Antibodies are obtained from blood, so confer some of the risks associated with blood products (p. 933). The protection afforded by passive immunisation is immediate but of short duration (a few weeks or months); it is used to prevent or attenuate infection before or after exposure (Box 6.12).

Vaccination

Active immunisation is achieved by vaccination with whole organisms or organism components (Box 6.13).

Types of vaccine

Whole-cell vaccines consist of live or inactivated (killed) microorganisms. Component vaccines contain only extracted or synthesised components of microorganisms (e.g. polysaccharides or proteins). Live vaccines contain organisms with attenuated (reduced) virulence, which cause only mild symptoms but induce T-lymphocyte and humoral responses (p. 68) and are therefore more immunogenic than inactivated whole-cell vaccines. The use of live vaccines in immunocompromised individuals is not generally recommended, but they may be used by specialists following a risk/benefit assessment.

Component vaccines consisting only of polysaccharides, such as the pneumococcal polysaccharide vaccine (PPV), are poor activators of T lymphocytes and produce a short-lived antibody response without long-lasting memory. Conjugation of polysaccharide to a protein, as in the *Haemophilus influenzae* type B (Hib) vaccine and the protein conjugate pneumococcal

6.12 Indications for post-exposure prophylaxis with immunoglobulins

Human normal immunoglobulin (pooled immunoglobulin)

- Hepatitis A (unvaccinated contacts*)
- Measles (exposed child with heart or lung disease)

Human specific immunoglobulin

- Hepatitis B (sexual partners, inoculation injuries, infants born to infected mothers)
- Tetanus (high-risk wounds or incomplete or unknown immunisation status)
- Rabies
- Chickenpox (immunosuppressed children and adults, pregnant women)

*Active immunisation is preferred if contact is with a patient who is within 1 week of onset of jaundice.

6.13 Vaccines in current clinical use

Live attenuated vaccines

- Measles, mumps, rubella (MMR)
- Oral poliomyelitis (OPV, not used in UK)
- Rotavirus
- Tuberculosis (bacille Calmette–Guérin, BCG)
- Typhoid (oral typhoid vaccine)
- Varicella zoster virus

Inactivated (killed) whole-cell vaccines

- Cholera
- Hepatitis A
- Influenza
- Poliomyelitis (inactivated polio virus, IPV)
- Rabies

Component vaccines

- Anthrax (adsorbed extracted antigens)
- Diphtheria (adsorbed toxoid)
- Hepatitis B (adsorbed recombinant hepatitis B surface antigen, HBsAg)
- *Haemophilus influenzae* type B (conjugated capsular polysaccharide)
- Human papillomavirus (recombinant capsid proteins)
- Meningococcal, quadrivalent A, C, Y, W135 (conjugated capsular polysaccharide)
- Meningococcal, serogroup C (conjugated capsular polysaccharide)
- Pertussis (adsorbed extracted antigens)
- Pneumococcal conjugate (PCV; conjugated capsular polysaccharide, 13 serotypes)
- Pneumococcal polysaccharide (PPV; purified capsular polysaccharide, 23 serotypes)
- Tetanus (adsorbed toxoid)
- Typhoid (purified Vi capsular polysaccharide)

vaccine (PCV), activates T lymphocytes, which results in a sustained response and immunological memory. Toxoids are bacterial toxins that have been modified to reduce toxicity but maintain antigenicity. Vaccine response can be improved by co-administration with mildly pro-inflammatory adjuvants, such as aluminium hydroxide.

Use of vaccines

Vaccination may be applied to entire populations or to subpopulations at specific risk through travel, occupation or other activities. In ring vaccination, the population immediately surrounding a case or outbreak of infectious disease is

6.14 Guidelines for vaccination against infectious disease

- The principal contraindication to inactivated vaccines is an anaphylactic reaction to a previous dose or a vaccine component
- Live vaccines should not be given during an acute infection, to pregnant women or to the immunosuppressed, unless the immunosuppression is mild and the benefits outweigh the risks
- If two live vaccines are required, they should be given either simultaneously in opposite arms or 4 weeks apart
- Live vaccines should not be given for 3 months after an injection of human normal immunoglobulin (HNI)
- HNI should not be given for 2 weeks after a live vaccine
- Hay fever, asthma, eczema, sickle-cell disease, topical glucocorticoid therapy, antibiotic therapy, prematurity and chronic heart and lung diseases, including tuberculosis, are not contraindications to vaccination

vaccinated to curtail further spread. Vaccination is aimed mainly at preventing infectious disease. However, vaccination against human papillomavirus (HPV) was introduced to prevent cervical and other cancers that complicate HPV infection. Vaccination guidelines for individuals are shown in Box 6.14.

Vaccination becomes successful once the number of susceptible hosts in a population falls below the level required to sustain continued transmission of the target organism (herd immunity). Naturally acquired smallpox was declared to have been eradicated worldwide in 1980 through mass vaccination. In 1988, the WHO resolved to eradicate poliomyelitis by vaccination; the number of cases worldwide has since fallen from approximately 350 000 per annum to 74 in 2015. Recommended vaccination schedules vary between countries. In addition to standard vaccination schedules, catch-up schedules are specified for individuals who join vaccination programmes later than the recommended age.

Antimicrobial stewardship

Antimicrobial stewardship (AMS) refers to the systems and processes applied to a population to optimise the use of antimicrobial agents. The populations referred to here may be a nation, region, hospital, or a unit within a health-care organisation (e.g. ward or clinic). AMS aims to improve patient outcomes and reduce antimicrobial resistance (AMR). IPC and AMS complement each other (Fig. 6.14). Elements of AMS include treatment guidelines, antimicrobial formularies and ward rounds by infection specialists.

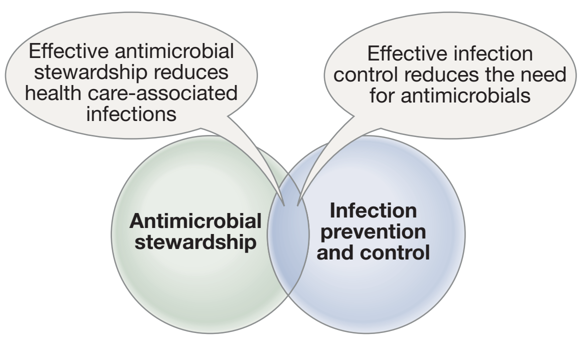

Fig. 6.14 The relationship between infection prevention and control (IPC) and antimicrobial stewardship (AMS).

Treatment of infectious diseases

Key components of treating infection are:

- optimising antimicrobial therapy while minimising selection for antimicrobial resistance and the impact on commensal flora
- addressing predisposing factors, e.g. glycaemic control in diabetes mellitus; viral load control in HIV-1-associated opportunistic infection
- considering adjuvant therapy, e.g. removal of an infected medical device or necrotic tissue
- managing complications, e.g. severe sepsis (systemic inflammatory response syndrome, or SIRS, p. 196) and acute kidney injury (p. 411).

For communicable disease, treatment must also take into account contacts of the infected patient, and may include IPC interventions such as isolation, antimicrobial prophylaxis, vaccination and contact tracing.

Principles of antimicrobial therapy

In some situations (e.g. pneumonia) it is important to start appropriate antimicrobial therapy promptly, whereas in others prior confirmation of the diagnosis and pathogen is preferred. The principles underlying the choice of antimicrobial agent(s) are discussed below. The WHO 'World Antibiotic Awareness Week' campaign is a yearly event aimed at highlighting the importance of prudent antimicrobial prescribing (see 'Further information').

Antimicrobial action and spectrum

Antimicrobial agents may kill or inhibit microorganisms by targeting essential and non-essential cellular processes, respectively. The range, or spectrum, of microorganisms that is killed or inhibited by a particular antimicrobial agent needs consideration when selecting therapy. Mechanisms of action of the major classes of antibacterial agent are listed in Box 6.15 and appropriate agents for some common infecting organisms are shown in Box 6.16. In severe infections and/or immunocompromised patients, it is customary to use bactericidal agents in preference to bacteriostatic agents.

Empiric versus targeted therapy

Empiric antimicrobial therapy is selected to treat a suspected infection (e.g. meningitis) before the microbiological cause is known. Targeted or 'directed' therapy can be prescribed when the pathogen(s) is known. Empirical antimicrobial regimens need to have activity against the range of pathogens that could be causing the infection in question; because broad-spectrum agents affect many more bacteria than needed, they select for antimicrobial resistance. 'Start Smart – Then Focus' (Fig. 6.15) describes the principle of converting from empiric therapy to narrow-spectrum targeted therapy. Optimum empiric therapy depends on the site of infection, patient characteristics and local antimicrobial resistance patterns. National or local guidelines are often used to inform antimicrobial prescribing decisions.

Combination therapy

It is sometimes appropriate to combine antimicrobial agents:

- when there is a need to increase clinical effectiveness (e.g. biofilm infections)
- when no single agent's spectrum covers all potential pathogens (e.g. polymicrobial infection)
- when there is a need to reduce development of antimicrobial resistance in the target pathogen, as the organism would need to develop resistance to multiple agents simultaneously (e.g. antituberculous chemotherapy, p. 592; antiretroviral therapy (ART), p. 324).

i 6.15 Target and mechanism of action of common antibacterial agents

Aminoglycosides, chloramphenicol, macrolides, lincosamides, oxazolidinones
- Inhibition of bacterial protein synthesis by binding to subunits of bacterial ribosomes

Tetracyclines
- Inhibition of protein synthesis by preventing transfer RNA binding to ribosomes

Beta-lactams
- Inhibition of cell wall peptidoglycan synthesis by competitive inhibition of transpeptidases ('penicillin-binding proteins')

Cyclic lipopeptide (daptomycin)
- Insertion of lipophilic tail into plasma membrane causing depolarisation and cell death

Glycopeptides
- Inhibition of cell wall peptidoglycan synthesis by forming complexes with D-alanine residues on peptidoglycan precursors

Nitroimidazoles
- The reduced form of the drug causes strand breaks in DNA

Quinolones
- Inhibition of DNA replication by binding to DNA topoisomerases (DNA gyrase and topoisomerase IV), preventing supercoiling and uncoiling of DNA

Rifamycins
- Inhibition of DNA synthesis by inhibiting DNA-dependent RNA polymerase

Sulphonamides and trimethoprim
- Inhibition of folate synthesis by dihydropteroate synthase (sulphonamides) and dihydrofolate reductase (trimethoprim) inhibition

Antimicrobial resistance

Microorganisms have evolved in the presence of naturally occurring antibiotics and have therefore developed resistance mechanisms (categorised in Fig. 6.16) to all classes of antimicrobial agent (antibiotics and their derivatives). Intrinsic resistance is an innate property of a microorganism, whereas acquired resistance arises by spontaneous mutation or horizontal transfer of genetic material from another organism (e.g. via a plasmid, p. 100). Plasmids often encode resistance to multiple antibiotics.

The *mecA* gene encodes a penicillin-binding protein, which has a low affinity for penicillins and therefore confers resistance to β-lactam antibiotics in staphylococci. Extended-spectrum β-lactamases (ESBLs) are frequently encoded on plasmids, which are transferred relatively easily between bacteria, including Enterobacteriaceae. Plasmid-encoded carbapenemases have been detected in strains of *Klebsiella pneumoniae* (e.g. New Delhi metallo-β-lactamase 1, NDM-1). Strains of MRSA have been described that also have reduced susceptibility to glycopeptides through the development of a relatively impermeable cell wall.

6.16 Antimicrobial options for common infecting bacteria

Organism	Antimicrobial options*
Gram-positive organisms	
Enterococcus faecalis	Ampicillin, vancomycin/teicoplanin
Enterococcus faecium	Vancomycin/teicoplanin, linezolid
Glycopeptide-resistant enterococci	Linezolid, tigecycline, daptomycin
MRSA	Clindamycin, vancomycin, rifampicin (never used as monotherapy), linezolid, daptomycin, tetracyclines, tigecycline, co-trimoxazole
Staphylococcus aureus	Flucloxacillin, clindamycin
Streptococcus pyogenes	Penicillin, clindamycin, vancomycin
Streptococcus pneumoniae	Penicillin, cephalosporins, levofloxacin, vancomycin
Gram-negative organisms	
Escherichia coli, 'coliforms' (enteric Gram-negative bacilli)	Amoxicillin, trimethoprim, cefuroxime, ciprofloxacin, co-amoxiclav
Enterobacter spp., *Citrobacter* spp.	Ciprofloxacin, meropenem, ertapenem, aminoglycosides
ESBL-producing Enterobacteriaceae	Ciprofloxacin, meropenem, ertapenem (if sensitive), temocillin, aminoglycosides
Carbapenemase-producing Enterobacteriaceae	Ciprofloxacin, aminoglycosides, tigecycline, colistin
Haemophilus influenzae	Amoxicillin, co-amoxiclav, macrolides, cefuroxime, cefotaxime, ciprofloxacin
Legionella pneumophila	Azithromycin, levofloxacin, doxycycline
Neisseria gonorrhoeae	Ceftriaxone/cefixime, spectinomycin
Neisseria meningitidis	Penicillin, cefotaxime/ceftriaxone, chloramphenicol
Pseudomonas aeruginosa	Ciprofloxacin, piperacillin–tazobactam, aztreonam, meropenem, aminoglycosides, ceftazidime/cefepime
Salmonella typhi	Ceftriaxone, azithromycin (uncomplicated typhoid), chloramphenicol (resistance common)
Strict anaerobes	
Bacteroides spp.	Metronidazole, clindamycin, co-amoxiclav, piperacillin–tazobactam, meropenem
Clostridium difficile	Metronidazole, vancomycin (oral), fidaxomicin
Clostridium spp.	Penicillin, metronidazole, clindamycin
Fusobacterium spp.	Penicillin, metronidazole, clindamycin
Other organisms	
Chlamydia trachomatis	Azithromycin, doxycycline
Treponema pallidum	Penicillin, doxycycline

*Antibiotic selection depends on multiple factors, including local susceptibility patterns, which vary enormously between geographical areas. There are many appropriate alternatives to those listed. (ESBL = extended-spectrum β-lactamase; MRSA = meticillin-resistant *Staphylococcus aureus*)

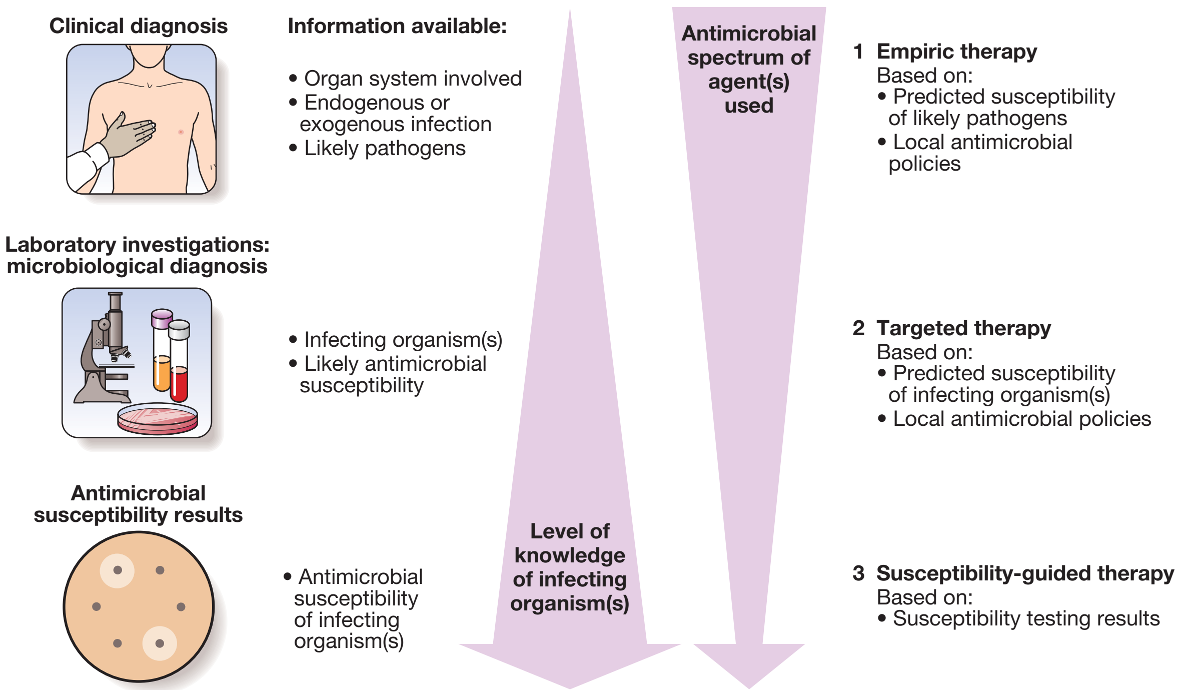

Fig. 6.15 Stages in the selection and refinement of antimicrobial therapy: 'Start Smart – Then Focus'.

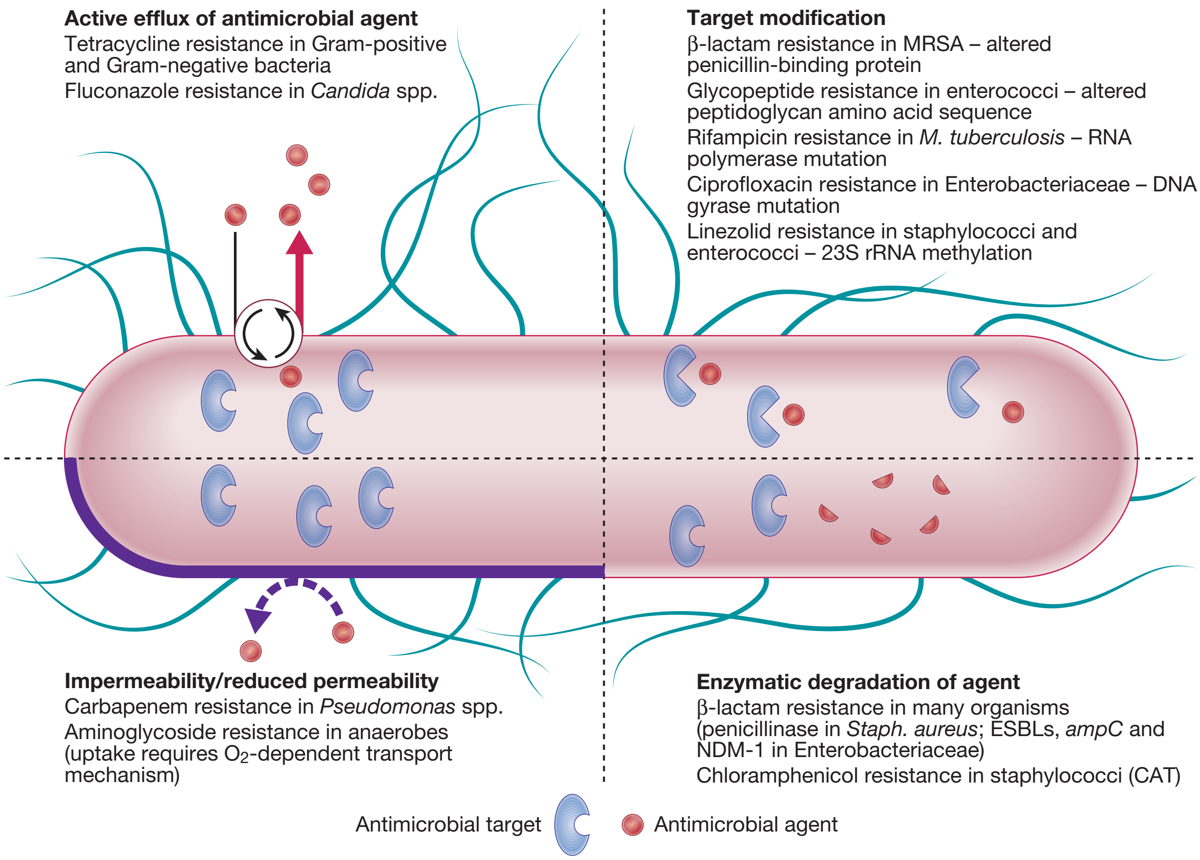

Fig. 6.16 Examples of mechanisms of antimicrobial resistance. (CAT = chloramphenicol acetyltransferase; ESBLs = extended-spectrum β-lactamases; MRSA = meticillin-resistant *Staph. aureus*; NDM-1 = New Delhi metallo-β-lactamase 1).

Factors promoting antimicrobial resistance include the inappropriate use of antibiotics (e.g. to treat viral infections), inadequate dosage or unnecessarily prolonged treatment, and use of antimicrobials as growth promoters in agriculture. However, *any* antimicrobial use exerts a selection pressure that favours the development of resistance. Combination antimicrobial therapy may reduce the emergence of resistance in the target pathogen but not in the normal flora that it also affects. Despite use of combination therapy for *M. tuberculosis*, multidrug-resistant tuberculosis (MDR-TB, resistant to isoniazid and rifampicin) and extremely drug-resistant tuberculosis (XDR-TB, resistant to isoniazid and rifampicin, any fluoroquinolone and at least one injectable antimicrobial antituberculous agent) have been reported worldwide and are increasing in incidence.

The term 'post-antibiotic era' has been coined to describe a future in which the acquisition of resistance by bacteria will have been so extensive that antibiotic therapy is rendered useless. A more realistic scenario, which is currently being experienced, is a gradual but inexorable progression of resistance, necessitating the use of ever more toxic and expensive antimicrobials.

Duration of therapy

Treatment duration reflects the severity of infection and accessibility of the infected site to antimicrobial agents. For most infections, there is limited evidence available to support a specific duration of treatment (Box 6.17). Depending on the indication, initial intravenous therapy can often be switched to oral as soon as the patient is apyrexial and improving. In the absence of specific guidance, antimicrobial therapy should be stopped when there is no longer any clinical evidence of infection.

Pharmacokinetics and pharmacodynamics

Pharmacokinetics of antimicrobial agents determine whether adequate concentrations are obtained at the sites of infection. Septic patients often have poor gastrointestinal absorption, so the preferred initial route of therapy is intravenous. Knowledge of anticipated antimicrobial drug concentrations at sites of infection is critical. For example, achieving a 'therapeutic' blood level of gentamicin is of little practical use in treating meningitis, as CSF penetration of the drug is poor. Knowledge of routes of antimicrobial elimination is also critical; for instance, urinary tract infection is ideally treated with a drug that is excreted unchanged in the urine.

Pharmacodynamics describes the relationship between antimicrobial concentration and microbial killing. For many agents, antimicrobial effect can be categorised as 'concentration-dependent' or 'time-dependent'. The concentration of antimicrobial achieved after a single dose is illustrated in Figure 6.17. The maximum concentration achieved is C_{max} and the measure of overall exposure is the area under the curve (AUC). The efficacy of antimicrobial agents whose killing is concentration-dependent (e.g. aminoglycosides) increases with the amount by which C_{max} exceeds the minimum inhibitory concentration (C_{max} : MIC ratio). For this reason, it has become customary to administer aminoglycosides (e.g. gentamicin) infrequently at high doses (e.g. 7 mg/kg) rather than frequently at low doses. This has the added advantage of minimising toxicity by reducing the likelihood

i 6.17 Duration of antimicrobial therapy for some common infections*

Infection	Duration of therapy
Viral infections	
Herpes simplex encephalitis	2–3 weeks
Bacterial infections	
Gonorrhoea	Single dose
Infective endocarditis (streptococcal, native valve)	4 weeks ± gentamicin for first 2 weeks
Infective endocarditis (prosthetic valve)	6 weeks
Osteomyelitis	6 weeks
Pneumonia (community-acquired, severe)	7–10 days (no organism identified), 14–21 days (*Staph. aureus* or *Legionella* spp.)
Septic arthritis	2–4 weeks
Urinary tract infection (male)	2 weeks
Urinary tract infection, upper tract, uncomplicated (female)	7 days
Urinary tract infection, lower (female)	3 days
Mycobacterial infections	
Tuberculosis (meningeal)	12 months
Tuberculosis (pulmonary)	6 months
Fungal infections	
Invasive pulmonary aspergillosis	Until clinical/radiological resolution and reversal of predisposition
Candidaemia (acute disseminated)	2 weeks after last positive blood culture and resolution of signs and symptoms

*All recommendations are indicative. Actual duration takes into account predisposing factors, specific organisms and antimicrobial susceptibility, adjuvant therapies, current guidelines and clinical response.

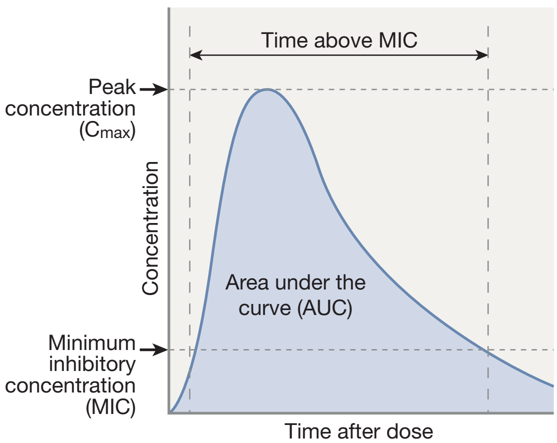

Fig. 6.17 Antimicrobial pharmacodynamics. The curve represents drug concentrations after a single dose of an antimicrobial agent. Factors that determine microbial killing are C_{max} : MIC ratio (concentration-dependent killing), time above MIC (time-dependent killing) and AUC : MIC ratio.

of drug accumulation. Conversely, the β-lactam antibiotics and vancomycin exhibit time-dependent killing, and their efficacy depends on C_{max} exceeding the MIC for a certain time (which is different for each class of agent). This is reflected in the dosing interval of benzylpenicillin, which is usually given every 4 hours in severe infection (e.g. meningococcal meningitis), and may be administered by continuous infusion. For other antimicrobial agents, the pharmacodynamic relationships are more complex and often less well understood. With some agents, bacterial inhibition persists after antimicrobial exposure (post-antibiotic and post-antibiotic sub-MIC effects).

Therapeutic drug monitoring

Therapeutic drug monitoring is used to confirm that levels of antimicrobial agents with a low therapeutic index (e.g. aminoglycosides) are not excessive, and that levels of agents with marked pharmacokinetic variability (e.g. vancomycin) are adequate. Specific recommendations for monitoring depend on individual clinical circumstances; for instance, different pre- and post-dose levels of gentamicin are recommended, depending on whether it is being used in traditional divided doses, once daily or for synergy in endocarditis (p. 530).

Antimicrobial prophylaxis

Antimicrobial prophylaxis is the use of antimicrobial agents to prevent infection. Primary prophylaxis is used to reduce the risk of infection following certain medical procedures (e.g. colonic resection or prosthetic hip insertion), following exposure to a specific pathogen (e.g. *Bordetella pertussis*) or in specific situations such as post-splenectomy (Box 6.18). It should be

i 6.18 Recommendations for antimicrobial prophylaxis in adults*

Infection risk	Recommended antimicrobial
Bacterial	
Diphtheria (prevention of secondary cases)	Erythromycin
Gas gangrene (after high amputation or major trauma)	Penicillin or metronidazole
Lower gastrointestinal tract surgery	Cefuroxime + metronidazole, gentamicin + metronidazole, or co-amoxiclav (single dose only)
Meningococcal disease (prevention of secondary cases)	Rifampicin or ciprofloxacin
Rheumatic fever (prevention of recurrence)	Phenoxymethylpenicillin or sulfadiazine
Tuberculosis (prevention of secondary cases)	Isoniazid ± rifampicin
Whooping cough (prevention of secondary cases)	Erythromycin
Viral	
HIV, occupational exposure (sharps injury)	Combination tenofovir/ emtricitabine and raltegravir. Modified if index case's virus known to be resistant
Influenza A (prevention of secondary cases in adults with chronic respiratory, cardiovascular or renal disease, immunosuppression or diabetes mellitus)	Oseltamivir
Fungal	
Aspergillosis (in high-risk haematology patients)	Posaconazole (voriconazole or itraconazole alternatives if intolerant)
Pneumocystis pneumonia (prevention in HIV and other immunosuppressed states)	Co-trimoxazole, pentamidine or dapsone
Protozoal	
Malaria (prevention of travel-associated disease)	Specific antimalarials depend on travel itinerary (p. 278)

*These are based on current UK practice. Recommendations may vary locally or nationally. Antimicrobial prophylaxis for infective endocarditis during dental procedures is not currently recommended in the UK.

associated with minimal adverse effects. In the case of exposure, it may be combined with passive immunisation (see Box 6.12). Secondary prophylaxis is used in patients who have been treated successfully for an infection but remain predisposed to it. It is used in haemato-oncology patients in the context of fungal infection and in HIV-positive individuals with an opportunistic infection until a defined level of immune reconstitution is achieved.

Antibacterial agents

For details of antibacterial usage in pregnancy and old age, see Boxes 6.19 and 6.20.

6.19 Antimicrobial agents in pregnancy[1]

Contraindicated

- Chloramphenicol: neonatal 'grey baby' syndrome – collapse, hypotension and cyanosis
- Fluconazole: teratogenic in high doses
- Quinolones: arthropathy in animal studies
- Sulphonamides: neonatal haemolysis and methaemoglobinaemia
- Tetracyclines, glycylcyclines: skeletal abnormalities in animals in first trimester; fetal dental discoloration and maternal hepatotoxicity with large parenteral doses in second or third trimesters
- Trimethoprim: teratogenic in first trimester

Relatively contraindicated

- Aminoglycosides: potential damage to fetal auditory and vestibular nerves in second and third trimesters
- Metronidazole: avoidance of high dosages is recommended[2]

Not known to be harmful; use only when necessary

- Aciclovir
- Cephalosporins
- Clarithromycin
- Clindamycin
- Erythromycin
- Glycopeptides
- Linezolid
- Meropenem
- Penicillins

[1]Data extracted from Joint Formulary Committee. British National Formulary (online). London: BMJ Group and Pharmaceutical Press; (medicinescomplete.com) [accessed on 16 March 2013]. [2]Theoretical risk of teratogenicity, not supported by available clinical evidence.

6.20 Problems with antimicrobial therapy in old age

- ***Clostridium difficile* infection**: all antibiotics predispose to some extent, but second- and third-generation cephalosporins, co-amoxiclav and fluoroquinolones (e.g. ciprofloxacin) especially so.
- **Hypersensitivity reactions**: rise in incidence due to increased previous exposure.
- **Renal impairment**: may be significant in old age, despite 'normal' creatinine levels (p. 386).
- **Nephrotoxicity**: more likely, e.g. first-generation cephalosporins, aminoglycosides.
- **Accumulation of β-lactam antibiotics**: may result in myoclonus, seizures or coma.
- **Reduced gastric acid production**: gastric pH is higher, which causes increased penicillin absorption.
- **Reduced hepatic metabolism**: results in a higher risk of isoniazid-related hepatotoxicity.
- **Quinolones**: associated with delirium and may increase the risk of seizures.

Beta-lactam antibiotics

These antibiotics have a β-lactam ring structure and exert a bactericidal action by inhibiting enzymes involved in cell wall synthesis (penicillin-binding proteins, PBPs). They are classified in Box 6.21.

Pharmacokinetics

- Good drug levels are achieved in lung, kidney, bone, muscle and liver, and in pleural, synovial, pericardial and peritoneal fluids.
- CSF levels are low, except when meninges are inflamed.
- Activity is not inhibited in abscess (e.g. by low pH and PO_2, high protein or neutrophils).
- Beta-lactams are subject to an 'inoculum effect' – activity is reduced in the presence of a high organism burden (PBP expression is down-regulated by high organism density).
- Generally safe in pregnancy (except imipenem/cilastatin).

Adverse effects

Immediate (IgE-mediated) allergic reactions are rare but life-threatening. Approximately 90% of patients who report a penicillin allergy do not have a true IgE-mediated allergy. Other reactions, such as rashes, fever and haematological effects (e.g. low white cell count), usually follow more prolonged therapy (more than 2 weeks). A large proportion of patients with infectious mononucleosis develop a rash if given aminopenicillins; this does not imply lasting allergy. The relationship between allergy to penicillin and allergy to cephalosporins depends on the specific cephalosporin used; there is significant cross-reactivity with first-generation cephalosporins but cross-reactivity to second-/third-generation cephalosporins is less common. Avoidance of cephalosporins, however, is recommended in patients who have IgE-mediated penicillin allergy (p. 84). Cross-reactivity between penicillin and carbapenems is rare (approximately 1% by skin testing) and carbapenems may be administered if there are no suitable alternatives and appropriate resuscitation facilities are available. The monobactam aztreonam (p. 121) is the β-lactam least likely to cross-react in patients with penicillin allergy.

Gastrointestinal upset and diarrhoea are common, and a mild reversible hepatitis is recognised with many β-lactams. More severe forms of hepatitis can be observed with flucloxacillin and co-amoxiclav. Leucopenia, thrombocytopenia, coagulation

6.21 Beta-lactam antibiotics

Penicillins

- Natural penicillins: benzylpenicillin, phenoxymethylpenicillin
- Penicillinase-resistant penicillins: meticillin, flucloxacillin, nafcillin, oxacillin
- Aminopenicillins: ampicillin, amoxicillin
- Carboxy- and ureido-penicillins: ticarcillin, piperacillin, temocillin

Cephalosporins

- See Box 6.22

Monobactams

- Aztreonam

Carbapenems

- Imipenem, meropenem, ertapenem, doripenem

deficiencies, interstitial nephritis and potentiation of aminoglycoside-mediated kidney damage are also recognised (p. 122). Seizures and encephalopathy have been reported, particularly with high doses in the presence of renal insufficiency. Thrombophlebitis occurs in up to 5% of patients receiving parenteral β-lactams.

Drug interactions

Synergism occurs in combination with aminoglycosides in vitro. Ampicillin decreases the biological effect of oral contraceptives and the whole class is significantly affected by concurrent administration of probenecid, producing a 2–4-fold increase in the peak serum concentration.

Penicillins

Natural penicillins are primarily effective against Gram-positive organisms (except staphylococci, most of which produce a penicillinase) and anaerobic organisms. *Strep. pyogenes* has remained sensitive to natural penicillins worldwide. According to the European Antimicrobial Resistance Surveillance Network (EARS-Net), the prevalence of non-susceptibility to penicillin in *Strep. pneumoniae* in Europe in 2014 varied widely from 0% (Cyprus) to 46.7% (Romania).

Penicillinase-resistant penicillins are the mainstay of treatment for infections with *Staph. aureus*, other than MRSA. However, EARS-Net data from 2014 indicate that MRSA rates in Europe vary widely from 0.9% (Netherlands) to 56% (Romania).

Aminopenicillins have the same spectrum of activity as the natural penicillins, with additional Gram-negative cover against Enterobacteriaceae. Amoxicillin has better oral absorption than ampicillin. Unfortunately, resistance to these agents is widespread (57.1% of *E. coli* Europe-wide in 2014, range 34.7–73%), so they are no longer appropriate for empirical use in Gram-negative infections. In many organisms, resistance is due to β-lactamase production, which can be overcome by the addition of β-lactamase inhibitors (clavulanic acid or sulbactam).

Carboxypenicillins (e.g. ticarcillin) and ureidopenicillins (e.g. piperacillin) are particularly active against Gram-negative organisms, especially *Pseudomonas* spp., which are resistant to the aminopenicillins. Beta-lactamase inhibitors may be added to extend their spectrum of activity (e.g. piperacillin–tazobactam). Temocillin is derived from ticarcillin; it has good activity against Enterobacteriaceae, including those that produce ESBL enzymes, but poor activity against *Pseudomonas aeruginosa* and Gram-positive bacteria.

Cephalosporins and cephamycins

Cephalosporins are broad-spectrum agents. Unfortunately, their use is associated with CDI (p. 264). With the exception of ceftobiprole, the group has no activity against enterococci. Only the cephamycins have anti-anaerobic activity. All cephalosporins are inactivated by ESBL. Cephalosporins are arranged in 'generations' (Box 6.22).

- *First-generation compounds* have excellent activity against Gram-positive organisms and some activity against Gram-negatives.
- *Second-generation drugs* retain Gram-positive activity but have extended Gram-negative activity. Cephamycins (e.g. cefoxitin), included in this group, are active against anaerobic Gram-negative bacilli.
- *Third-generation agents* further improve anti-Gram-negative cover. For some (e.g. ceftazidime), this is extended to include *Pseudomonas* spp. Cefotaxime and ceftriaxone have excellent Gram-negative activity and retain good activity against *Strep. pneumoniae* and β-haemolytic streptococci. Ceftriaxone is administered once daily and is therefore a suitable agent for outpatient intravenous (parenteral) antimicrobial therapy (OPAT).
- *Fourth-generation agents*, e.g. cefipime, have a broad spectrum of activity, including streptococci and some Gram-negatives, including *P. aeruginosa.*
- *Fifth-generation agents*, such as ceftobiprole and ceftaroline, have an enhanced spectrum of Gram-positive activity that includes MRSA, and also have activity against Gram-negative bacteria; some, such as ceftobiprole, are active against *P. aeruginosa*.

i 6.22 Cephalosporins

First generation	
• Cefalexin, cefradine (oral)	• Cefazolin (IV)
Second generation	
• Cefuroxime (oral/IV) • Cefaclor (oral)	• Cefoxitin (IV)
Third generation	
• Cefixime (oral) • Cefotaxime (IV)	• Ceftriaxone (IV) • Ceftazidime (IV)
Fourth generation	
• Cefepime (IV)	
Fifth generation (also referred to as 'next generation')	
• Ceftobiprole (IV)	• Ceftaroline (IV)

The spectrum of cephalosporins has also been enhanced by adding β-lactamase inhibitors.

Monobactams

Aztreonam is the only available monobactam. It is active against Gram-negative bacteria, except ESBL-producing organisms, but inactive against Gram-positive organisms or anaerobes. It is a parenteral-only agent and may be used safely in most penicillin-allergic patients other than those with an allergy to ceftazidime, which shares a common side chain with aztreonam.

Carbapenems

These intravenous agents have the broadest antibiotic activity of the β-lactam antibiotics, covering most clinically significant bacteria, including anaerobes (e.g. imipenem, meropenem, ertapenem).

Macrolide and lincosamide antibiotics

Macrolides (e.g. erythromycin, clarithromycin and azithromycin) and lincosamides (e.g. clindamycin) are bacteriostatic agents. Both classes bind to the same component of the ribosome, so they are not administered together. Macrolides are used for *Legionella*, *Mycoplasma*, *Chlamydia* and *Bordetella* infections. Azithromycin is employed for single-dose/short-course therapy for genitourinary *Chlamydia/Mycoplasma* spp. infections. Clindamycin is used primarily for skin, soft tissue, bone and joint infections.

Pharmacokinetics

Macrolides

- Variable bioavailability (intravenous and oral preparations available).

- Frequency of administration: erythromycin is administered 4 times daily, clarithromycin twice daily, azithromycin once daily.
- High protein binding.
- Excellent intracellular accumulation.

Lincosamides (e.g. clindamycin)

- Good oral bioavailability.
- Food has no effect on absorption.
- Good bone/joint penetration; limited CSF penetration.

Adverse effects

- Gastrointestinal upset, especially in young adults (erythromycin 30%).
- Cholestatic jaundice with erythromycin estolate.
- Prolongation of QT interval can cause torsades de pointes (p. 476).
- Clindamycin predisposes to CDI.

Aminoglycosides and spectinomycin

Aminoglycosides are effective mainly in Gram-negative infections and are therefore commonly used in regimens for intra-abdominal infection. Some aminoglycosides, e.g. amikacin, are important components of therapy for MDR-TB. Because they act synergistically with β-lactam antibiotics they are used in combinations to treat biofilm infections, including infective endocarditis and orthopaedic implant infections. They cause very little local irritation at injection sites and negligible allergic responses. Oto- and nephrotoxicity must be avoided by monitoring of renal function and drug levels and by use of short treatment regimens. Aminoglycosides are not subject to an inoculum effect (p. 120) and they all exhibit a post-antibiotic effect (p. 119).

Pharmacokinetics

- Negligible oral absorption.
- Hydrophilic, so excellent penetration to extracellular fluid in body cavities and serosal fluids.
- Very poor intracellular penetration (except hair cells in cochlea and renal cortical cells).
- Negligible CSF and corneal penetration and may require intrathecal administration during neurosurgical infections.
- Peak plasma levels 30 minutes after infusion.
- Monitoring of therapeutic levels required.

Gentamicin dosing

- Except in certain forms of endocarditis, pregnancy, severe burns, end-stage renal disease and paediatric patients, gentamicin is administered at 7 mg/kg body weight. The appropriate dose interval depends on drug clearance and is determined by reference to the Hartford nomogram (Fig. 6.18).
- In streptococcal and enterococcal endocarditis, gentamicin is used with a cell wall active agent (usually a β-lactam), to provide synergy. Commonly used doses are 1 mg/kg 2–3 times daily for enterococcal endocarditis and 3 mg/kg once daily for most strains of oral streptococci. Target pre- and post-dose levels are <1 mg/L and 3–5 mg/L, respectively, when gentamicin is dosed 3 times daily.
- When not used according to the Hartford regimen or for endocarditis, gentamicin is administered twice or 3 times daily at 3–5 mg/kg/day. Target pre- and post-dose levels are <1 mg/L and 5–10 mg/L (7–10 mg/L with less sensitive organisms, e.g. *P. aeruginosa*), respectively.
- For other aminoglycosides, consult local guidance.

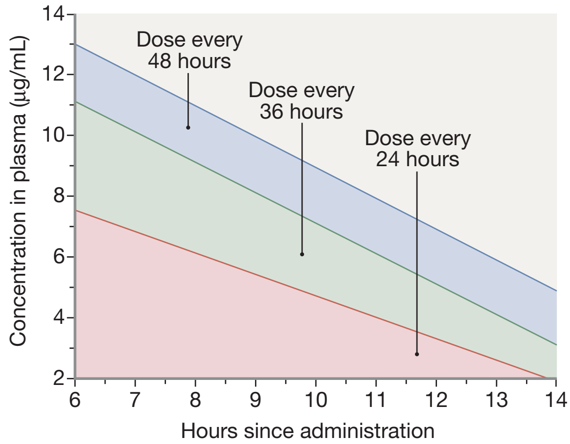

Fig. 6.18 Dosing of aminoglycosides using the Hartford nomogram. The nomogram is used to determine the dose interval for 7 mg doses of gentamicin or tobramycin, using measurements of drug levels in plasma 6–14 hours after a single dose.

Adverse effects

- Renal toxicity (usually reversible) accentuated by other nephrotoxic agents.
- Cochlear toxicity (permanent) more likely in older people and those with a predisposing mitochondrial gene mutation.
- Neuromuscular blockade after rapid intravenous infusion (potentiated by calcium channel blockers, myasthenia gravis and hypomagnesaemia).

Spectinomycin

Chemically similar to the aminoglycosides and given intramuscularly, spectinomycin was developed to treat strains of *Neisseria gonorrhoeae* resistant to β-lactam antibiotics. Unfortunately, resistance to spectinomycin is very common. Its only indication is the treatment of gonococcal urethritis in pregnancy or in patients allergic to β-lactam antibiotics.

Quinolones and fluoroquinolones

These are effective and generally well-tolerated bactericidal agents. The quinolones have purely anti-Gram-negative activity, whereas the fluoroquinolones are broad-spectrum agents (Box 6.23). Ciprofloxacin has anti-pseudomonal activity but resistance emerges rapidly. In 2014, European surveillance showed that resistance to fluoroquinolones in *E. coli* ranged between 7.8% (Iceland) and 46.4% (Cyprus). Quinolones and fluoroquinolones are used for a variety of common infections, including urinary tract infection and pneumonia, and less common problems like MDR-TB.

Pharmacokinetics

- Well absorbed after oral administration but delayed by food, antacids, ferrous sulphate and multivitamins.
- Wide volume of distribution; tissue concentrations twice those in serum.
- Good intracellular penetration, concentrating in phagocytes.

i 6.23 Quinolones and fluoroquinolones

Agent	Route of administration	Typical antimicrobial spectrum
Quinolones		
Nalidixic acid	Oral	Enteric Gram-negative bacilli (not *Pseudomonas aeruginosa*)
Fluoroquinolones		
Ciprofloxacin	IV/oral	Enteric Gram-negative bacilli, *P. aeruginosa*, *Haemophilus* spp., 'atypical' respiratory pathogens*
Norfloxacin	Oral	
Ofloxacin	IV/oral/topical	
Levofloxacin (L-isomer of ofloxacin)	IV/oral	*Haemophilus* spp., *Strep. pneumoniae*, 'atypical' respiratory pathogens*
Moxifloxacin	Oral	*Strep. pneumoniae*, *Staph. aureus*, 'atypical' respiratory pathogens*, Mycobacteria and anaerobes

*'Atypical' pathogens include *Mycoplasma pneumoniae* and *Legionella* spp. Fluoroquinolones have variable activity against *M. tuberculosis* and other mycobacteria.

Adverse effects

- Gastrointestinal side-effects in 1–5%.
- Rare skin reactions (phototoxicity).
- Tendinitis and Achilles tendon rupture, especially in older people.
- Central nervous system effects (delirium, tremor, dizziness and occasional seizures in 5–12%), especially in older people.
- Reduces clearance of xanthines and theophyllines, potentially inducing insomnia and increased seizure potential.
- Prolongation of QT interval on ECG, cardiac arrhythmias.
- Ciprofloxacin use is associated with the acquisition of MRSA and emergence of *C. difficile* ribotype 027 (p. 264).

Glycopeptides

Glycopeptides (vancomycin and teicoplanin) are effective against Gram-positive organisms only, and are used against MRSA and ampicillin-resistant enterococci. Some staphylococci and enterococci demonstrate intermediate sensitivity or resistance. Vancomycin use should be restricted to limit emergence of resistant strains. Teicoplanin is not available in all countries. Neither drug is absorbed after oral administration but vancomycin is used orally to treat CDI.

Pharmacokinetics

Vancomycin

- Administered by slow intravenous infusion, good tissue distribution and short half-life.
- Enters the CSF only in the presence of inflammation and may require intrathecal administration during neurosurgical infections.
- Therapeutic monitoring of intravenous vancomycin is recommended, to maintain pre-dose levels of >10 mg/L (15–20 mg/L in serious staphylococcal infections).

Teicoplanin

- Long half-life allows once-daily dosing.

Adverse effects

- Histamine release due to rapid vancomycin infusion produces a 'red man' reaction (rare with modern preparations).
- Nephrotoxicity is rare but may occur with concomitant aminoglycoside use, as may ototoxicity.
- Teicoplanin can cause rash, bronchospasm, eosinophilia and anaphylaxis.

Lipopeptides

Daptomycin is a cyclic lipopeptide with bactericidal activity against Gram-positive organisms (including MRSA and GRE) but not Gram-negatives. It is not absorbed orally, and is used intravenously to treat Gram-positive infections, such as soft tissue infections and *Staph. aureus* infective endocarditis. Daptomycin is not effective for community-acquired pneumonia. Treatment can be associated with increased levels of creatine kinase and eosinophilic pneumonitis.

Polymyxins

Colistin is a polymyxin antibiotic that binds and disrupts the outer cell membrane of Gram-negative bacteria, including *P. aeruginosa* and *Acinetobacter baumannii*. Its use has increased with the emergence and spread of multi-resistant Gram-negative bacteria, including CPEs. It can be administered by oral, intravenous and nebulised routes. Significant adverse effects include neurotoxicity, including encephalopathy, and nephrotoxicity.

Folate antagonists

These are bacteriostatic antibacterials (p. 109). A combination of a sulphonamide and either trimethoprim or pyrimethamine is most commonly used, which interferes with two consecutive steps in the metabolic pathway. Available combinations include trimethoprim/sulfamethoxazole (co-trimoxazole) and pyrimethamine with either sulfadoxine (used to treat malaria) or sulfadiazine (used in toxoplasmosis). Co-trimoxazole is the first-line drug for *Pneumocystis jirovecii* infection, the second-line drug for treatment and prevention of *B. pertussis* (whooping cough) infection, and is also used for a variety of other infections, including *Staph. aureus*. Dapsone is used to treat leprosy (Hansen's disease) and to prevent toxoplasmosis and pneumocystis when patients are intolerant of other medications. Folinic acid should be given to prevent myelosuppression if these drugs are used long-term or unavoidably in early pregnancy.

Pharmacokinetics

- Well absorbed orally.
- Sulphonamides are hydrophilic, distributing well to the extracellular fluid.
- Trimethoprim is lipophilic with high tissue concentrations.

Adverse effects

- Trimethoprim is generally well tolerated, with few adverse effects.
- Sulphonamides and dapsone may cause haemolysis in glucose-6-phosphate dehydrogenase deficiency (p. 948).
- Sulphonamides and dapsone cause skin and mucocutaneous reactions, including Stevens–Johnson syndrome and 'dapsone syndrome' (rash, fever and lymphadenopathy).
- Dapsone causes methaemoglobinaemia (p. 135) and peripheral neuropathy.

Tetracyclines and glycylcyclines

Tetracyclines

Of this mainly bacteriostatic class, the newer drugs doxycycline and minocycline show better absorption and distribution than older ones. Many streptococci and Gram-negative bacteria are now resistant, in part due to their use in animals (which is banned in Europe). Tetracyclines are indicated for *Mycoplasma* spp., *Chlamydia* spp., *Rickettsia* spp., *Coxiella* spp., *Bartonella* spp., *Borrelia* spp., *Helicobacter pylori*, *Treponema pallidum* and atypical mycobacterial infections. Tetracyclines can also be used for malaria prevention.

Pharmacokinetics

- Best oral absorption is in the fasting state (doxycycline is 100% absorbed unless gastric pH rises) and absorption is inhibited by cations, e.g. calcium or iron, which should not be administered at the same time.

Adverse effects

- All tetracyclines except doxycycline are contraindicated in renal failure.
- Dizziness with minocycline.
- Binding to metallic ions in bones and teeth causes discoloration (avoid in children and pregnancy) and enamel hypoplasia.
- Oesophagitis/oesophageal ulcers with doxycycline.
- Phototoxic skin reactions.

Glycylcyclines (tigecycline)

Chemical modification of tetracycline has produced tigecycline, a broad-spectrum, parenteral-only antibiotic with activity against resistant Gram-positive and Gram-negative pathogens, such as MRSA and ESBL (but excluding *Pseudomonas* spp.). Re-analysis of trial data has shown that there was excess mortality following tigecycline treatment as opposed to comparator antibiotics, so tigecycline should be used only when there has been adequate assessment of risk versus benefit.

Nitroimidazoles

Nitroimidazoles are highly active against strictly anaerobic bacteria, especially *Bacteroides fragilis*, *C. difficile* and other *Clostridium* spp. They also have significant antiprotozoal activity against amoebae and *Giardia lamblia*.

Pharmacokinetics

- Almost completely absorbed after oral administration (60% after rectal administration).
- Well distributed, especially to brain and CSF.
- Safe in pregnancy.

Adverse effects

- Metallic taste (dose-dependent).
- Severe vomiting if taken with alcohol – ‘Antabuse effect’.
- Peripheral neuropathy with prolonged use.

Phenicols

Chloramphenicol is the only example in clinical use. In developed countries its use tends to be reserved for severe and life-threatening infections when other antibiotics are either unavailable or impractical, largely because of concerns about toxicity. It is bacteriostatic to most organisms but apparently bactericidal to *H. influenzae*, *Strep. pneumoniae* and *N. meningitidis*. It has a very broad spectrum of activity against aerobic and anaerobic organisms, spirochaetes, *Rickettsia*, *Chlamydia* and *Mycoplasma* spp. It competes with macrolides and lincosamides for ribosomal binding sites, so should not be used in combination with these agents. Significant adverse effects are ‘grey baby’ syndrome in infants (cyanosis and circulatory collapse due to inability to conjugate drug and excrete the active form in urine); reversible dose-dependent bone marrow depression in adults receiving high cumulative doses; and severe aplastic anaemia in 1 in 25 000–40 000 exposures (unrelated to dose, duration of therapy or route of administration).

Oxazolidinones

Linezolid and tedizolid are examples and their good activity against Gram-positive organisms means they are often used to treat skin and soft tissue infections. They may also be used in infection caused by resistant Gram-positive bacteria, including MRSA and GRE. Administration can be intravenous or oral. Common linezolid adverse effects include mild gastrointestinal upset and tongue discoloration. Myelodysplasia and peripheral and optic neuropathy can occur with prolonged use. Linezolid has monoamine oxidase inhibitor (MAOI) activity, and co-administration with other MAOIs or serotonin re-uptake inhibitors should be avoided, as this may precipitate a ‘serotonin syndrome’ (p. 1199).

Other antibacterial agents

Fusidic acid

This antibiotic, active against Gram-positive bacteria, is available in intravenous, oral or topical formulations. It is lipid-soluble and distributes well to tissues. Its antibacterial activity is, however, unpredictable. Fusidic acid is used in combination, typically with antistaphylococcal penicillins, or for MRSA with clindamycin or rifampicin. It interacts with coumarin derivatives and oral contraceptives.

Nitrofurantoin

This drug has very rapid renal elimination and is active against aerobic Gram-negative and Gram-positive bacteria, including enterococci. It is used only for treatment of urinary tract infection, being generally safe in pregnancy and childhood. With prolonged treatment, however, it can cause eosinophilic lung infiltrates, fever, pulmonary fibrosis, peripheral neuropathy, hepatitis and haemolytic anaemia so its use must be carefully balanced against risks.

Fidaxomicin

Fidaxomicin is an inhibitor of RNA synthesis, and was introduced for the treatment of CDI in 2012. In non-severe CDI it is non-inferior to oral vancomycin and is associated with a lower recurrence rate. Its effectiveness has not been assessed in severe CDI.

Fosfomycin

Fosfomycin acts by inhibiting cell wall synthesis. It has activity against Gram-negative but also Gram-positive bacteria and can demonstrate in vitro synergy against MRSA when combined with other antimicrobials. It is used for treatment of urinary tract infections but can be employed in other situations against multi-resistant bacteria.

Antimycobacterial agents

Isoniazid

Isoniazid is bactericidal for replicating bacteria and bacteriostatic for non-replicating bacteria. It is activated by mycobacterial catalase-peroxidase (KatG) and inhibits the *InhA* gene product, a reductase involved in mycolic acid synthesis. Mutations in *KatG* or *InhA* result in isoniazid resistance, which was reported in 15% of cases of *M. tuberculosis* infection globally in 2013. Isoniazid is well absorbed orally and metabolised by acetylation in the liver. The major side-effects are hepatitis, neuropathy (ameliorated by co-administration of pyridoxine) and hypersensitivity reactions.

Rifampicin

Rifampicin inhibits DNA-dependent RNA polymerase and is bactericidal against replicating bacteria. It is also active in necrotic foci, where mycobacteria have low levels of replication, and is therefore important in sterilisation and sputum conversion. Resistance most often involves the β-subunit of RNA polymerase and most often occurs with isoniazid-resistant MDR-TB. Rifampicin is well absorbed orally. It is metabolised by the liver via the microsomal cytochrome P450 system and is one the most potent inducers of multiple P450 isoenzymes, so is subject to extensive drug–drug interactions. Common side-effects include hepatitis, influenza-like symptoms and hypersensitivity reactions. Orange discoloration of urine and body secretions is expected.

Pyrazinamide

The mechanism of action of pyrazinamide is incompletely defined but includes inhibition of fatty acid synthase and ribosomal trans-translation. Pyrazinamide is often bacteriostatic but can be bactericidal and is active against semidormant bacteria in a low-pH environment. Primary resistance is rare but MDR-TB strains are frequently pyrazinamide-resistant and intrinsic resistance is a feature of *Mycobacterium bovis* strains. Pyrazinamide is well absorbed orally and metabolised by the liver. Side-effects include nausea, hepatitis, asymptomatic elevation of uric acid and myalgia.

Ethambutol

Ethambutol is a bacteriostatic agent. It inhibits arabinosyl transferase, which is involved in the synthesis of arabinogalactan, a component of the mycobacterial cell wall. Resistance is usually seen when resistance to other antimycobacterial agents is also present, e.g. in MDR-TB strains. It is orally absorbed but, in contrast to the first-line agents described above, it achieves poor CSF penetration and is renally excreted. The major side-effect is optic neuritis with loss of red–green colour discrimination and impaired visual acuity. It can also cause hepatitis.

Streptomycin

Streptomycin is an aminoglycoside whose mechanism of action and side-effects are similar to those of other aminoglycosides. It is administered intramuscularly.

Other antituberculous agents

Second-line agents used in MDR or XDR strains (p. 116) include aminoglycosides (amikacin, capreomycin or kanamycin) and fluoroquinolones (moxifloxacin or levofloxacin), discussed above. Other established second-line agents administered orally are cycloserine (which causes neurological side-effects); ethionamide or prothionamide (which are not active with *InhA*-gene-mediated resistance but have reasonable CSF penetration; their side-effect profile includes gastrointestinal disturbance, hepatotoxicity and neurotoxicity); and paraminosalicylic acid (which causes rashes and gastrointestinal upset). Linezolid may also be used and has good CSF penetration, while meropenem with co-amoxiclav is occasionally chosen. New drugs developed for XDR-TB include delamanid and bedaquiline; their adverse effects include QT prolongation and cardiac arrhythmias. Their co-administration with other agents with a similar side-effect profile (e.g. fluoroquinolones) therefore requires careful risk assessment.

Clofazimine

Clofazimine is used against *M. leprae* and resistant strains of *M. tuberculosis*. Its mode of action may involve induction of oxidative stress and it is weakly bactericidal. Oral absorption is variable and it is excreted in the bile. Side-effects include gastrointestinal upset, dry eyes and skin, and skin pigmentation, especially in those with pigmented skin.

Antifungal agents

See Box 6.24.

i 6.24 Antifungal agents

Agent	Usual route(s) of administration	Clinically relevant antifungal spectrum
Imidazoles		
Miconazole Econazole Clotrimazole	Topical	*Candida* spp., dermatophytes
Ketoconazole	Topical, oral	*Malassezia* spp., dermatophytes, agents of eumycetoma
Triazoles		
Fluconazole	Oral, IV	Yeasts (*Candida* and *Cryptococcus* spp.)
Itraconazole	Oral, IV	Yeasts, dermatophytes, dimorphic fungi (p. 300), *Aspergillus* spp.
Voriconazole	Oral, IV	Yeasts and most filamentous fungi (excluding mucoraceous moulds)
Posaconazole	Oral, IV	Yeasts and many filamentous fungi (including most mucoraceous moulds)
Isavuconazole	Oral, IV	Yeasts and many filamentous fungi (variable activity against mucoraceous moulds)
Echinocandins		
Anidulafungin Caspofungin Micafungin	IV only	*Candida* spp., *Aspergillus* spp. (no activity against *Cryptococcus* spp. or mucoraceous moulds)
Polyenes		
Amphotericin B	IV	Yeasts and most dimorphic and filamentous fungi (including mucoraceous moulds)
Nystatin	Topical	
Others		
5-fluorocytosine	Oral, IV	Yeasts
Griseofulvin	Oral	Dermatophytes
Terbinafine	Topical, oral	Dermatophytes

Azole antifungals

The azoles (imidazoles and triazoles) inhibit synthesis of ergosterol, a constituent of the fungal cell membrane. Side-effects vary but include gastrointestinal upset, hepatitis and rash. Azoles are inhibitors of cytochrome P450 enzymes, so tend to increase exposure to cytochrome P450-metabolised drugs (p. 24).

Imidazoles

Miconazole, econazole, clotrimazole and ketoconazole are relatively toxic and therefore administered topically. Clotrimazole is used extensively to treat superficial fungal infections. Triazoles are used for systemic treatment because they are less toxic.

Triazoles

Fluconazole is effective against yeasts (*Candida* and *Cryptococcus* spp.) and has a long half-life (approximately 30 hours) and an excellent safety profile. The drug is highly water-soluble and distributes widely to all body sites and tissues, including CSF. Itraconazole is lipophilic and distributes extensively, including to toenails and fingernails. CSF penetration is poor. Because oral absorption is erratic, therapeutic drug monitoring is required. Voriconazole is well absorbed orally but variability in levels requires therapeutic drug monitoring. It is used mainly in aspergillosis (p. 596). Side-effects include photosensitivity, hepatitis and transient retinal toxicity. Posaconazole and isavuconazole are broad-spectrum azoles, with activity against *Candida* spp., *Aspergillus* spp. and some mucoraceous moulds. Isavuconazole is non-inferior to voriconazole in the management of invasive aspergillosis and may be considered as an alternative when voriconazole is not tolerated.

Echinocandins

The echinocandins inhibit β-1,3-glucan synthesis in the fungal cell wall. They have few significant adverse effects. Caspofungin, anidulafungin and micafungin are used to treat systemic candidosis, and caspofungin is also used in aspergillosis.

Polyenes

Amphotericin B (AmB) deoxycholate causes cell death by binding to ergosterol and damaging the fungal cytoplasmic membrane. Its use in resource-rich countries has been largely supplanted by less toxic agents. Its long half-life enables once-daily administration. CSF penetration is poor.

Adverse effects include immediate anaphylaxis, other infusion-related reactions and nephrotoxicity. Nephrotoxicity may be sufficient to require dialysis and occurs in most patients who are adequately dosed. It may be ameliorated by concomitant infusion of normal saline. Irreversible nephrotoxicity occurs with large cumulative doses of AmB.

Nystatin has a similar spectrum of antifungal activity to AmB. Its toxicity limits it to topical use, e.g. in oral and vaginal candidiasis.

Lipid formulations of amphotericin B

Lipid formulations of AmB have been developed to reduce AmB toxicity and have replaced AmB deoxycholate in many regions. They consist of AmB encapsulated in liposomes (liposomal AmB, L-AmB) or complexed with phospholipids (AmB lipid complex, ABLC). The drug becomes active on dissociating from its lipid component. Adverse effects are similar to, but considerably less frequent than, those with AmB deoxycholate, and efficacy is similar. Lipid formulations of AmB are used in invasive fungal disease, as empirical therapy in patients with neutropenic fever (p. 1327), and also in visceral leishmaniasis (p. 282).

Other antifungal agents

Flucytosine

Flucytosine (5-fluorocytosine) has particular activity against yeasts. When it is used as monotherapy, acquired resistance develops rapidly, so it should be given in combination with another antifungal agent. Adverse effects include myelosuppression, gastrointestinal upset and hepatitis.

Griseofulvin

Griseofulvin has been largely superseded by terbinafine and itraconazole for treatment of dermatophyte infections, except in children, for whom these agents remain largely unlicensed. It is deposited in keratin precursor cells, which become resistant to fungal invasion.

Terbinafine

Terbinafine distributes with high concentration to sebum and skin, with a half-life of more than 1 week. It is used topically for dermatophyte skin infections and orally for onychomycosis. The major adverse reaction is hepatic toxicity (approximately 1: 50 000 cases). Terbinafine is not recommended for breastfeeding mothers.

Antiviral agents

Most viral infections in immunocompetent individuals resolve without intervention. Antiviral therapy is available for a limited number of infections only (Box 6.25).

Antiretroviral agents

These agents, used predominantly against HIV, are discussed on page 324.

Anti-herpesvirus agents

Aciclovir, valaciclovir, penciclovir and famciclovir

These antivirals are acyclic analogues of guanosine, which inhibit viral DNA polymerase after being phosphorylated by virus-derived thymidine kinase (TK). Aciclovir is poorly absorbed after oral dosing; better levels are achieved intravenously or by use of the prodrug valaciclovir. Famciclovir is the prodrug of penciclovir. Resistance is mediated by viral TK or polymerase mutations.

Ganciclovir

Chemical modification of the aciclovir molecule allows preferential phosphorylation by protein kinases of cytomegalovirus (CMV) and other β-herpesviruses (e.g. human herpesvirus (HHV) 6/7) and hence greater inhibition of the DNA polymerase, but at the expense of increased toxicity. Ganciclovir is administered intravenously or as a prodrug (valganciclovir) orally.

Cidofovir

Cidofovir inhibits viral DNA polymerases with potent activity against CMV, including most ganciclovir-resistant CMV. It also has activity against aciclovir-resistant herpes simplex virus (HSV) and varicella zoster virus (VZV), HHV6 and occasionally adenovirus, poxvirus, papillomavirus or polyoma virus, and may be used to treat these infections in immunocompromised hosts.

6.25 Antiviral agents

Drug	Route(s) of administration	Indications	Significant side-effects
Antiretroviral therapy (ART, p. 324)	Oral	HIV infection (including AIDS)	CNS symptoms, anaemia, lipodystrophy
Anti-herpesvirus agents			
Aciclovir	Topical/oral/IV	Herpes zoster Chickenpox (esp. in immunosuppressed) Herpes simplex infections: encephalitis (IV only), genital tract, oral, ophthalmic	Significant side-effects rare Hepatitis, renal impairment and neurotoxicity reported rarely
Valaciclovir	Oral	Herpes zoster, herpes simplex	As for aciclovir
Famciclovir	Oral	Herpes zoster, herpes simplex (genital)	As for aciclovir
Penciclovir	Topical	Labial herpes simplex	Local irritation
Ganciclovir	IV	Treatment and prevention of CMV infection in immunosuppressed	Gastrointestinal symptoms, liver dysfunction, neurotoxicity, myelosuppression, renal impairment, fever, rash, phlebitis at infusion sites Potential teratogenicity
Valganciclovir	Oral	Treatment and prevention of CMV infection in immunosuppressed	As for ganciclovir but neutropenia is predominant
Cidofovir	IV/topical	HIV-associated CMV infections and occasionally other viruses (see text)	Renal impairment, neutropenia
Foscarnet	IV	CMV and aciclovir-resistant HSV and VZV infections in immunosuppressed	Gastrointestinal symptoms, renal impairment, electrolyte disturbances, genital ulceration, neurotoxicity
Anti-influenza agents			
Zanamivir	Inhalation	Influenza A and B	Allergic reactions (very rare)
Oseltamivir	Oral	Influenza A and B	Gastrointestinal side-effects, rash, hepatitis (very rare)
Peramivir	IV, IM		
Amantadine, rimantadine	Oral	Influenza A (but see text)	CNS symptoms, nausea
Agents used in other virus infections*			
Ribavirin	Oral/IV/inhalation	Lassa fever (IV) RSV infection in infants (inhalation)	Haemolytic anaemia, cough, dyspnoea, bronchospasm and ocular irritation (when given by inhalation)

*Antiviral agents used in viral hepatitis are discussed on pages 875 and 878. (AIDS = acquired immunodeficiency syndrome; CMV = cytomegalovirus; CNS = central nervous system; HIV = human immunodeficiency virus; HSV = herpes simplex virus; IM = intramuscular; IV = intravenous; RSV = respiratory syncytial virus; VZV = varicella zoster virus)

Foscarnet

This analogue of inorganic pyrophosphate acts as a non-competitive inhibitor of HSV, VZV, HHV6/7 or CMV DNA polymerase. It does not require significant intracellular phosphorylation and so may be effective when HSV or CMV resistance is due to altered drug phosphorylation. It has variable CSF penetration.

Anti-influenza agents

Zanamivir and oseltamivir

These agents inhibit influenza A and B neuraminidase, which is required for release of virus from infected cells (see Fig. 6.2, p. 101). They are used in the treatment and prophylaxis of influenza. Administration within 48 hours of disease onset reduces the duration of symptoms by approximately 1–1½ days. In the UK, their use is limited mainly to adults with chronic respiratory or renal disease, significant cardiovascular disease, immunosuppression or diabetes mellitus, during known outbreaks. Peramivir has been developed as a distinct chemical structure, which means that it retains activity against some oseltamivir- and zanamivir-resistant strains. It has poor oral bioavailability and has been developed as an intravenous or intramuscular formulation for treatment of severe cases of influenza, e.g. in intensive care units. It is now approved for use in adults in a number of countries. An intravenous formulation of zanamivir is also in development for critically ill patients. Laninamivir is approved as an intranasal formulation in Japan.

Amantadine and rimantadine

These drugs reduce replication of influenza A by inhibition of viral M2 protein ion channel function, which is required for uncoating (see Fig. 6.2). Resistance develops rapidly and is widespread, and amantadine and rimantadine should be used only if the prevalence of resistance locally is known to be low. They are no longer recommended for treatment or prophylaxis in the UK or USA, having been superseded by zanamivir and oseltamivir. However, they may still be indicated to treat oseltamivir-resistant influenza A in patients unable to take zanamivir (e.g. ventilated patients).

Other agents used to treat viruses

Antiviral agents used to treat hepatitis B and C virus are discussed on pages 875 and 878, and those used against HIV-1 are described on page 324.

Ribavirin

Ribavirin is a guanosine analogue that inhibits nucleic acid synthesis in a variety of viruses. It is used in particular in the treatment of hepatitis C virus but also against certain viral haemorrhagic fevers, e.g. Lassa fever, although it has not been useful against Ebola virus.

Antiparasitic agents

Antimalarial agents

Artemisinin (qinghaosu) derivatives

Artemisinin originates from a herb (sweet wormwood, *Artemisia annua*), which was used in Chinese medicine to treat fever. Its derivatives, artemether and artesunate, were developed for use in malaria in the 1970s. Their mechanism of action is unknown. They are used in the treatment, but not prophylaxis, of malaria, usually in combination with other antimalarials, and are effective against strains of *Plasmodium* spp. that are resistant to other antimalarials. Artemether is lipid-soluble and may be administered via the intramuscular and oral routes. Artesunate is water-soluble and is administered intravenously or orally. Serious adverse effects are uncommon. Current advice for malaria in pregnancy is that the artemisinin derivatives should be used to treat uncomplicated *falciparum* malaria in the second and third trimesters, but should not be prescribed in the first trimester until more information becomes available.

Atovaquone

Atovaquone inhibits mitochondrial function. It is an oral agent, used for treatment and prophylaxis of malaria, in combination with proguanil (see below), without which it is ineffective. It is also employed in the treatment of mild cases of *Pneumocystis jirovecii* pneumonia, where there is intolerance to co-trimoxazole. Significant adverse effects are uncommon.

Folate synthesis inhibitors (proguanil, pyrimethamine–sulfadoxine)

Proguanil inhibits dihydrofolate reductase and is used for malaria prophylaxis. Pyrimethamine–sulfadoxine may be used in the treatment of malaria.

Quinoline-containing compounds

Chloroquine and quinine are believed to act by intraparasitic inhibition of haem polymerisation, resulting in toxic build-up of intracellular haem. The mechanisms of action of other agents in this group (quinidine, amodiaquine, mefloquine, primaquine, etc.) may differ. They are employed in the treatment and prophylaxis of malaria. Primaquine is used for radical cure of malaria due to *Plasmodium vivax* and *P. ovale* (destruction of liver hypnozoites). Chloroquine may also be given for extra-intestinal amoebiasis.

Chloroquine can cause a pruritus sufficient to compromise adherence to therapy. If used in long-term, high-dose regimens, it causes an irreversible retinopathy. Overdosage leads to life-threatening cardiotoxicity. The side-effect profile of mefloquine includes neuropsychiatric effects ranging from mood change, nightmares and agitation to hallucinations and psychosis. Quinine may cause hypoglycaemia and cardiotoxicity, especially when administered parenterally. Primaquine causes haemolysis in people with glucose-6-phosphate dehydrogenase deficiency (p. 948), which should be excluded before therapy. Chloroquine is considered safe in pregnancy but mefloquine should be avoided in the first trimester.

Lumefantrine

Lumefantrine is used in combination with artemether to treat uncomplicated *falciparum* malaria, including chloroquine-resistant strains. Its mechanism of action is unknown. Significant adverse effects are uncommon.

Drugs used in trypanosomiasis

Benznidazole

Benznidazole is an oral agent used to treat South American trypanosomiasis (Chagas' disease, p. 279). Significant and common adverse effects include dose-related peripheral neuropathy, purpuric rash and granulocytopenia.

Eflornithine

Eflornithine inhibits biosynthesis of polyamines by ornithine decarboxylase inhibition, and is used in West African trypanosomiasis (*T. brucei gambiense* infection) of the central nervous system. It is administered as an intravenous infusion 4 times daily, which may be logistically difficult in the geographical areas affected by this disease. Significant adverse effects are common and include convulsions, gastrointestinal upset and bone marrow depression.

Melarsoprol

This is an arsenical agent, used to treat central nervous system infections in East and West African trypanosomiasis (*T. brucei rhodesiense* and *gambiense*). It is administered intravenously. Melarsoprol treatment is associated with peripheral neuropathy and reactive arsenical encephalopathy (RAE), which carries a significant mortality.

Nifurtimox

Nifurtimox is administered orally to treat South American trypanosomiasis (Chagas' disease). Gastrointestinal and neurological adverse effects are common.

Pentamidine isetionate

Pentamidine is an inhibitor of DNA replication used in West African trypanosomiasis (*T. brucei gambiense*) and, to a lesser extent, in visceral and cutaneous leishmaniasis. It is also prescribed in *Pneumocystis jirovecii* pneumonia. It is administered via intravenous or intramuscular routes. It is a relatively toxic drug, commonly causing rash, renal impairment, profound hypotension (especially on rapid infusion), electrolyte disturbances, blood dyscrasias and hypoglycaemia.

Suramin

Suramin is a naphthaline dye derivative, used to treat East African trypanosomiasis (*T. brucei rhodesiense*). It is administered intravenously. Adverse effects are common and include rash, gastrointestinal disturbance, blood dyscrasias, peripheral neuropathies and renal impairment.

Other antiprotozoal agents

Pentavalent antimonials

Sodium stibogluconate and meglumine antimoniate inhibit protozoal glycolysis by phosphofructokinase inhibition. They are used parenterally (intravenous or intramuscular) to treat leishmaniasis. Adverse effects include arthralgia, myalgias, raised hepatic transaminases, pancreatitis and electrocardiogram changes. Severe cardiotoxicity leading to death is not uncommon.

Diloxanide furoate

This oral agent is used to eliminate luminal cysts following treatment of intestinal amoebiasis, or in asymptomatic cyst excreters. The drug is absorbed slowly (enabling luminal persistence) and has no effect in hepatic amoebiasis. It is a relatively non-toxic drug, the most significant adverse effect being flatulence.

Iodoquinol (di-iodohydroxyquinoline)

Iodoquinol is a quinoline derivative (p. 128) with activity against *Entamoeba histolytica* cysts and trophozoites. It is used orally to treat asymptomatic cyst excreters or, in association with another amoebicide (e.g. metronidazole), to treat extra-intestinal amoebiasis. Long-term use of this drug is not recommended, as neurological adverse effects include optic neuritis and peripheral neuropathy.

Nitazoxanide

Nitazoxanide is an inhibitor of pyruvate–ferredoxin oxidoreductase-dependent anaerobic energy metabolism in protozoa. It is a broad-spectrum agent, active against various nematodes, tapeworms, flukes and intestinal protozoa. Nitazoxanide also has activity against some anaerobic bacteria and viruses. It is administered orally in giardiasis and cryptosporidiosis. Adverse effects are usually mild and involve the gastrointestinal tract (e.g. nausea, diarrhoea and abdominal pain).

Paromomycin

Paromomycin is an aminoglycoside (p. 122) that is used to treat visceral leishmaniasis and intestinal amoebiasis. It is not significantly absorbed when administered orally, and is therefore given orally for intestinal amoebiasis and by intramuscular injection for leishmaniasis. It showed early promise in the treatment of HIV-associated cryptosporidiosis but subsequent trials have demonstrated that this effect is marginal at best.

Drugs used against helminths

Benzimidazoles (albendazole, mebendazole)

These agents act by inhibiting both helminth glucose uptake, causing depletion of glycogen stores, and fumarate reductase. Albendazole is used for hookworm, ascariasis, threadworm, *Strongyloides* infection, trichinellosis, *Taenia solium* (cysticercosis) and hydatid disease. Mebendazole is used for hookworm, ascariasis, threadworm and whipworm. The drugs are administered orally. Absorption is relatively poor but is increased by a fatty meal. Significant adverse effects are uncommon.

Bithionol

Bithionol is used to treat fluke infections with *Fasciola hepatica*. It is well absorbed orally. Adverse effects are mild (e.g. nausea, vomiting, diarrhoea, rashes) but relatively common (approximately 30%).

Diethylcarbamazine

Diethylcarbamazine (DEC) is an oral agent used to treat filariasis and loiasis. Treatment of filariasis is often followed by fever, headache, nausea, vomiting, arthralgia and prostration. This is caused by the host response to dying microfilariae, rather than the drug, and may be reduced by pre-treatment with glucocorticoids.

Ivermectin

Ivermectin binds to helminth nerve and muscle cell ion channels, causing increased membrane permeability. It is an oral agent, used in *Strongyloides* infection, filariasis and onchocerciasis. Significant side-effects are uncommon.

Niclosamide

Niclosamide inhibits oxidative phosphorylation, causing paralysis of helminths. It is an oral agent, used in *Taenia saginata* and intestinal *T. solium* infection. Systemic absorption is minimal and it has few significant side-effects.

6

Piperazine

Piperazine inhibits neurotransmitter function, causing helminth muscle paralysis. It is an oral agent, used in ascariasis and threadworm (*Enterobius vermicularis*) infection. Significant adverse effects are uncommon but include neuropsychological reactions such as vertigo, delirium and convulsions.

Praziquantel

Praziquantel increases membrane permeability to Ca^{2+}, causing violent contraction of worm muscle. It is the drug of choice for schistosomiasis and is also used in *T. saginata*, *T. solium* (cysticercosis) and fluke infections (*Clonorchis*, *Paragonimus*) and in echinococcosis. It is administered orally and is well absorbed. Adverse effects are usually mild and transient, and include nausea and abdominal pain.

Pyrantel pamoate

This agent causes spastic paralysis of helminth muscle through a suxamethonium-like action. It is used orally in ascariasis and threadworm infection. Systemic absorption is poor and adverse effects are uncommon.

Thiabendazole

Thiabendazole inhibits fumarate reductase, which is required for energy production in helminths. It is used orally in *Strongyloides* infection and topically to treat cutaneous larva migrans. Significant adverse effects are uncommon.

Poisoning

Comprehensive evaluation of the poisoned patient

1 Airway, breathing, circulation
Respiration rate, oxygen saturation, pulse, BP, dysrhythmias

2 Level of consciousness
Presence of seizures, delirium, agitation or psychosis

3 Chest
Evidence of aspiration, bronchoconstriction

4 Movement and muscles
Tone, fasciculations, myoclonus, tremor, paralysis, ataxia

5 Reflexes
Tendon reflexes, plantar responses, inducible clonus

6 Eyes
Miosis or mydriasis, diplopia or strabismus, lacrimation

▲ Pinpoint pupil

▲ Injected conjunctiva

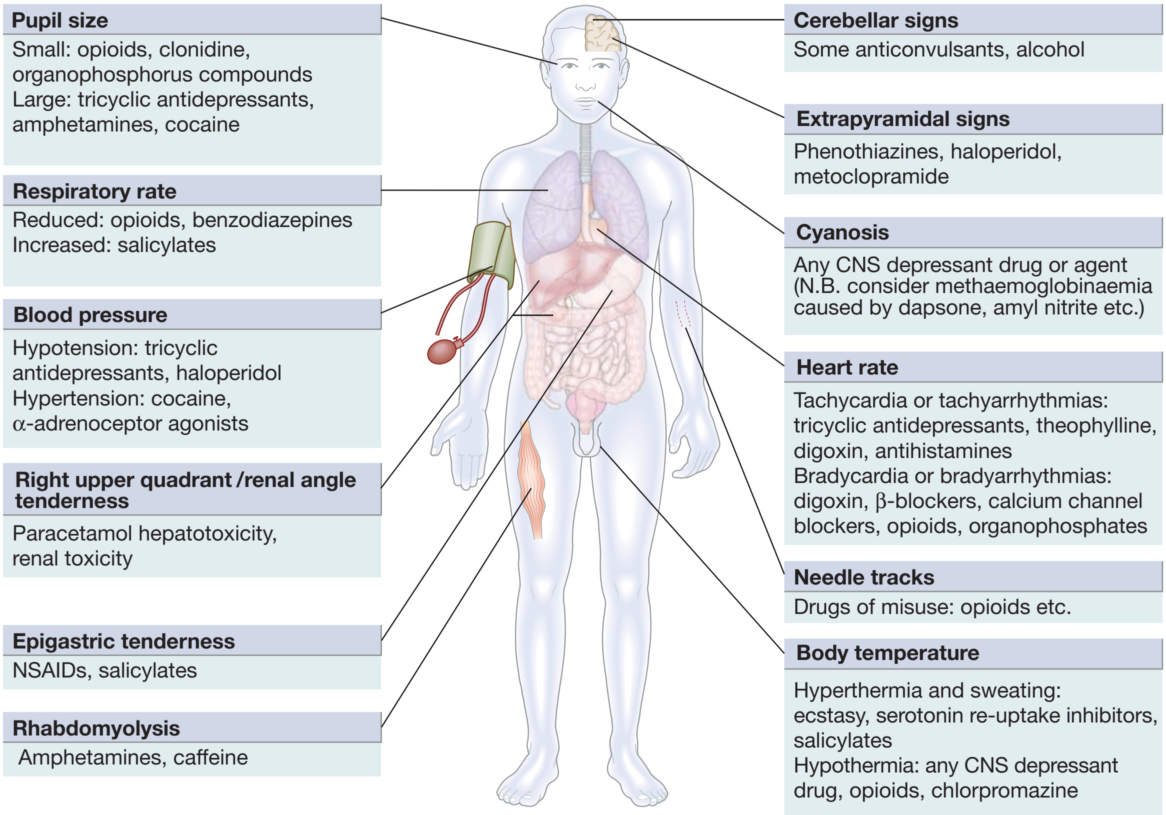
7 Abdomen
Hepatic or epigastric tenderness, ileus, palpable bladder

8 Skin
Temperature, cyanosis, flushing, sweating, blisters, pressure areas, piloerection, evidence of self-harm

▲ Self-cutting

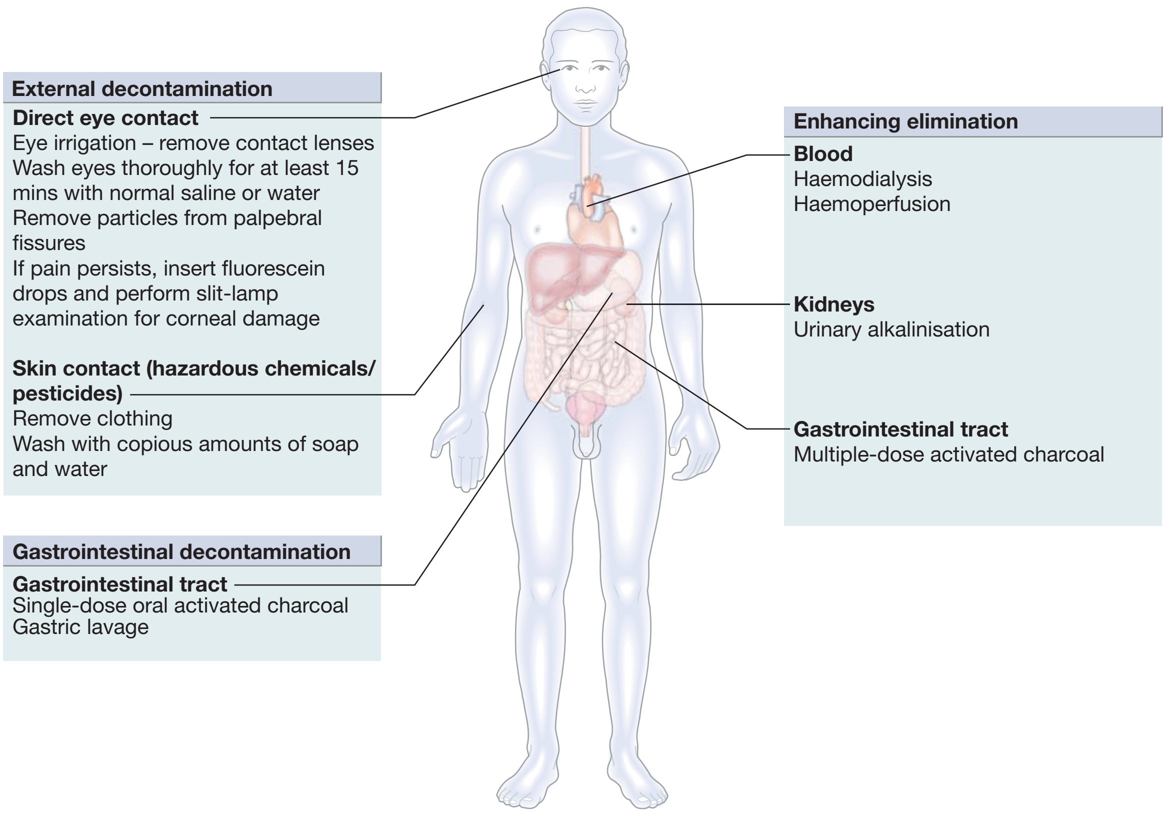
▲ Chemical burn

▲ Needle tracks



9 Mouth
Dry mouth, excessive salivation

10 Psychiatric evaluation
Features of psychiatric illness, mental capacity



Insets (Self-cutting) From Douglas G, Nicol F, Robertson C (eds). Macleod's Clinical examination, 11th edn. Churchill Livingstone, Elsevier Ltd; 2005. (Chemical burn) www.firewiki.net. i Taking a history in poisoning

- What toxin(s) have been taken and how much?
- What time were they taken and by what route?
- Has alcohol or any other substance (or substances, including drugs of misuse) been taken as well?
- Obtain details from witnesses (e.g. family, friends, ambulance personnel) of the circumstances of the overdose
- Assess immediate suicide risk in those with apparent self-harm (full psychiatric evaluation when patient has recovered physically)
- Assess capacity to make decisions about accepting or refusing treatment
- Establish past medical history, drug history and allergies, social and family history
- Record all information carefully

Clinical signs of poisoning by pharmaceutical agents and drugs of misuse.

Decontamination and enhanced elimination. One of the key aspects in the evaluation of a poisoned patient is deciding if decontamination and/or enhanced elimination is required.

Acute poisoning is common, accounting for about 1% of hospital admissions in the UK. Common or otherwise important substances involved are shown in Box 7.1. In developed countries, the most frequent cause is intentional drug overdose in the context of self-harm, often involving prescribed or 'over-the-counter' medicines. Accidental poisoning is also common, especially in children and the elderly (Box 7.2). Toxicity also results from alcohol or recreational substance use, or following occupational or environmental exposure. Poisoning is a major cause of death in young adults, but most deaths occur before patients reach medical attention, and mortality is low (<1%) in those admitted to hospital.

In developing countries, the frequency of self-harm is more difficult to estimate. Because of their widespread availability and use, household and agricultural products, such as pesticides and herbicides, are common sources of poisoning and have a much higher case fatality. In China and South-east Asia, pesticides account for about 300 000 suicides each year. Snake bite and other forms of envenomation are also important causes of morbidity and mortality internationally and are discussed in Chapter 8.

i 7.1 Important substances involved in poisoning

In the UK

- Analgesics: paracetamol and non-steroidal anti-inflammatory drugs (NSAIDs)
- Antidepressants: tricyclic antidepressants (TCAs), selective serotonin re-uptake inhibitors (SSRIs) and lithium
- Cardiovascular agents: β-blockers, calcium channel blockers and cardiac glycosides
- Drugs of misuse: depressants (e.g. opiates, benzodiazepines), stimulants and entactogens (e.g. amphetamines, MDMA, mephedrone, cocaine), hallucinogens (e.g. cannabis, synthetic cannabinoid receptor agonists, LSD)
- Carbon monoxide
- Alcohol

In South and South-east Asia

- Organophosphorus and carbamate insecticides
- Aluminium and zinc phosphide
- Oleander
- Corrosives
- Snake venoms (Ch. 8)

(LSD = lysergic acid diethylamide; MDMA = 3,4-methylene-dioxymethamphetamine, ecstasy)

7.2 Poisoning in old age

- **Aetiology**: may result from accidental poisoning (e.g. due to delirium or dementia) or drug toxicity as a consequence of impaired renal or hepatic function or drug interaction. Toxic prescription medicines are more likely to be available.
- **Psychiatric illness**: self-harm is less common than in younger adults but more frequently associated with depression and other psychiatric illness, as well as chronic illness and pain. There is a higher risk of subsequent suicide.
- **Severity of poisoning**: increased morbidity and mortality result from reduced renal and hepatic function, lower functional reserve, increased sensitivity to sedative agents and frequent comorbidity.

General approach to the poisoned patient

A general approach is shown on pages 132–133. In many countries, poisons centres are available to provide advice on management of suspected poisoning with specific substances. Information is also available online (p. 150).

Triage and resuscitation

Patients who are seriously poisoned must be identified early so that appropriate management is not delayed. Triage involves:

- immediately assessing vital signs
- identifying the poison(s) involved and obtaining adequate information about them
- identifying patients at risk of further attempts at self-harm and removing any remaining hazards.

Those with possible external contamination with chemical or environmental toxins should undergo appropriate decontamination (p. 133). Critically ill patients must be resuscitated (p. 174).

The Glasgow Coma Scale (GCS) is commonly employed to assess conscious level, although not specifically validated in poisoning. The AVPU (alert/verbal/painful/unresponsive) scale is also a rapid and simple method. An electrocardiogram (ECG) should be performed and cardiac monitoring instituted in all patients with cardiovascular features or where exposure to potentially cardiotoxic substances is suspected. Patients who may need antidotes should be weighed if possible, so that appropriate weight-related doses can be prescribed.

Substances unlikely to be toxic in humans should be identified so that inappropriate admission and intervention are avoided (Box 7.3).

Clinical assessment and investigations

History and examination are described on page 132. Occasionally, patients may be unaware of or confused about what they have taken, or may exaggerate (or, less commonly, underestimate) the size of the overdose, but rarely mislead medical staff deliberately. In regions of the world where self-poisoning is illegal, patients may be reticent about giving a history.

Toxic causes of abnormal physical signs are shown on page 133. The patient may have a cluster of clinical features ('toxidrome') suggestive of poisoning with a particular drug type, e.g. anticholinergic, serotoninergic (see Box 7.10), stimulant, sedative, opioid (see Box 7.12) or cholinergic (see Box 7.14) feature clusters. Poisoning is a common cause of coma, especially

i 7.3 Substances of very low toxicity

- Writing/educational materials, e.g. pencil lead, crayons, chalk
- Decorating products, e.g. emulsion paint, wallpaper paste
- Cleaning/bathroom products (except dishwasher tablets and liquid laundry detergent capsules, which can be corrosive)
- Pharmaceuticals: oral contraceptives, most antibiotics (but not tetracyclines or antituberculous drugs), vitamins B, C and E, prednisolone, emollients and other skin creams, baby lotion
- Miscellaneous: plasticine, silica gel, most household plants, plant food, pet food, soil

Causes

Non-toxic

- Congenital methaemoglobinaemias

Toxic (Oxidising agents)

- Organic nitrites
- Nitrates
- Benzocaine
- Dapsone
- Chloroquine
- Aniline dyes
- Chlorobenzene
- Naphthalene
- Copper sulphate

Consequences

- Haemoglobin–oxygen dissociation curve is shifted to the left (see Fig. 23.5)
- Oxygen delivery to tissues is reduced
- There is apparent 'cyanosis'
- Breathlessness, fatigue, headache and chest pain occur
- Delirium, impaired consciousness and seizures may occur in severe cases

Treatment

- Methylthionium chloride ('methylene blue') 1–2 mg/kg (intravenous) is given
- Reduces methaemoglobin (see below)
- Used for symptomatic patients with severe methaemoglobinaemia (e.g. >30%)
- Patients with anaemia or other comorbidities may need treatment at lower concentrations

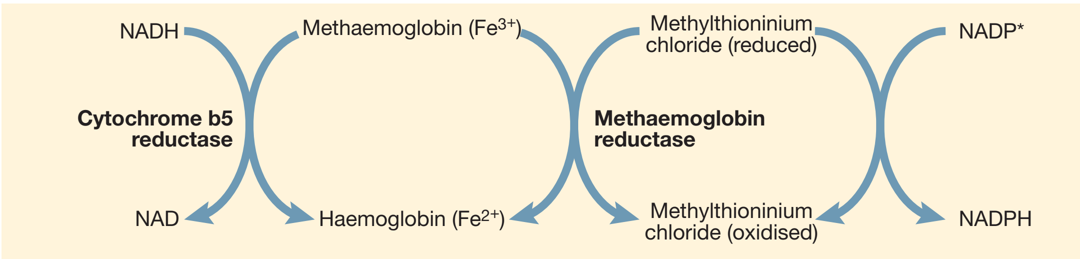

Fig. 7.1 Methaemoglobinaemia.

7.4 Causes of acidosis in the poisoned patient

Cause	Normal lactate*	High lactate
Toxic	Salicylates Methanol Ethylene glycol Paraldehyde	Metformin Iron Cyanide Sodium valproate Carbon monoxide
Other	Renal failure Ketoacidosis Severe diarrhoea	Shock

*Unless circulatory shock is present, when it will be high in any case.

7.5 Anion and osmolar gaps in poisoning

	Anion gap	Osmolar gap
Calculation	$[Na^+ + K^+] - [Cl^- + HCO_3^-]$	[Measured osmolality] – [(2 × Na) + Urea + Glucose][1]
Reference range	12–16 mmol/L	< 10
Common toxic causes of elevation[2]	Ethanol Ethylene glycol Methanol Salicylates Iron Cyanide	Ethanol Ethylene glycol Methanol

[1]All units should be in mmol/L, except osmolality, which should be in mOsmol/kg. For non-SI units, the corresponding formula is [Measured osmolality (mOsmol/kg)] – [(2 × Na (mEq/L)) + Urea/2.8 (mg/dL) + Glucose/18 (mg/dL)]. [2]Box 14.19 (p. 365) gives non-toxic causes.

in younger people, but it is important to exclude other potential causes (p. 194).

Urea, electrolytes and creatinine should be measured in all patients with suspected systemic poisoning. Arterial blood gases should be checked in those with significant respiratory or circulatory compromise, or after poisoning with substances likely to affect acid–base status (Box 7.4). Calculation of anion and osmolar gaps may help to inform diagnosis and management (Box 7.5). Potent oxidising agents may cause methaemoglobinaemia, with consequent blue discoloration of skin and blood, and reduced oxygen delivery to the tissues (Fig. 7.1).

For some substances, management may be facilitated by measurement of the amount of toxin in the blood. Qualitative urine screens for potential toxins, including near-patient testing kits, have a limited clinical role.

Psychiatric assessment

Patients presenting with drug overdose in the context of self-harm should undergo psychiatric evaluation prior to discharge by a health professional with appropriate training (p. 1187). This should occur after they have recovered from poisoning, unless there is an urgent issue, such as uncertainty about their capacity to decline medical treatment.

General management

Patients presenting with eye/skin contamination should undergo local decontamination measures. These are described on page 133.

Gastrointestinal decontamination

Patients who have ingested potentially life-threatening quantities of toxins may be considered for gastrointestinal decontamination if poisoning has been recent (p. 133).

Activated charcoal

Given orally as a slurry, activated charcoal absorbs toxins in the bowel as a result of its large surface area. It can prevent absorption of an important proportion of the ingested dose of toxin, but efficacy decreases with time and current guidelines do not encourage use more than 1 hour after overdose, unless a sustained-release preparation has been taken or when gastric emptying may be delayed. Use is ineffective for some toxins that do not bind to activated charcoal (Box 7.6). In patients with impaired swallowing or a reduced level of consciousness, activated charcoal, even via a nasogastric tube, carries a risk of aspiration pneumonitis, which can be reduced (but not eliminated) by protecting the airway with a cuffed endotracheal tube.

Multiple doses of oral activated charcoal (50 g 6 times daily in an adult) may enhance the elimination of some substances at any time after poisoning (Box 7.7). This interrupts enterohepatic circulation or reduces the concentration of free drug in the gut lumen, to the extent that drug diffuses from the blood back into the bowel to be absorbed on to the charcoal ('gastrointestinal dialysis'). A laxative is generally given with the charcoal to reduce the risk of constipation or intestinal obstruction by charcoal 'briquette' formation in the gut lumen.

Evidence suggests that single or multiple doses of activated charcoal do not improve clinical outcomes after poisoning with pesticides or oleander.

Gastric aspiration and lavage

Gastric aspiration and/or lavage is very infrequently indicated in acute poisoning, as it is no more effective than activated charcoal for most substances and complications are common, especially pulmonary aspiration. It is contraindicated if strong acids, alkalis or petroleum distillates have been ingested. Use may be justified for life-threatening overdoses of those substances that are not absorbed by activated charcoal (see Box 7.6).

7.6 Substances poorly adsorbed by activated charcoal

Medicines	
• Iron	• Lithium
Chemicals	
• Acids*	• Mercury
• Alkalis*	• Methanol
• Ethanol	• Petroleum distillates*
• Ethylene glycol	

*Gastric lavage contraindicated.

7.7 Poisons effectively eliminated by multiple doses of activated charcoal, haemodialysis or haemoperfusion

Multiple doses of activated charcoal	
• Carbamazepine	• Quinine
• Dapsone	• Theophylline
• Phenobarbital	
Haemodialysis	
• Ethylene glycol	• Salicylates
• Isopropanol	• Sodium valproate
• Methanol	• Lithium
Haemoperfusion	
• Theophylline	• Phenobarbital
• Phenytoin	• Amobarbital
• Carbamazepine	

Whole bowel irrigation

This involves the administration of large quantities of osmotically balanced polyethylene glycol and electrolyte solution (1–2 L/hr for an adult), usually by a nasogastric tube, until the rectal effluent is clear. It is occasionally indicated to enhance the elimination of ingested packets of illicit drugs or slow-release tablets such as iron and lithium that are not absorbed by activated charcoal. Contraindications include inadequate airway protection, haemodynamic instability, gastrointestinal haemorrhage, obstruction or ileus. Whole bowel irrigation may precipitate nausea and vomiting, abdominal pain and electrolyte disturbances.

Urinary alkalinisation

Urinary excretion of weak acids and bases is affected by urinary pH, which changes the extent to which they are ionised. Highly ionised molecules pass poorly through lipid membranes and therefore little tubular reabsorption occurs and urinary excretion is increased. If the urine is alkalinised (pH>7.5) by the administration of sodium bicarbonate (e.g. 1.5 L of 1.26% sodium bicarbonate over 2 hrs), weak acids (e.g. salicylates, methotrexate) are highly ionised, resulting in enhanced urinary excretion.

Urinary alkalinisation is currently recommended for patients with clinically significant salicylate poisoning when the criteria for haemodialysis are not met (see below). It is also sometimes used for poisoning with methotrexate. Complications include alkalaemia, hypokalaemia and occasionally alkalotic tetany (p. 367). Hypocalcaemia may occur but is rare.

Haemodialysis and haemoperfusion

These techniques can enhance the elimination of poisons that have a small volume of distribution and a long half-life after overdose; use is appropriate when poisoning is sufficiently severe. The toxin must be small enough to cross the dialysis membrane (haemodialysis) or must bind to activated charcoal (haemoperfusion) (see Box 7.7). Haemodialysis can also correct acid–base and metabolic disturbances associated with poisoning (p. 135).

Lipid emulsion therapy

Lipid emulsion therapy is increasingly used for poisoning with lipid-soluble agents, such as local anaesthetics, tricyclic antidepressants, calcium channel blockers and lipid-soluble β-adrenoceptor antagonists (β-blockers) such as propranolol. It involves intravenous infusion of 20% lipid emulsion (e.g. Intralipid, suggested initial dose 1.5 mL/kg, followed by a continued infusion of 0.25 mL/kg/min until there is clinical improvement). It is thought that lipid-soluble toxins partition into the intravenous lipid, reducing target tissue concentrations. The elevated myocardial free fatty acid concentrations may also have beneficial effects on myocardial metabolism and performance by counteracting the inhibition of myocardial fatty acid oxidation produced by some cardiotoxins, enabling increased adenosine triphosphate (ATP) synthesis and energy production. Some animal studies have suggested efficacy and case reports of use in human poisoning have also been

7.8 Complications of poisoning and their management

Complication	Examples of causative agents	Management
Coma	Sedative agents	Appropriate airway protection and ventilatory support Oxygen saturation and blood gas monitoring Pressure area and bladder care Identification and treatment of aspiration pneumonia
Seizures	NSAIDs Anticonvulsants TCAs Theophylline	Appropriate airway and ventilatory support IV benzodiazepine (e.g. diazepam 10–20 mg, lorazepam 2–4 mg) Correction of hypoxia, acid–base and metabolic abnormalities
Acute dystonias	Typical antipsychotics Metoclopramide	Procyclidine, benzatropine or diazepam
Hypotension		
Due to vasodilatation	Vasodilator antihypertensives Anticholinergic agents TCAs	IV fluids Vasopressors (rarely indicated; p. 206)
Due to myocardial suppression	β-blockers Calcium channel blockers TCAs	Optimisation of volume status Inotropic agents (p. 206)
Ventricular tachycardia		
Monomorphic, associated with QRS prolongation	Sodium channel blockers	Correction of electrolyte and acid–base abnormalities and hypoxia Sodium bicarbonate (e.g. 50 mL 8.4% solution, repeated if necessary)
Torsades de pointes, associated with QT_c prolongation	Anti-arrhythmic drugs (quinidine, amiodarone, sotalol) Antimalarials Organophosphate insecticides Antipsychotic agents Antidepressants Antibiotics (erythromycin)	Correction of electrolyte and acid–base abnormalities and hypoxia Magnesium sulphate, 2 g IV over 1–2 mins, repeated if necessary

(NSAID = non-steroidal anti-inflammatory drug; TCA = tricyclic antidepressant)

encouraging, with recovery of circulatory collapse reported in cases where other treatment modalities have been unsuccessful. No controlled trials of this technique have been performed, however, and efficacy remains uncertain.

Supportive care

For most poisons, antidotes and methods to accelerate elimination are inappropriate, unavailable or incompletely effective. Outcome is dependent on appropriate nursing and supportive care, and treatment of complications (Box 7.8).

Antidotes

Antidotes are available for some poisons and work by a variety of mechanisms (Box 7.9). The use of some of these in the management of specific poisons is described below.

Poisoning by specific pharmaceutical agents

Analgesics

Paracetamol

Paracetamol (acetaminophen) is the drug most commonly used in overdose in the UK. Toxicity is caused by an intermediate reactive metabolite that binds covalently to cellular proteins,

7.9 Specific antidotes used to treat poisoning

Mechanism of action	Examples of antidote	Poisoning treated
Glutathione repleters	Acetylcysteine Methionine	Paracetamol
Receptor antagonists	Naloxone	Opioids
	Flumazenil	Benzodiazepines
	Atropine	Organophosphorus compounds Carbamates
Alcohol dehydrogenase inhibitors	Fomepizole Ethanol	Ethylene glycol Methanol
Chelating agents	Desferrioxamine	Iron
	Hydroxocobalamin Dicobalt edetate	Cyanide
	DMSA Sodium calcium edetate	Lead
Reducing agents	Methylthioninium chloride	Organic nitrites
Cholinesterase reactivators	Pralidoxime	Organophosphorus compounds
Antibody fragments	Digoxin Fab fragments	Digoxin

(DMSA = dimercaptosuccinic acid)

causing cell death. This results in hepatic and occasionally renal failure. In therapeutic doses, the toxic metabolite is detoxified in reactions requiring glutathione, but in overdose, glutathione reserves become exhausted.

Management

Activated charcoal may be used in patients presenting within 1 hour. Antidotes for paracetamol act by replenishing hepatic glutathione and should be administered to all patients with acute poisoning and paracetamol concentrations above a 'treatment line' provided on paracetamol poisoning nomograms (Fig. 7.2). The threshold used for these nomograms varies between countries, however, and local guidance should be followed. Acetylcysteine given intravenously (or orally in some countries) is highly efficacious if administered within 8 hours of the overdose. However, efficacy declines thereafter, so administration should not be delayed in patients presenting after 8 hours to await a paracetamol blood concentration result. The antidote can be stopped if the paracetamol concentration is shown to be below the nomogram treatment line. Liver and renal function, International Normalised Ratio (INR) and a venous bicarbonate should also be measured. Arterial blood gases and lactate should be assessed in patients with reduced bicarbonate or severe liver function abnormalities; metabolic acidosis indicates severe poisoning.

Anaphylactoid reactions are the most important adverse effects of acetylcysteine and are related to dose-related histamine release. Common features are itching and urticaria, and in severe cases, bronchospasm and hypotension. Most cases can be managed by temporary discontinuation of acetylcysteine and administration of an antihistamine.

An alternative antidote is methionine 2.5 g orally (adult dose) every 4 hours to a total of four doses, but this may be less effective, especially after delayed presentation. Liver transplantation should be considered for paracetamol poisoning with life-threatening liver failure (p. 856).

If multiple ingestions of paracetamol have taken place over several hours ('staggered overdose') or days (e.g. chronic therapeutic excess), acetylcysteine may be indicated; specific treatment recommendations vary between countries.

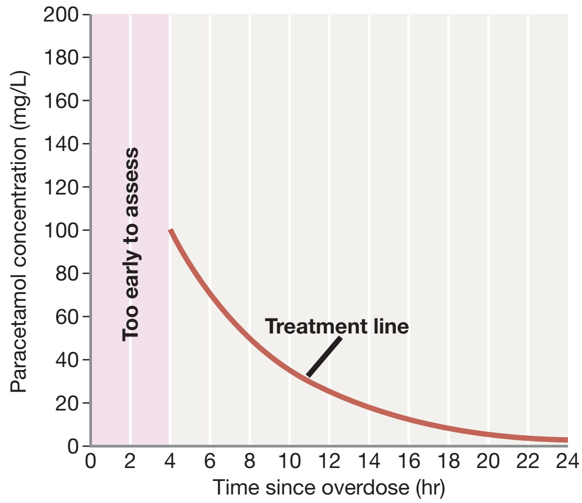

Fig. 7.2 Paracetamol treatment nomogram (UK). Above the treatment line, benefits of treatment outweigh risk. Below it, risks of treatment outweigh benefits.

Salicylates (aspirin)

Clinical features

Salicylate overdose commonly causes nausea, vomiting, sweating, tinnitus and deafness. Direct stimulation of the respiratory centre produces hyperventilation and respiratory alkalosis. Peripheral vasodilatation with bounding pulses and profuse sweating occurs in moderately severe cases. Serious poisoning is associated with metabolic acidosis, hypoprothrombinaemia, hyperglycaemia, hyperpyrexia, renal failure, pulmonary oedema, shock and cerebral oedema. Agitation, delirium, coma and fits may occur, especially in children. Toxicity is enhanced by acidosis, which increases salicylate transfer across the blood–brain barrier.

Management

Activated charcoal should be administered if the patient presents within 1 hour. Multiple doses may enhance salicylate elimination but are not routinely recommended.

The plasma salicylate concentration should be measured at least 2 (symptomatic patients) or 4 hours (asymptomatic patients) after overdose and repeated in suspected serious poisoning, as concentrations may continue to rise for several hours. Clinical status, however, is more important than the salicylate concentration when assessing severity.

Dehydration should be corrected carefully because of the risk of pulmonary oedema. Metabolic acidosis should be treated with intravenous sodium bicarbonate (8.4%), after plasma potassium has been corrected. Urinary alkalinisation is indicated for adults with salicylate concentrations above 500 mg/L.

Haemodialysis is very effective for removing salicylate and correcting associated acid–base and fluid balance abnormalities. It should be considered when serum concentrations are above 700 mg/L in adults with severe toxic features, or in renal failure, pulmonary oedema, coma, convulsions or refractory acidosis.

Non-steroidal anti-inflammatory drugs

Clinical features

Overdose of most non-steroidal anti-inflammatory drugs (NSAIDs) usually causes only minor abdominal discomfort, vomiting and/or diarrhoea, but convulsions can occur occasionally, especially with mefenamic acid. Coma, prolonged seizures, apnoea, liver dysfunction and renal failure may follow substantial overdose but are rare. Features of toxicity are unlikely to develop in patients who are asymptomatic more than 6 hours after overdose.

Management

Electrolytes, liver function tests and a full blood count should be checked in all but the most trivial cases. Activated charcoal may be given if the patient presents within 1 hour. Symptomatic treatment for nausea and gastrointestinal irritation may be needed.

Antidepressants

Tricyclic antidepressants

Overdose with tricyclic antidepressants (TCAs) carries a high morbidity and mortality because of their sodium channel-blocking, anticholinergic and α-adrenoceptor-blocking effects.

Clinical features

Anticholinergic effects are common (Box 7.10). Severe complications include convulsions, coma and arrhythmias (ventricular

i 7.10 Anticholinergic and serotonergic feature clusters

(MAOI = monoamine oxidase inhibitor; SSRI = selective serotonin re-uptake inhibitor; TCA = tricyclic antidepressant)

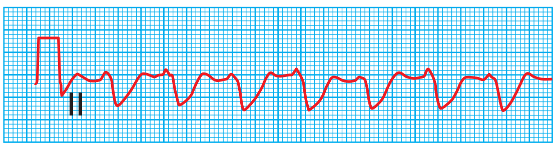

Fig. 7.3 ECG in severe tricyclic antidepressant poisoning. This rhythm strip shows a broad QRS complex due to impaired conduction.

tachycardia, ventricular fibrillation and, less commonly, heart block). Hypotension results from inappropriate vasodilatation or impaired myocardial contractility. Serious complications appear more common with dosulepin and amitriptyline.

Management

Activated charcoal should be administered if the patient presents within 1 hour. A 12-lead ECG should be taken and continuous cardiac monitoring maintained for at least 6 hours. Prolongation of the QRS interval (especially if >0.16 secs) indicates severe sodium channel blockade and a high risk of arrhythmia (Fig. 7.3). QT interval prolongation may also occur. Arterial blood gases should be measured in suspected severe poisoning.

In patients with arrhythmias, significant QRS or QT prolongation or acidosis, intravenous sodium bicarbonate (50 mL of 8.4% solution) should be administered and repeated to correct pH. The correction of the acidosis and the sodium loading that results may bring about rapid improvement in ECG features and arrhythmias. Hypoxia and electrolyte abnormalities should also be corrected. Anti-arrhythmic drugs should only be given on specialist advice. Prolonged seizures should be treated initially with intravenous benzodiazepines (see Box 7.8).

Selective serotonin and noradrenaline re-uptake inhibitors

Selective serotonin re-uptake inhibitor (SSRI) antidepressants (e.g. fluoxetine, paroxetine, fluvoxamine, sertraline, citalopram, escitalopram) are increasingly used to treat depression and are less toxic in overdose than TCAs. The related serotonin–noradrenaline re-uptake inhibitors (SNRIs), such as venlafaxine and duloxetine, are also commonly used but are more toxic than SSRIs in overdose.

Clinical features and management

Overdose of SSRIs may produce nausea and vomiting, tremor, insomnia and sinus tachycardia. Agitation, drowsiness and convulsions occur infrequently and may be delayed for several hours. Serotonin syndrome may occur (see Box 7.10), especially if SSRIs are taken in combination or with other serotonergic agents. Cardiac arrhythmias occur infrequently and most patients require supportive care only. The toxic effects of SNRIs are similar but tachycardia, hypertension or hypotension and ECG changes (QRS and QT prolongation) may be more prominent and hypoglycaemia can also arise.

Lithium

Severe lithium toxicity is uncommon after intentional acute overdose but is more often encountered in patients taking therapeutic doses, frequently as a result of interactions with drugs such as diuretics or NSAIDs. Severe toxicity is more common after acute overdose in patients already taking chronic therapy (‘acute on chronic’ poisoning).

Clinical features

Nausea, diarrhoea, polyuria, dizziness and tremor may progress to muscular weakness, drowsiness, delirium, myoclonus, fasciculations, choreoathetosis and renal failure. Coma, seizures, ataxia, cardiac dysrhythmias such as heart block, blood pressure disturbances and renal failure may occur in severe poisoning.

Management

Activated charcoal is ineffective. Early gastric lavage is of theoretical benefit, but lithium tablets are likely to remain intact in the stomach and may be too large for aspiration via a lavage tube. Whole bowel irrigation is often used after substantial overdose but efficacy is unproven.

Lithium concentrations should be measured immediately (symptomatic patients) or after at least 6 hours (asymptomatic patients) following acute overdose. The usual therapeutic range is 0.4–1.0 mmol/L. Adequate hydration should be maintained with intravenous fluids. Seizures should be treated as in Box 7.8.

Haemodialysis should be considered for severe toxicity associated with high lithium concentrations (e.g. >4.0 mmol/L after chronic or ‘acute on chronic’ poisoning, or >7.5 mmol/L after acute poisoning). Lithium concentrations are reduced substantially during dialysis, but rebound increases occur after discontinuation and multiple sessions are usually required.

Cardiovascular medications

Although not common, cardiovascular drug overdose is important because features of toxicity are often severe.

Beta-blockers

Major features of toxicity are bradycardia and hypotension; heart block, pulmonary oedema and cardiogenic shock occur in severe poisoning. Those with additional sodium channel-blocking effects (e.g. propranolol, acebutolol, carvedilol) may cause seizures, delirium and coma, while sotalol, which also blocks potassium channels, may cause QT_c prolongation and torsades de pointes (Box 7.8 and p. 476).

Management

Intravenous fluids may reverse hypotension but care is required to avoid pulmonary oedema. Bradycardia and hypotension may respond to high doses of atropine (up to 3 mg in an adult) or an infusion of isoproterenol. Glucagon (5–10 mg over 10 mins, then 1–5 mg/hr by infusion) counteracts β-blockade by stimulating intracellular cyclic adenosine monophosphate (cAMP) production and is now more commonly used. In severe cases, 'hyperinsulinaemia euglycaemic therapy' has been used, as described under calcium channel blockers below. The efficacy of lipid emulsion therapy in severe poisoning with lipid-soluble β-blockers, such as propranolol, carvedilol and oxprenolol, is uncertain.

Calcium channel blockers

L-type calcium channel blockers are highly toxic in overdose. Dihydropyridines (e.g. nifedipine, amlodipine) cause vasodilatation, whereas diltiazem and verapamil have predominantly cardiac effects, including bradycardia and reduced myocardial contractility.

Clinical features

Hypotension due to vasodilatation or myocardial depression is common and bradycardias and heart block may also occur, especially with verapamil and diltiazem. Gastrointestinal disturbances, delirium, metabolic acidosis, hyperglycaemia and hyperkalaemia may also be present.

Management

Hypotension should be corrected with intravenous fluids, taking care to avoid pulmonary oedema. Persistent hypotension may respond to intravenous calcium gluconate (10 mg IV over 5 mins, repeated as required). Isoproterenol and glucagon may also be useful. Successful use of intravenous insulin with glucose (10–20% dextrose with insulin initially at 0.5–2.0 U/kg/hr, increasing to 5–10 U/kg/hr according to clinical response), so-called 'hyperinsulinaemia euglycaemic therapy', has been reported in patients unresponsive to other strategies. The mechanism of action remains to be fully elucidated, but in states of shock myocardial metabolism switches from use of free fatty acids to glucose. Calcium channel blocker poisoning is also associated with hypoinsulinaemia and insulin resistance, impeding glucose uptake by myocytes. High doses of insulin inhibit lipolysis and increase glucose uptake and the efficiency of glucose utilisation. Cardiac pacing may be needed for severe unresponsive bradycardias or heart block. Lipid emulsion therapy has also been used in severe poisoning with apparent benefit, although evidence is largely anecdotal.

Digoxin and oleander

Poisoning with digoxin is usually accidental, arising from prescription of an excessive dose, impairment of renal function or drug interactions. In South Asia, deliberate self-poisoning with yellow oleander (*Thevetia peruviana*), containing cardiac glycosides, is common.

Clinical features

Cardiac effects include tachyarrhythmias (either atrial or ventricular) and bradycardias, with or without atrioventricular block. Ventricular bigeminy is common and atrial tachycardia with evidence of atrioventricular block is highly suggestive of the diagnosis. Severe poisoning is often associated with hyperkalaemia. Non-cardiac features include delirium, headache, nausea, vomiting, diarrhoea and (rarely) altered colour vision. Digoxin poisoning can be confirmed by elevated plasma concentration (usual therapeutic range 1.3–2.5 mmol/L). After chronic exposure, concentrations >5 mmol/L suggest serious poisoning.

Management

Activated charcoal is commonly administered to patients presenting soon after acute ingestion, although evidence of benefit is lacking. Urea, electrolytes and creatinine should be measured, a 12-lead ECG performed and cardiac monitoring instituted. Hypoxia, hypokalaemia (sometimes caused by concurrent diuretic use), hypomagnesaemia and acidosis increase the risk of arrhythmias and should be corrected. Significant bradycardias may respond to atropine, although temporary pacing is sometimes needed. Ventricular arrhythmias may respond to intravenous magnesium (see Box 7.8). If available, digoxin-specific antibody fragments should be administered when there are severe refractory ventricular arrhythmias or bradycardias. These are effective for both digoxin and yellow oleander poisoning.

Iron

Overdose with iron can cause severe and sometimes fatal poisoning, with toxicity of individual iron preparations related to their elemental iron content.

Clinical features

Early features include gastrointestinal disturbance with the passage of grey or black stools, progressing to hyperglycaemia, leucocytosis, haematemesis, rectal bleeding, drowsiness, convulsions, coma, metabolic acidosis and cardiovascular collapse in severe cases. Early symptoms may improve or resolve within 6–12 hours, but hepatocellular necrosis can develop 12–24 hours after overdose and occasionally progresses to hepatic failure. Gastrointestinal strictures are late complications.

Management

Activated charcoal is ineffective but gastric lavage may be considered in patients presenting soon after substantial overdose, although efficacy is unknown. Serum iron concentration should be measured at least 4 hours after overdose or earlier if there are features of toxicity. Desferrioxamine chelates iron and should be administered immediately in patients with severe features, without waiting for serum iron concentrations, as well as symptomatic patients with high serum iron concentrations (e.g. >5 mg/L). Desferrioxamine may cause hypotension, allergic reactions and occasionally pulmonary oedema. Otherwise, treatment is supportive and directed at complications.

Antipsychotic drugs

Antipsychotic drugs (p. 1198) are often prescribed for patients at high risk of self-harm or suicide and are often taken in overdose.

Clinical features

Anticholinergic features (see Box 7.10) including drowsiness, tachycardia and hypotension, are common and convulsions may occur. Acute dystonias, including oculogyric crisis, torticollis and trismus, may occur after overdose with typical antipsychotics like haloperidol or chlorpromazine. QT interval prolongation and torsades de pointes can occur with some typical (e.g. haloperidol) and atypical (e.g. quetiapine, amisulpride, ziprasidone) agents.

Management

Activated charcoal may be of benefit if given early. Cardiac monitoring should be undertaken for at least 6 hours. Management is largely supportive, with treatment directed at complications (see Box 7.8).

Antidiabetic agents

Overdose is uncommon but toxic effects can be severe.

Clinical features

Sulphonylureas, meglitinides (e.g. nateglinide, repaglinide) and parenteral insulin cause hypoglycaemia when taken in overdose, although insulin is non-toxic if ingested by mouth. The duration of hypoglycaemia depends on the half-life or release characteristics of the preparation and may be prolonged over several days with long-acting agents such as glibenclamide, insulin zinc suspension or insulin glargine.

Features of hypoglycaemia include nausea, agitation, sweating, aggression, delirium, tachycardia, hypothermia, drowsiness, convulsions and coma (p. 738). Permanent neurological damage can occur if hypoglycaemia is prolonged. Hypoglycaemia can be diagnosed using bedside glucose strips but venous blood should also be sent for laboratory confirmation.

Metformin is uncommonly associated with hypoglycaemia. Its major toxic effect is lactic acidosis, which can have a high mortality, and is particularly common in older patients and those with renal or hepatic impairment, or when ethanol has been co-ingested. Other features of metformin overdose are nausea, vomiting, diarrhoea, abdominal pain, drowsiness, coma, hypotension and cardiovascular collapse.

There is limited experience of overdose involving thiazolidinediones (e.g. pioglitazone) and dipeptidyl peptidase 4 (DPP-4) inhibitors (e.g. sitagliptin) but significant hypoglycaemia is unlikely.

Management

Activated charcoal should be considered for recent substantial overdose. Venous blood glucose and urea and electrolytes should be measured and measurement repeated regularly. Hypoglycaemia should be corrected using oral or intravenous glucose (50 mL of 50% dextrose); an infusion of 10–20% dextrose may be required to prevent recurrence. Intramuscular glucagon can be used as an alternative, especially if intravenous access is unavailable. Failure to regain consciousness within a few minutes of normalisation of the blood glucose can indicate that a central nervous system (CNS) depressant has also been ingested, the hypoglycaemia has been prolonged, or there is another cause of coma (e.g. cerebral haemorrhage or oedema).

7.11 Clinical features and specific management of drugs less commonly involved in poisoning

Substance	Clinical features	Management
Anticonvulsants		
Carbamazepine, phenytoin	Cerebellar signs Convulsions Cardiac arrhythmias Coma	Multiple-dose activated charcoal (carbamazepine)
Sodium valproate	Coma Metabolic acidosis	Haemodialysis for severe poisoning
Isoniazid	Peripheral neuropathy Convulsions	Activated charcoal IV pyridoxine
Theophylline	Cardiac arrhythmias Convulsions Coma	Multiple-dose activated charcoal
Antimalarial drugs		
Chloroquine	Acidosis and hypokalaemia Visual loss Convulsions, coma ECG changes and arrhythmias	Correction of pH (but not potassium) Monitoring and treatment of cardiac rhythm High-dose diazepam with mechanical ventilation
Quinine	Tremor, tinnitus, deafness, ataxia, convulsions, coma Haemolysis ECG changes and arrhythmias Retinal toxicity	Correction of pH (but not potassium) Monitoring and treatment of cardiac rhythm Multiple-dose activated charcoal No effective treatment for visual loss

Arterial blood gases and plasma lactate should be taken after metformin overdose; acidosis should be corrected with intravenous sodium bicarbonate (250 mL 1.26% solution or 50 mL 8.4% solution, repeated as necessary). In severe cases, haemodialysis or haemodiafiltration is used.

Pharmaceutical agents less commonly taken in poisoning

An overview of the clinical features and management for drugs less commonly involved in poisoning is provided in Box 7.11.

Drugs of misuse

Drugs of misuse are common causes of toxicity requiring hospital admission. Management has recently become more complex because of the emergence of 'novel psychoactive substances' (NPS). These are often chemically related to traditional drugs of misuse, but with structural modifications made to evade legal control. The constituents of branded NPS products are often unknown and knowledge about the clinical features and management of NPS toxicity is limited.

Depressants

These produce CNS depression, including drowsiness, ataxia, delirium and coma, sometimes with respiratory depression, airway compromise, aspiration pneumonia and respiratory arrest

7.12 Stimulant, sedative and opioid feature clusters

	Stimulant	Sedative hypnotic	Opioid
Common causes	Amphetamines MDMA ('ecstasy') Ephedrine Pseudoephedrine Cocaine Cannabis Phencyclidine Cathinones (e.g. mephedrone) Benzylpiperazine	Benzodiazepines Barbiturates Ethanol GHB	Heroin Morphine Methadone Fentanyl and derivatives Oxycodone Dihydrocodeine Codeine Pethidine Buprenorphine Dextropropoxyphene Tramadol
Clinical features			
Respiratory	Tachypnoea	Reduced respiratory rate and ventilation[1]	Reduced respiratory rate and ventilation
Cardiovascular	Tachycardia, hypertension	Hypotension[1]	Hypotension, relative bradycardia
Central nervous system	Restlessness, anxiety, anorexia, insomnia Hallucinations	Delirium, hallucinations, slurred speech Sedation, coma[1]	Delirium, hallucinations, slurred speech Sedation, coma[2]
Muscle	Tremor	Ataxia, reduced muscle tone	Ataxia, reduced muscle tone
Temperature	Fever	Hypothermia	Hypothermia
Eyes	Mydriasis	Diplopia, strabismus, nystagmus Normal pupil size	Miosis
Abdomen	Abdominal pain, diarrhoea	–	Ileus
Mouth	Dry	–	–
Skin	Piloerection	Blisters, pressure sores	Needle tracks[2]
Complications	Seizures Myocardial infarction Dysrhythmias Rhabdomyolysis Renal failure Intracerebral haemorrhage or infarction	Respiratory failure[1] Aspiration	Respiratory failure[2] Non-cardiogenic pulmonary oedema Aspiration

[1]Especially barbiturates. [2]IV use.
(GHB = gamma hydroxybutyrate; MDMA = 3,4-methylene-dioxymethamphetamine)

(Box 7.12). Other complications of coma include pressure blisters or sores and rhabdomyolysis. Effects are potentiated by other CNS depressants, including alcohol.

Essential supportive care is detailed in Box 7.8. Antidotes are available for some depressants.

Benzodiazepines

Benzodiazepines (e.g. diazepam) and related substances (e.g. zopiclone) are of low toxicity when taken alone in overdose but can enhance CNS and respiratory depression when taken with other sedative agents, including alcohol. They are more hazardous in the elderly and those with chronic lung or neuromuscular disease (see Box 7.12).

The specific benzodiazepine antagonist flumazenil (0.5 mg IV, repeated if needed) increases conscious level in patients with benzodiazepine overdose, but carries a risk of seizures and is contraindicated in patients co-ingesting pro-convulsants (e.g. TCAs) and those with a history of epilepsy.

Opioids

Toxicity may result from misuse of illicit drugs such as heroin or from intentional or accidental overdose of medicinal opiates. Intravenous or smoked heroin gives a rapid, intensely pleasurable experience, often accompanied by heightened sexual arousal. Physical dependence occurs within a few weeks of regular high-dose use. Withdrawal can start within 12 hours, causing intense craving, rhinorrhoea, lacrimation, yawning, perspiration, shivering, piloerection, vomiting, diarrhoea and abdominal cramps. Examination reveals tachycardia, hypertension, mydriasis and facial flushing.

Commonly encountered opioids and clinical features of poisoning are shown in Box 7.12. Needle tracks may be visible in intravenous users and there may be drug-related paraphernalia. Methadone may also cause QT_c prolongation and torsades de pointes. Features of opioid poisoning can be prolonged for up to 48 hours after use of long-acting agents such as methadone or oxycodone.

Use of the specific opioid antagonist naloxone (0.4–2 mg IV in an adult, repeated if necessary) may obviate the need for intubation, although excessive doses may precipitate acute withdrawal in chronic opiate users and breakthrough pain in those receiving opioids for pain management. Repeated doses or an infusion are often required because the half-life of the antidote is short compared to that of most opiates, especially those with prolonged elimination. Patients should be monitored for at least 6 hours after the last naloxone dose. Rare complications of naloxone therapy include fits, ventricular arrhythmias and pulmonary oedema.

Gamma hydroxybutyrate

Gamma hydroxybutyrate (GHB), and the related compounds gamma butyrolactone (GBL) and 1,4 butanediol are sedative liquids with psychedelic and body-building effects.

As well as sedative hypnotic features (see Box 7.12), toxicity may cause nausea, diarrhoea, vertigo, tremor, myoclonus, extrapyramidal signs, euphoria, bradycardia, convulsions, metabolic acidosis, hypokalaemia and hyperglycaemia. Coma usually resolves abruptly within a few hours but occasionally persists for several days. Dependence may develop in regular users, who experience severe, prolonged withdrawal effects if use is discontinued suddenly.

Management is largely supportive. All patients should be observed for a minimum of 2 hours and until symptoms resolve, with monitoring of blood pressure, heart rate, respiratory rate and oxygenation. Withdrawal symptoms may require treatment with very high doses of benzodiazepine.

Stimulants and entactogens

These are sympathomimetic and serotonergic amines that have overlapping clinical features, depending on the balance of their stimulant (see Box 7.12) and serotonergic (see Box 7.10) effects. As well as traditional drugs such as cocaine, amphetamines and ecstasy, the group includes many more recently emerging novel psychoactive substances, including cathinones (e.g. mephedrone), piperazines (e.g. benzylpiperazine), piperadines (e.g. ethylphenidate), benzofurans (e.g. 5-aminopropylbenzofuran) and NBOMe compounds (e.g. 25I-NBOMe).

Cocaine

Cocaine is available as a water-soluble hydrochloride salt powder suitable for nasal inhalation ('snorting'), or as insoluble free-base ('crack' cocaine) 'rocks' that, unlike the hydrochloride salt, vaporise at high temperature and can be smoked, giving a more rapid and intense effect.

Effects appear rapidly after inhalation and especially after smoking. Sympathomimetic stimulant effects predominate (see Box 7.12). Serious complications usually occur within 3 hours of use and include coronary artery spasm, leading to myocardial ischaemia or infarction, hypotension and ventricular arrhythmias. Cocaine toxicity should be considered in younger adults presenting with ischaemic chest pain. Hyperpyrexia, rhabdomyolysis, acute renal failure and disseminated intravascular coagulation may occur.

A 12-lead ECG and ECG monitoring should be undertaken. ST segment elevation may occur in the absence of myocardial infarction and troponin T estimations are the most sensitive and specific markers of myocardial damage. Benzodiazepines and intravenous nitrates are useful for managing patients with chest pain or hypertension. Acidosis should be corrected and physical cooling measures used for hyperthermia. Beta-blockers may be contraindicated because of the risk of unopposed α-adrenoceptor stimulation, but this is debated. Coronary angiography should be considered in patients with myocardial infarction or acute coronary syndromes.

Amphetamines and cathinones

Amphetamine-related compounds include amphetamine sulphate ('speed'), methylamphetamine ('crystal meth') and 3,4-methylenedioxymethamphetamine (MDMA, 'ecstasy'). Synthetic cathinones include mephedrone and methylenedioxypyrovalerone. Tolerance is common, leading regular users to seek ever higher doses.

Toxic features usually appear within a few minutes of use and last 4–6 hours, or substantially longer after a large overdose. Sympathomimetic stimulant and serotonergic effects are common (see Boxes 7.10 and 7.12). Some users develop hyponatraemia as a result of excessive water-drinking or inappropriate vasopressin (antidiuretic hormone, ADH) secretion. Muscle rigidity, pain and bruxism (clenching of the jaw), hyperpyrexia, rhabdomyolysis, metabolic acidosis, acute renal failure, disseminated intravascular coagulation, hepatocellular necrosis, acute respiratory distress syndrome (ARDS) and cardiovascular collapse have all been described following MDMA use. Cerebral infarction and haemorrhage have been reported, especially after intravenous amphetamine use.

Management is supportive and directed at complications (see Box 7.8).

Hallucinogens

Cannabis

Derived from the dried leaves and flowers of *Cannabis sativa*, cannabis produces euphoria, perceptual alterations and conjunctival injection, followed by enhanced appetite, relaxation and occasionally hypertension, tachycardia, slurred speech and ataxia. Effects occur 10–30 minutes after smoking or 1–3 hours after ingestion, and last 4–8 hours. High doses may produce anxiety, delirium, hallucinations and psychosis. Psychological dependence is common, but tolerance and withdrawal symptoms are unusual. Long-term use is thought to increase the lifetime risk of psychosis. Serious acute toxicity is uncommon and supportive treatment is all that is required.

Synthetic cannabinoid receptor agonists

Large numbers of synthetic cannabinoid receptor agonists (SCRAs), synthetic compounds sometimes referred to collectively as 'spice', are now used as legal alternatives to cannabis; examples include PB-22, 5F-PB-22, 5F-AKB-48, STS-135, SF-ADB and MDMB-CHMICA. They are usually sprayed on to a herbal smoking mix and packaged as smoking products with appealing brand names. These may contain more than one SCRA and content may change with time.

The toxic effects of SCRAs differ from those of cannabis, being generally more marked and including agitation, panic, delirium, hallucinations, tachycardia, ECG changes, hypertonia, dyspnoea and vomiting. Coma, respiratory acidosis, seizures, hypokalaemia and renal dysfunction are also reported. Treatment of intoxication is supportive.

Tryptamines

These are predominantly 5-hydroxytryptamine (5-HT, serotonin; especially 5-HT2a) agonists with associated stimulant effects. Typical clinical features include hallucinations, agitation, delirium, hypertension, tachycardia, sweating, anxiety and headache. Serotonin syndrome may occur (see Box 7.10), especially if tryptamines are used in combination with other serotonergic agents. Naturally occurring examples are psilocin and psilocybin, found in 'magic mushrooms', and dimethyltryptamine (DMT) in traditional ayahuasca brews. Synthetic tryptamines, such as alpha-methyltryptamine (AMT), have been encountered recently.

d-Lysergic acid diethylamide

d-Lysergic acid diethylamide (LSD) is a synthetic ergoline usually ingested as small squares of impregnated absorbent paper (often printed with a distinctive design) or as 'microdots'. The drug causes perceptual effects, such as heightened visual awareness of colours or distortion of images. Hallucinations may be pleasurable or terrifying ('bad trip'). Other features are delirium, agitation, aggression, dilated pupils, hypertension, pyrexia and metabolic acidosis. Psychosis may sometimes last several days.

Patients with psychotic reactions or CNS depression should be observed in hospital, preferably in a quiet, dimly lit room to minimise external stimulation. A benzodiazepine that can be used for sedation is required, avoiding antipsychotics if possible, as they may precipitate cardiovascular collapse or convulsions.

Dissociative drugs

Ketamine, its *N*-ethyl derivative methoxetamine and phencyclidine (now rarely encountered) produce a sense of dissociation from reality, often associated with visual and auditory distortions. Memory loss, impaired consciousness, agitation, hallucinations, tremors and numbness may also occur. Long-term ketamine (and probably methoxetamine) use can cause severe chronic cystitis with dysuria, frequency, urgency, haematuria and incontinence. Treatment of intoxication is supportive.

Volatile substances

Inhalation of volatile nitrites (e.g. amyl nitrite, isobutyl nitrite), often sold in bottles or vials as 'poppers', is reported to produce a feeling of pleasure and warmth, relax the anal sphincter and prolong orgasm. These potent vasodilators commonly provoke headache, dizziness, hypotension and tachycardia. They also oxidise haemoglobin to produce methaemoglobinaemia, with resulting breathlessness and delirium. Severe cases are treated with methylthioninium chloride ('methylene blue', see Fig 7.1).

Several volatile solvents found in household products, such as propane, butane, toluene and trichloroethylene, have a mild euphoriant effect if inhaled. Serious toxic effects can occur, including reduced level of consciousness, seizures and cardiac arrhythmias; there is also a risk of asphyxia from some methods of inhalation.

Nitrous oxide is an anaesthetic gas, but small canisters of it are sold for the domestic production of whipped cream and the contents of these can be transferred to balloons for inhalation. The gas has euphoriant effects ('laughing gas'), but hazards include asphyxia from inhalation without oxygen, or vitamin B_{12} inactivation from chronic use leading to megaloblastic anaemia, psychosis and other neurological sequelae.

Body packers and body stuffers

Body packers ('mules') attempt to smuggle illicit drugs (usually cocaine, heroin or amphetamines) by ingesting multiple small packages wrapped in several layers of clingfilm or in condoms. Body stuffers are those who have ingested unpackaged or poorly wrapped substances, often to avoid arrest. Both groups are at risk of severe toxicity if the packages rupture. This is more likely for body stuffers, who may develop symptoms of poisoning within 8 hours of ingestion. The risk of poisoning depends on the quality of the wrapping, and the amount and type of drug ingested. Cocaine, for example, presents a much higher risk than heroin because of its high toxicity and lack of a specific antidote.

Fig. 7.4 Abdominal X-ray of a body packer showing multiple drug-filled condoms.

Patients suspected of body packing or stuffing should be admitted for observation. A careful history taken in private is important, but for obvious reasons patients may withhold details of the drugs involved. The mouth, rectum and vagina should be examined as possible sites for concealed drugs. A urine toxicology screen performed at intervals may provide evidence of leakage, although positive results may reflect earlier drug use. Packages may be visible on plain abdominal films (Fig. 7.4) but ultrasound and computed tomography (CT) are more sensitive. One of these (preferably CT) should be performed in all suspected body packers.

Antimotility agents are often used by body packers to prevent premature passage of packages; it can take several days for packages to pass spontaneously, during which the carrier is at risk from package rupture. Whole bowel irrigation is commonly used to accelerate passage and is continued until all packages have passed. Surgery may be required when there is mechanical bowel obstruction or when evolving clinical features suggest package rupture, especially with cocaine.

Chemicals and pesticides

Carbon monoxide

Carbon monoxide (CO) is a colourless, odourless gas produced by faulty appliances burning organic fuels. It is also present in vehicle exhaust fumes and sometimes in smoke from house fires. It binds with haemoglobin and cytochrome oxidase, reducing tissue oxygen delivery and inhibiting cellular respiration. CO is a common cause of death by poisoning and most patients die before reaching hospital.

Clinical features

Early features include headache, nausea, irritability, weakness and tachypnoea. The cause of these non-specific features may not be obvious if the exposure is occult, such as from a

faulty domestic appliance. Subsequently, ataxia, nystagmus, drowsiness and hyper-reflexia may develop, progressing to coma, convulsions, hypotension, respiratory depression, cardiovascular collapse and death. Myocardial ischaemia may result in arrhythmias or myocardial infarction. Cerebral oedema is common and rhabdomyolysis may cause myoglobinuria and renal failure. In those who recover from acute toxicity, longer-term neuropsychiatric effects are common, such as personality change, memory loss and concentration impairment. Extrapyramidal effects, urinary or faecal incontinence, and gait disturbance may also occur. Poisoning during pregnancy may cause fetal hypoxia and intrauterine death.

Management

Patients should be removed from exposure as soon as possible and resuscitated as necessary. A high concentration of oxygen should be administered via a tightly fitting facemask; this reduces the half-life of carboxyhaemoglobin from 4–6 hours to about 40 minutes. Measurement of carboxyhaemoglobin is useful for confirming exposure; levels >20% suggest significant exposure but do not correlate well with the severity of poisoning, partly because concentrations fall rapidly after removal of the patient from exposure, especially if supplemental oxygen has been given.

An ECG should be performed in all patients with acute CO poisoning, especially those with pre-existing heart disease. Arterial blood gas analysis should be checked in those with serious poisoning. Pulse oximetry may provide misleading oxygen saturations because carboxyhaemoglobin and oxyhaemoglobin are both measured. Excessive intravenous fluid administration should be avoided, particularly in the elderly, because of the risk of pulmonary and cerebral oedema. Convulsions should be controlled with diazepam.

Hyperbaric oxygen therapy is controversial. At 2.5 atmospheres, this reduces the half-life of carboxyhaemoglobin to about 20 minutes and increases the amount of oxygen dissolved in plasma 10-fold, but systematic reviews have not consistently shown improved clinical outcomes. The logistical difficulties of transporting sick patients to hyperbaric chambers and managing them therein are substantial.

Organophosphorus insecticides and nerve agents

Organophosphorus (OP) compounds (Box 7.13) are widely used as pesticides, especially in developing countries. Case fatality following deliberate ingestion is high (5–20%).

Nerve agents, developed for chemical warfare, are derived from OP insecticides and are much more toxic. They are commonly classified as G (originally synthesised in Germany) or V ('venomous') agents. The 'G' agents, such as tabun, sarin and soman, are volatile, absorbed by inhalation or via the skin, and dissipate rapidly after use. 'V' agents, such as VX, are contact poisons unless aerosolised, and contaminate ground for weeks or months.

The toxicology and management of nerve agent and pesticide poisoning are similar.

Mechanism of toxicity

OP compounds inactivate acetylcholinesterase (AChE), resulting in the accumulation of acetylcholine (ACh) in cholinergic synapses (Fig. 7.5). Initially, spontaneous hydrolysis of the OP–enzyme complex allows reactivation of the enzyme but, subsequently, loss of a chemical group from the OP–enzyme complex prevents further enzyme reactivation. After this process (termed 'ageing') has taken place, new enzyme needs to be synthesised before function can be restored. The rate of 'ageing' is an important determinant of toxicity and is more rapid with dimethyl (3.7 hrs) than diethyl (31 hrs) compounds (Box 7.13) and especially rapid after exposure to nerve agents (soman in particular), which cause 'ageing' within minutes.

Clinical features and management

OP poisoning causes an acute cholinergic phase, which may occasionally be followed by the intermediate syndrome or organophosphate-induced delayed polyneuropathy (OPIDN). The onset, severity and duration of poisoning depend on the route of exposure and agent involved.

7.13 Organophosphorus compounds

Nerve agents	
• G agents: sarin, tabun, soman	• V agents: VX,VE

Dimethyl compounds	**Diethyl compounds**
• Dichlorvos	• Chlorpyrifos
• Fenthion	• Diazinon
• Malathion	• Parathion-ethyl
• Methamidophos	• Quinalphos

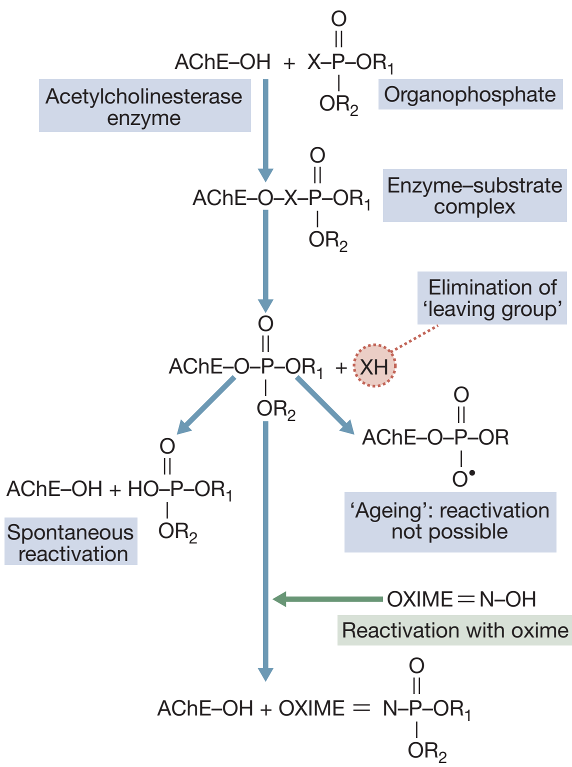

Fig. 7.5 Mechanism of toxicity of organophosphorus compounds and treatment with oxime.

i 7.14 Cholinergic features in poisoning*

	Muscarinic	Nicotinic
Respiratory	Bronchorrhoea, bronchoconstriction	Reduced ventilation
Circulation	Bradycardia, hypotension	Tachycardia, hypertension
Higher mental function	Anxiety, delirium, psychosis	
Muscle	–	Fasciculation, paralysis
Temperature	Fever	–
Eyes	Diplopia, miosis, lacrimation	Mydriasis
Abdomen	Vomiting, profuse diarrhoea	–
Mouth	Salivation	–
Skin	Sweating	–
Complications	Coma, seizures, respiratory depression	

*Both muscarinic and nicotinic features occur in OP poisoning. Nicotinic features occur in nicotine poisoning and black widow spider bites. Cholinergic features are sometimes seen with some mushrooms.

Acute cholinergic syndrome

This usually starts within a few minutes of exposure and nicotinic or muscarinic features may be present (Box 7.14). Vomiting and profuse diarrhoea are typical following ingestion. Bronchoconstriction, bronchorrhoea and salivation may cause severe respiratory compromise. Excess sweating and miosis are characteristic and the presence of muscular fasciculations strongly suggests the diagnosis, although this feature is often absent, even in serious poisoning. Subsequently, generalised flaccid paralysis may develop and affect respiratory and ocular muscles, resulting in respiratory failure. Ataxia, coma, convulsions, cardiac repolarisation abnormalities and torsades de pointes may occur.

Management

The airway should be cleared of excessive secretions, breathing and circulation assessed, high-flow oxygen administered and intravenous access obtained. Appropriate external decontamination is needed (p. 133). Gastric lavage or activated charcoal may be considered if the patient presents sufficiently early. Seizures should be treated as described in Box 7.8. The ECG, oxygen saturation, blood gases, temperature, urea and electrolytes, amylase and glucose should be monitored closely.

Early use of sufficient doses of atropine is potentially life-saving in patients with severe toxicity. Atropine reverses ACh-induced bronchospasm, bronchorrhoea, bradycardia and hypotension. When the diagnosis is uncertain, a marked increase in heart rate associated with skin flushing after a 1 mg intravenous dose makes OP poisoning unlikely. In OP poisoning, atropine (2 mg IV) should be administered and this dose should be doubled every 5–10 minutes until clinical improvement occurs. Further bolus doses should be given until secretions are controlled, the skin is dry, blood pressure is adequate and heart rate is >80 bpm. Large doses may be needed, but excessive doses may cause anticholinergic effects (see Box 7.10).

In severe poisoning requiring atropine, an oxime such as pralidoxime chloride or obidoxime is generally recommended, if available, although efficacy is debated. This may reverse or prevent muscle weakness, convulsions or coma, especially if given rapidly after exposure. Oximes reactivate AChE that has not undergone 'ageing' and are therefore less effective with dimethyl compounds and nerve agents, especially soman. Oximes may provoke hypotension, especially if administered rapidly.

Intravenous magnesium sulphate has been reported to increase survival in animals and in small human studies of OP poisoning; however, further clinical trial evidence is needed before this can be recommended routinely.

Ventilatory support should be instituted before the patient develops respiratory failure. Benzodiazepines may be used to treat agitation, fasciculations and seizures and for sedation during mechanical ventilation.

Exposure is confirmed by measurement of plasma or red blood cell cholinesterase activity but antidote use should not be delayed pending results. Plasma cholinesterase is reduced more rapidly but is less specific than red cell cholinesterase. Values correlate poorly with the severity of clinical features but are usually <10% in severe poisoning, 20–50% in moderate poisoning and >50% in subclinical poisoning.

The acute cholinergic phase usually lasts 48–72 hours, with most patients requiring intensive cardiorespiratory support and monitoring. Cholinergic features may be prolonged over several weeks with some lipid-soluble agents.

Intermediate syndrome

About 20% of patients with OP poisoning develop weakness that spreads rapidly from the ocular muscles to those of the head and neck, proximal limbs and the muscles of respiration, resulting in ventilatory failure. This 'intermediate syndrome' generally develops 1–4 days after exposure, often after resolution of the acute cholinergic syndrome, and may last 2–3 weeks. There is no specific treatment and supportive care is needed, including maintenance of airway and ventilation.

Organophosphate-induced delayed polyneuropathy

Organophosphate-induced delayed polyneuropathy (OPIDN) is a rare complication that usually occurs 2–3 weeks after acute exposure. It is a mixed sensory/motor polyneuropathy, affecting long myelinated neurons especially, and appears to result from inhibition of enzymes other than AChE. It is a feature of poisoning with some OPs such as triorthocresyl phosphate but is less common with nerve agents. Early clinical features are muscle cramps followed by numbness and paraesthesiae, proceeding to flaccid paralysis of the lower and subsequently the upper limbs, with foot and wrist drop and a high-stepping gait, progressing to paraplegia. Sensory loss may also be present but is variable. Initially, tendon reflexes are reduced or lost but mild spasticity may develop later.

There is no specific therapy for OPIDN. Regular physiotherapy may limit deformity caused by muscle-wasting. Recovery is often incomplete and may be limited to the hands and feet, although substantial functional recovery after 1–2 years may occur, especially in younger patients.

Carbamate insecticides

Carbamate insecticides such as bendiocarb, carbofuran, carbaryl and methomyl inhibit a number of tissue esterases, including AChE. The mechanism, clinical features and management of toxicity are similar to those of OP compounds. However, clinical features are usually less severe and of shorter duration, because the carbamate–AChE complex dissociates quickly, with a half-life of 30–40 minutes, and does not undergo ageing. Also, carbamates penetrate the CNS poorly. Intermediate syndrome

and OPIDN are not common features of carbamate poisoning. In spite of this, case fatality can be high for some carbamates, depending on their formulation.

Atropine may be given intravenously as for OP poisoning (p. 146). Diazepam may be used to relieve anxiety. The use of oximes is unnecessary.

Paraquat

Paraquat is a herbicide that is widely used across the world, although it has been banned in the European Union and some other countries for several years. It is highly toxic if ingested, with clinical features including oral burns, vomiting and diarrhoea, progressing to pneumonitis, pulmonary fibrosis and multi-organ failure.

Exposure can be confirmed by a urinary dithionite test, while the plasma paraquat concentration indicates prognosis. There is no specific antidote but activated charcoal is commonly administered. Immunosuppression with glucocorticoids and cyclophosphamide is sometimes used but evidence for benefit is weak. Irrespective of treatment, death is common and may occur within 24 hours with substantial poisoning or after 1–2 weeks with lower doses.

Methanol and ethylene glycol

Ethylene glycol (1,2-ethanediol) is found in antifreeze, brake fluids and, in lower concentrations, windscreen washes. Methanol is present in some antifreeze products and commercially available industrial solvents, and in low concentrations in some screen washes and methylated spirits. It may also be an adulterant of illicitly produced alcohol. Both are rapidly absorbed after ingestion. Methanol and ethylene glycol are not of high intrinsic toxicity but are converted via alcohol dehydrogenase to toxic metabolites that are largely responsible for their clinical effects (Fig. 7.6).

Clinical features

Early features of poisoning with either methanol or ethylene glycol include vomiting, ataxia, drowsiness, dysarthria and nystagmus. As toxic metabolites are formed, metabolic acidosis, tachypnoea, coma and seizures may develop.

Toxic effects of ethylene glycol include ophthalmoplegia, cranial nerve palsies, hyporeflexia and myoclonus. Renal pain and acute tubular necrosis occur because of renal calcium oxalate precipitation. Hypocalcaemia, hypomagnesaemia and hyperkalaemia are common.

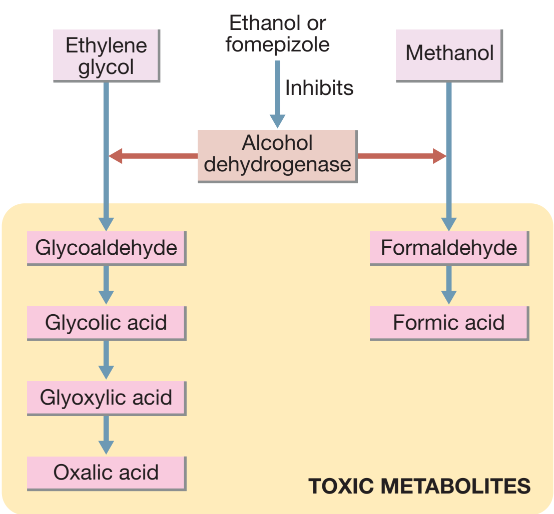

Fig. 7.6 Metabolism of methanol and ethylene glycol.

Methanol poisoning causes headache, delirium and vertigo. Visual impairment and photophobia develop, associated with optic disc and retinal oedema and impaired pupil reflexes. Blindness may be permanent, although some recovery may occur over several months. Pancreatitis and abnormal liver function have also been reported.

Management

Urea and electrolytes, chloride, bicarbonate, glucose, calcium, magnesium, albumin, plasma osmolarity and arterial blood gases should be measured in all patients with suspected methanol or ethylene glycol toxicity. The osmolar and anion gaps should be calculated (see Box 7.5). Initially, poisoning is associated with an increased osmolar gap, but as toxic metabolites are produced, an increased anion gap develops, associated with metabolic acidosis. The diagnosis can be confirmed by measurement of ethylene glycol or methanol concentrations but assays are not widely available.

An antidote, ideally fomepizole but otherwise ethanol, should be administered to all patients with suspected significant exposure while awaiting the results of laboratory investigations. These block alcohol dehydrogenase and delay the formation of toxic metabolites until the parent drug is eliminated in the urine or by dialysis. The antidote should be continued until ethylene glycol or methanol concentrations are undetectable. Metabolic acidosis should be corrected with sodium bicarbonate (e.g. 250 mL of 1.26% solution, repeated as necessary). Convulsions should be treated with an intravenous benzodiazepine. In ethylene glycol poisoning, hypocalcaemia should be corrected only if there are severe ECG features or if seizures occur, as this may increase calcium oxalate crystal formation. In methanol poisoning, folinic acid should be administered to enhance the metabolism of the toxic metabolite, formic acid.

Haemodialysis or haemodiafiltration should be used in severe poisoning, especially if renal failure is present or there is visual loss in the context of methanol poisoning. It should be continued until acute toxic features are no longer present and ethylene glycol/methanol concentrations are undetectable.

Corrosive substances

Products containing strong acids (e.g. hydrochloric or sulphuric acid) or alkalis (e.g. sodium hydroxide, calcium carbonate) may be ingested, accidentally or intentionally, causing gastrointestinal pain, ulceration and necrosis, with risk of perforation.

External decontamination (p. 133), if needed, should be performed after initial resuscitation. Gastric lavage should not be attempted and neutralising chemicals should not be administered after large ingestions because of the risk of tissue damage from heat release. Cardiorespiratory monitoring is necessary and full blood count, renal function, coagulation and acid–base status should be assessed. An erect chest X-ray should be performed if perforation is suspected and may show features of mediastinitis or gas under the diaphragm. Strong analgesics should be administered for pain.

Severe abdominal or chest pain, abdominal distension, shock or acidosis may indicate perforation and should prompt an urgent CT scan of chest and abdomen and surgical review. In the absence of perforation, drooling, dysphagia, stridor or oropharyngeal burns suggest possible severe oesophageal

damage and early endoscopy by an experienced operator should be considered. Delayed endoscopy (e.g. after several days) may carry a higher risk of perforation.

Aluminium and zinc phosphide

These rodenticides and fumigants are a common means of self-poisoning in northern India. The mortality rate for aluminium phosphide ingestion has been estimated at 60%; zinc phosphide ingestion appears less toxic, at about 2%. When ingested, both compounds react with gastric acid to form phosphine, a potent pulmonary and gastrointestinal toxicant. Clinical features include severe gastrointestinal disturbances, chest tightness, cough and breathlessness progressing to ARDS and respiratory failure, tremor, paraesthesiae, convulsions, coma, tachycardia, metabolic acidosis, electrolyte disturbances, hypoglycaemia, myocarditis, liver and renal failure, and leucopenia. Ingestion of a few tablets can be fatal.

Treatment is supportive and directed at correcting electrolyte abnormalities and treating complications; there is no specific antidote. Early gastric lavage is sometimes used, often with vegetable oil to reduce the release of toxic phosphine, but the benefit is uncertain.

Copper sulphate

This is used as a fungicide. If it is ingested, clinical features of toxicity include nausea, vomiting, abdominal pain, diarrhoea, discoloured (blue/green) secretions, corrosive effects on the gastrointestinal tract, renal or liver failure, methaemoglobinaemia, haemolysis, rhabdomyolysis, convulsions and coma. Treatment is as for other corrosive substances (see above) and should address complications, including use of methylthioninium chloride for methaemoglobinaemia (see Fig. 7.1). Chelation therapy is unlikely to be beneficial after acute exposure.

Chemicals less commonly taken in poisoning

An overview of the clinical features and management for chemicals less commonly involved in poisoning is provided in Box 7.15.

7.15 Clinical features and specific management of chemicals less commonly involved in poisoning

Substance	Clinical features	Management
Lead e.g. Chronic occupational exposure, leaded paint, water contaminated by lead pipes, use of kohl cosmetics	Abdominal pain Microcytic anaemia with basophilic stippling Headache and encephalopathy Motor neuropathy Nephrotoxicity Hypertension Hypocalcaemia	Prevention of further exposure Measurement of blood lead concentration, full blood count and blood film, urea and electrolytes, liver function tests and calcium Abdominal X-ray in children to detect pica Bone X-ray for 'lead lines' Chelation therapy with DMSA or sodium calcium edetate
Petroleum distillates e.g. White spirit, kerosene	Vomiting Aspiration pneumonitis	Gastric lavage contraindicated Activated charcoal ineffective Oxygen and nebulised bronchodilators Chest X-ray to assess pulmonary effects
Organochlorines e.g. DDT, lindane, dieldrin, endosulfan	Nausea, vomiting Agitation Fasciculation Paraesthesiae (face, extremities) Convulsions Coma Respiratory depression Cardiac arrhythmias Hyperthermia Rhabdomyolysis Pulmonary oedema Disseminated intravascular coagulation	Activated charcoal (with nasogastric aspiration for liquid preparations) within 1 hr of ingestion Cardiac monitoring
Pyrethroid insecticides e.g. Cypermethrin, permethrin, imiprothrin	Skin contact: dermatitis, skin paraesthesiae Eye contact: lacrimation, photophobia and oedema of the eyelids Inhalation: dyspnoea, nausea, headaches Ingestion: epigastric pain, nausea, vomiting, headache, coma, convulsions, pulmonary oedema	Symptomatic and supportive care Washing contaminated skin makes irritation worse
Anticoagulant rodenticides e.g. Brodifacoum, bromadialone and warfarin	Abnormal bleeding (prolonged)	Monitor INR/prothrombin time Vitamin K_1 by slow IV injection if there is coagulopathy Fresh frozen plasma or specific clotting factors for bleeding

(DMSA = dimercaptosuccinic acid)

7.16 Chemical warfare agents

Examples	Clinical effects	Antidotes*
Nerve agents Tabun Sarin Soman VX	See page 145 and Box 7.13	Atropine Oximes (p. 145)
Blistering agents Nitrogen/sulphur Mustard Lewisite	Eyes: watering, blepharospasm, corneal ulceration Skin: erythema, blistering Respiratory: cough, hoarseness, dyspnoea, pneumonitis	None
Choking agents Chlorine Phosgene	Eyes: watering, blepharospasm, corneal ulceration Respiratory: cough, hoarseness, dyspnoea, pneumonitis	None
Blood agents Cyanide	Cardiovascular: dizziness, shock Respiratory: dyspnoea, cyanosis CNS: anxiety, headache, delirium, convulsions, coma, fixed dilated pupils Other: vomiting, lactic acidosis	Dicobalt edetate Hydroxocobalamin

*Appropriate resuscitation, decontamination and supportive care are essential after exposure to all chemical warfare agents. Use appropriate personal protective equipment.

Chemical warfare agents

Some toxins have been developed for use as chemical warfare agents. These are summarised in Box 7.16.

Environmental poisoning

Arsenism

Chronic arsenic exposure from drinking water has been reported in many countries, especially India, Bangladesh, Nepal, Thailand, Taiwan, China, Mexico and South America, where a large proportion of the drinking water (ground water) has a high arsenic content, placing large populations at risk. The World Health Organisation (WHO) guideline value for arsenic content in tube well water is 10 μg/L.

Health effects associated with chronic exposure to arsenic in drinking water are shown in Box 7.17. In exposed individuals, high concentrations of arsenic are present in bone, hair and nails. Specific treatments are of no benefit in chronic arsenic toxicity and recovery from the peripheral neuropathy may never be complete, so the emphasis should be on prevention.

7.17 Clinical features of chronic arsenic poisoning

Gastrointestinal tract
- Anorexia, vomiting, weight loss, diarrhoea, increased salivation, metallic taste

Neurological
- Peripheral neuropathy (sensory and motor) with muscle wasting and fasciculation, ataxia

Skin
- Hyperpigmentation, palmar and plantar keratosis, alopecia, multiple epitheliomas, Mee's lines (transverse white lines on fingernails)

Eyes
- Conjunctivitis, corneal necrosis and ulceration

Bone marrow
- Aplastic anaemia

Other
- Low-grade fever, vasospasm and gangrene, jaundice, hepatomegaly, splenomegaly

Increased risk of malignancy
- Lung, liver, bladder, kidney, larynx and lymphoid system

Fluorosis

Fluoride poisoning can result from exposure to excessive quantities of fluoride (>10 ppm) in drinking water, industrial exposure to fluoride dust or consumption of brick teas. Clinical features include yellow staining and pitting of permanent teeth, osteosclerosis, soft tissue calcification, deformities (e.g. kyphosis) and joint ankylosis. Changes in the bones of the thoracic cage may lead to rigidity that causes dyspnoea on exertion. Very high doses of fluoride may cause abdominal pain, nausea, vomiting, seizures and muscle spasm. In calcium-deficient children, the toxic effects of fluoride manifest even at marginally high exposures to fluoride.

In endemic areas, such as Jordan, Turkey, Chile, India, Bangladesh, China and Tibet, fluorosis is a major public health problem, especially in communities engaged in physically strenuous agricultural or industrial activities. Dental fluorosis is endemic in East Africa and some West African countries.

Food-related poisoning

Paralytic shellfish poisoning

Paralytic shellfish poisoning is caused by consumption of bivalve molluscs (e.g. mussels, clams, oysters, cockles and scallops) contaminated with saxitoxins, which are concentrated in the shellfish as a result of constant filtration of toxic algae during algal blooms (e.g. 'red tide'). Symptoms develop within 10–120 minutes of eating the contaminated shellfish and include gastrointestinal disturbances, paraesthesia around the mouth or in the extremities, ataxia, mental state changes and dysphagia. In severe cases, paralysis and respiratory failure can develop. There is no specific antidote and treatment is supportive. Most cases resolve over a few days.

Ciguatera poisoning

Ciguatera toxin and related toxins are produced by dinoflagellate plankton that adhere to algae and seaweed. These accumulate in the tropical herbivorous fish that feed on these and in their larger predators (e.g. snapper, barracuda), especially in the

7.18 Some poisonous plants and fungi, with their clinical effects

Species (common name)	Toxins	Important features of toxicity
Plants		
Abrus precatorius (jequirity bean) *Ricinus communis* (castor oil plant)	Abrin Ricin	Gastrointestinal effects, drowsiness, delirium, convulsions, multi-organ failure
Aconitum napellus (aconite, wolf's bane, monkshood) *Aconitum ferox* (Indian aconite, bikh)	Aconite	Gastrointestinal effects, paraesthesiae, convulsions, ventricular tachycardia
Atropa belladonna (deadly nightshade) *Datura stramonium* (Jimson weed, thorn apple) *Brugmansia* spp. (angel's trumpet)	Atropine, scopolamine, hyocyamine	Anticholinergic toxidrome (see Box 7.10)
Colchicum autumnale (autumn crocus)	Colchicine	Gastrointestinal effects, hypotension, cardiogenic shock
Conium maculatum (hemlock)	Toxic nicotinic alkaloids	Hypersalivation, gastrointestinal effects, followed by muscular paralysis
Digitalis purpurea (foxglove) *Nerium oleander* (pink oleander) *Thevetia peruviana* (yellow oleander)	Cardiac glycosides	Cardiac glycoside toxicity (p. 140)
Laburnum anagyroides (laburnum)	Cytosine	Gastrointestinal effects; convulsions in severe cases
Taxus baccata (yew)	Taxane alkaloids	Hypotension, bradycardia, respiratory depression, convulsions, coma, arrhythmias
Fungi		
Amanita phalloides (death cap mushroom)	Amatoxins	Gastrointestinal effects, progressing to liver failure
Cortinarius spp.	Orellanine	Gastrointestinal effects, fever, progressing to renal failure
Psilocybe semilanceata ('magic mushrooms')	Psilocybin, psilocin	Hallucinations

Pacific and Caribbean. Human exposure occurs through eating contaminated fish, even if well cooked. Nausea, vomiting, diarrhoea and abdominal pain develop within a few hours, followed by paraesthesia, ataxia, blurred vision, ataxia and tremor. Convulsions and coma can occur, although death is uncommon. Fatigue and peripheral neuropathy can be long-term effects. There is no specific treatment. In the South Pacific and Caribbean, there are approximately 50 000 cases per year, with a case fatality of 0.1%.

Scombrotoxic fish poisoning

Under poor storage conditions, histidine in scombroid fish (e.g. tuna, mackerel, bonito, skipjack and the canned dark meat of sardines) may be converted by bacteria to histamine and other chemicals. Within minutes of consumption, flushing, burning, sweating, urticaria, pruritus, headache, colic, nausea and vomiting, diarrhoea, bronchospasm and hypotension may occur. Management is with nebulised salbutamol, intravenous antihistamines and, occasionally, intravenous fluid replacement.

Plant poisoning

A substantial number of plants and fungi are potentially toxic if consumed, with patterns of poisoning depending on their geographical distribution. Some toxic examples and the clinical features of toxicity are shown in Box 7.18.

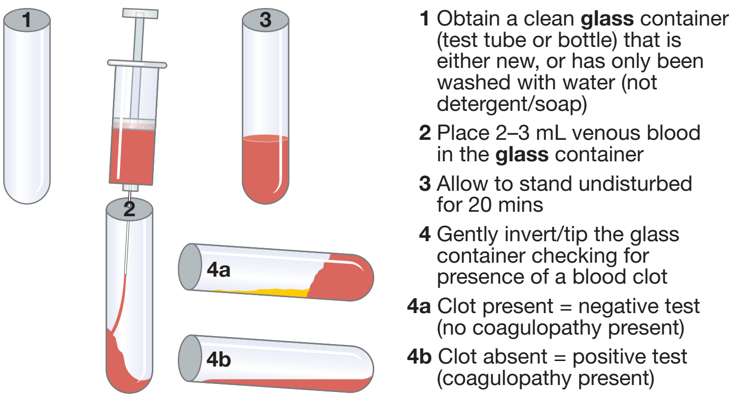
Geographical distribution of venomous snakes



The geographical location of a snakebite determines the likely animal(s) involved and the nature and risks of the envenomation. *Copyright © Julian White.*

Bedside tests in the envenomed patient

Examination of urine. Haematuria may indicate a coagulopathy. Dark urine is suggestive of myoglobinuria, which is a sign of extensive rhabdomyolysis. *Copyright © Julian White.*

Twenty-minute whole-blood clotting test (20WBCT). The presence of coagulopathy is a key indicator of major envenoming for some species. While full laboratory coagulation studies may be the ideal, the 20WBCT has emerged as a simple standardised bedside test of coagulopathy, applicable even in areas with limited health facilities. *Copyright © Julian White.*

Overview of envenomation

Envenomation occurs when a venomous animal injects sufficient venom by a bite or a sting into a prey item or perceived predator to cause deleterious local and/or systemic effects. This is defined as a venom-induced disease (VID). Venomous animals generally use their venom to acquire and, in some cases, pre-digest prey, with defensive use a secondary function for many species. Accidental encounters between venomous animals and humans are frequent, particularly in the rural tropics, where millions of cases of venomous bites and stings occur annually. Globally, an increasing number of exotic venomous animals are kept privately, so cases of envenoming may present to hospitals where doctors have insufficient knowledge to manage potentially complex presentations. Doctors everywhere should thus be aware of the basic principles of management of envenomation and how to seek expert support. It is important for doctors to know what types of venomous animal are likely to occur in their geographical area (hospital hinterland; p. 153) and the types of envenoming they may cause.

Venom

Venom is a complex mixture of diverse components (notably toxins), often with several separate toxins that can cause adverse effects in humans, and each is potentially capable of multiple effects (Box 8.1). Venom is produced at considerable metabolic cost, so is used sparingly; thus only some bites/stings by venomous animals result in significant envenoming, the remainder being 'dry bites'. The concept of dry bites is important in understanding approaches to first aid and medical management.

Venomous animals

There are many animal groups that contain venomous species (Box 8.2). The epidemiological estimates reflect the importance of snakes and scorpions as causes of severe or lethal envenomation, but also the fragmentary nature of the data. For snakes, recent studies have proposed widely varying estimates of epidemiological impact, but even the higher estimates may be too low. A recent

i 8.2 Venomous animals and human envenoming

Phyla	Principal venomous animal groups	Estimated number of human cases/year	Estimated number of human deaths/year
Chordata	Snakes	>2.5 million	>100 000
	Spiny fish	? >100 000	Close to zero
	Stingrays	? >100 000	? <10
Arthropoda	Scorpions	>1 million	? <5000
	Spiders	? >100 000	? <100
	Paralysis ticks	? >1000	? <10
	Insects	? >1 million	? >1000*
Mollusca	Cone snails	? <1000	? <10
	Blue-ringed octopus	? <100	? <10
Coelenterata	Jellyfish	? >1 million	? <10

*Social insect stings cause death by anaphylaxis rather than primary venom toxicity, except for massive multiple sting attacks.

i 8.1 Key venom effects*

Venom component	Clinical effects	Type of venomous animal
Neurotoxin		
Paralytic	Flaccid paralysis	Some snakes Paralysis ticks Cone snails Blue-ringed octopus
Excitatory	Neuroexcitation: autonomic storm, cardiotoxicity, pulmonary oedema	Some scorpions, spiders, jellyfish (irukandji)
Myotoxins	Systemic or local myolysis	Some snakes
Cardiotoxins	Direct or indirect cardiotoxicity; cardiac collapse, shock	Some snakes, scorpions, spiders and jellyfish (box jellyfish)
Haemostasis system toxins	Variation from rapid coagulopathy and bleeding to thrombosis, deep venous thrombosis and pulmonary emboli	Many snakes and a few scorpions (*Hemiscorpius*) Brazilian caterpillars (*Lonomia*)
Haemorrhagic toxins	Local vessel damage, fluid extravasation, blistering, ecchymosis, shock	Mainly some snakes
Nephrotoxins	Renal damage	Some snakes, massed bee and wasp stings
Necrotoxins	Local tissue injury/necrosis, shock	Some snakes, a few scorpions (*Hemiscorpius*), spiders (recluse spiders), jellyfish and stingrays
Allergic toxins	Induction of acute allergic response (direct and indirect)	Almost all venoms but particularly those of social insects (i.e. bees, wasps, ants)

*All venom components have lethal potential.

comprehensive study in India indicated there are at least 45 000 snakebite-related deaths in that country annually, far above both government figures and previous estimates. In many areas of the poor rural tropics, health resources are limited and few envenoming cases are either seen or recorded within the official hospital system, compared to the actual community burden of disease. While fatal cases may gain most attention, long-term disability from envenomation affects significantly more people and has a major social and economic cost.

Stings by social insects such as bees and wasps may also cause lethal anaphylaxis. Other venomous animals may commonly envenom humans but cause mostly non-lethal effects. A few animals only rarely envenom humans but have a high potential for severe or lethal envenoming. These include box jellyfish, cone snails, blue-ringed octopus, paralysis ticks and Australian funnel web spiders. Within any given group, particularly snakes, there may be a wide range of clinical presentations. Some are described here but for a more detailed discussion of the types of venomous animal, their venoms and their effects on humans, see toxinology.com.

Clinical effects

With the exception of dry bites, where no significant toxin effects occur, venomous bites/stings can result in three broad classes of effect.

Local effects

These vary from trivial to severe (Box 8.3). There may be minimal or no local effects with some snakebites (not even pain), yet lethal systemic envenoming may still be present. For other species, local effects predominate over systemic, and for some, such as certain snakes, both are important (p. 152). Some species commonly cause local necrosis, notably some snakes, brown recluse spiders, an Iranian scorpion (*Hemiscorpius lepturus*) and some stingrays.

i 8.3 Local and systemic effects of envenomation

Local effects

- Pain
- Sweating
- Erythema
- Major direct tissue trauma (e.g. stingray injuries)
- Blistering
- Necrosis
- Swelling
- Bleeding and bruising

Non-specific systemic effects

- Headache
- Nausea
- Vomiting and diarrhoea
- Abdominal pain
- Tachycardia or bradycardia
- Hypertension or hypotension
- Pulmonary oedema
- Dizziness
- Collapse
- Convulsions
- Shock
- Cardiac arrest

Specific systemic effects

- Neurotoxic flaccid paralysis (descending or ascending)
- Excitatory neurotoxicity (catecholamine storm-like and similar)
- Rhabdomyolysis (systemic or local)
- Coagulopathy (procoagulant/fibrinolytic or anticoagulant or thrombotic or antiplatelet)
- Cardiotoxicity (decreased/abnormal cardiac function or arrhythmia or arrest)
- Acute kidney injury (polyuria or oliguria or anuria or isolated elevated creatinine/urea)

General systemic effects

By definition, these are non-specific (Box 8.3). Shock is an important complication of major local envenoming by some snake species and, if inadequately treated, can prove lethal, especially in children.

Specific systemic effects

These are important in both diagnosis and treatment.

- *Neurotoxic flaccid paralysis* can develop very rapidly, progressing from mild weakness to full respiratory paralysis in less than 30 minutes (blue-ringed octopus bite, cone snail sting), or may develop far more slowly, over hours (some snakes) to days (paralysis tick). For neurotoxic snakes, the cranial nerves are usually involved first, with ptosis a common initial sign, often progressing to partial and later complete ophthalmoplegia, fixed dilated pupils, drooling and loss of upper airway protection (p. 152). From this, paralysis may extend to the limbs, with weakness and loss of deep tendon reflexes, the neck ('broken neck' sign), then finally respiratory paralysis affecting the diaphragm.
- *Excitatory neurotoxins* cause an 'autonomic storm', often with profuse sweating (p. 152), variable cardiac effects and cardiac failure, sometimes with pulmonary oedema (notably, Australian funnel web spider bite, some scorpions such as Indian red scorpion). This type of envenomation can be rapidly fatal (many scorpions, funnel web spiders), or may cause distressing symptoms but constitute a lesser risk of death (widow spiders, banana spiders).
- *Myotoxicity* can be localised in the bitten limb, or systemic, affecting mostly skeletal muscles. It can initially be silent, then present with generalised muscle pain, tenderness, myoglobinuria (p. 153) and huge rises in serum creatine kinase (CK). Secondary renal failure can precipitate potentially lethal hyperkalaemic cardiotoxicity.
- *Cardiotoxicity* is often secondary but symptoms and signs are non-specific in most cases. For some scorpions, envenomation can cause direct cardiac effects, including decreased cardiac output, arrhythmias and pulmonary oedema.
- *Haemostasis system toxins* cause a variety of effects, depending on the type of toxin (Fig. 8.1). Coagulopathy may present as bruising and bleeding from the bite site (p. 152), gums and intravenous sites. Surgical interventions are high-risk in such cases. Other venoms cause thrombosis, usually presenting as deep venous thrombosis (DVT), pulmonary embolus or stroke (particularly Caribbean/Martinique vipers).
- *Haemorrhagic toxins* cause vascular damage, especially in the bitten limb, with extravasation of fluid and sometimes hypotensive shock; this is a problem associated with some snakebites. The role of these toxins in causing late-developing capillary leak syndrome (p. 152), again

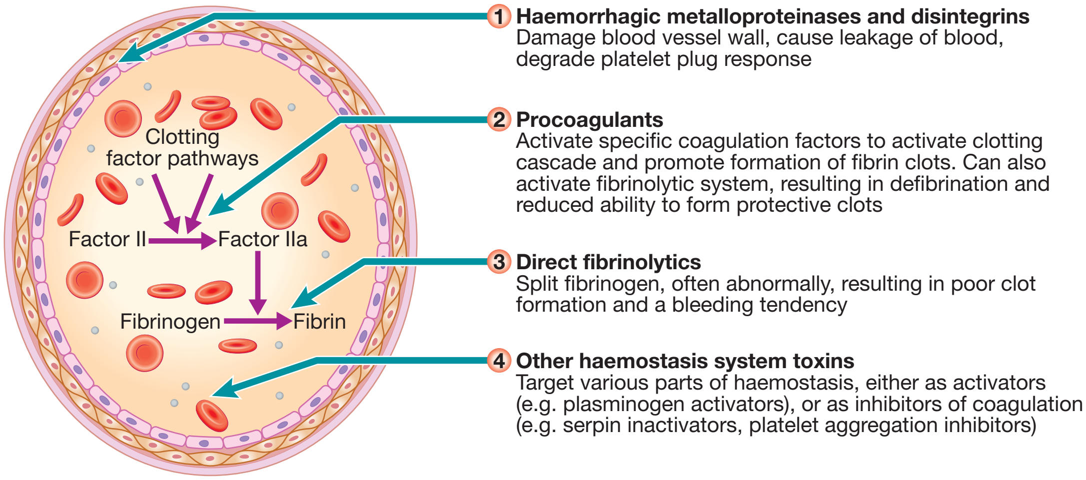


Fig. 8.1 Sites of action of venoms on the haemostasis system. *Copyright © Julian White.*

associated with some snakebites (notably Russell's viper), is uncertain.

- *Renal damage* in envenoming is mostly secondary, although some species, such as Russell's vipers, can cause primary renal damage. The presentation is similar in both cases, with changes in urine output (polyuria, oliguria or anuria) or rises in creatinine and urea. In cases with intravascular haemolysis, secondary renal damage is likely. The clinical effects of specific animals in different regions of the world are shown in Boxes 8.4–8.6.

General approach to the envenomed patient

First aid

First aid can be crucial in determining the outcome for envenomed patients, yet throughout much of the world inappropriate and dangerous first aid is often administered.

8.4 Selected important venomous animals in Asia

Scientific name[1]	Common name	Clinical effects	Antivenom/antidote/treatment
Indian subcontinent			
Bungarus spp. (E)	Kraits	Flaccid paralysis[2,3], myolysis[4], hyponatraemia[5]	Indian PV or specific
Naja spp. (E)	Cobras	Flaccid paralysis[3], local necrosis/blistering, shock	Indian PV or specific
Ophiophagus hannah (E)	King cobra	Flaccid paralysis[3], local necrosis, shock	Indian PV or specific
Echis spp. (Vv)	Saw-scaled vipers	Procoagulant coagulopathy, local necrosis/blistering, renal failure	Indian PV or specific
Daboia russelii (Vv)	Russell's viper	Procoagulant coagulopathy, local necrosis/blistering, myolysis, renal failure, shock, flaccid paralysis[2]	Indian PV or specific
Hypnale spp. (Vc)	Hump-nosed vipers	Procoagulant coagulopathy, shock, renal failure	Try Indian PV
Trimeresurus[6] spp. (Vc)	Green pit vipers	Procoagulant coagulopathy, local necrosis, shock	Indian PV or specific
Hottentotta spp. (Sc)	Indian scorpions	Neuroexcitation, cardiotoxicity	Indian specific AV Prazosin
East Asia			
Bungarus spp. (E)	Kraits	Flaccid paralysis[2,3]	Specific AV from country
Naja spp. (E)	Cobras (some spitters)	Flaccid paralysis[3], local necrosis/blistering, shock	Specific AV from country
Ophiophagus hannah (E)	King cobra	Flaccid paralysis[3], local necrosis, shock	King cobra AV
Calloselasma rhodostoma (Vc)	Malayan pit viper	Procoagulant coagulopathy, local necrosis/blistering, renal failure, shock	Specific AV from country
Daboia siamensis (Vv)	Russell's viper	Procoagulant coagulopathy, local necrosis/blistering, renal failure, shock	Specific AV from country
Gloydius spp. (Vc)	Mamushis, pit vipers	Procoagulant coagulopathy, local necrosis/blistering, shock, renal failure, flaccid paralysis[2]	Specific AV from country
Trimeresurus[6] spp. (Vc)	Green pit vipers, habus	Procoagulant coagulopathy, local necrosis/blistering, shock	Specific AV from country

[1]Family names: C = 'Colubridae' (mostly 'non-venomous'; family subject to major taxonomic revisions); E = Elapidae (all venomous); Sc = Scorpionoidea; Vc = Viperidae Crotalinae (New World and Asian vipers); Vv = Viperidae viperinae (Old World vipers). [2]Pre-synaptic. [3]Post-synaptic. [4]Only reported so far for *B. candidus*, *B. niger* and *B. caeruleus*. [5]Only reported so far for *B. multicinctus* and *B. candidus*. [6]Genus is subject to major taxonomic change (split into at least eight genera).
(AV = antivenom; PV = polyvalent)

8.5 Selected important venomous animals in the Americas and Australia

Scientific name[1]	Common name	Clinical effects	Antivenom/antidote/treatment
North America			
Crotalus spp. (Vc)	Rattlesnakes	Procoagulant coagulopathy, local necrosis/ blistering (flaccid paralysis[2] rare), shock	CroFab AV or Bioclon Antivipmyn AV
Sistrurus spp. (Vc)	Massasaugas	Procoagulant coagulopathy, local necrosis/ blistering, shock	CroFab AV or Bioclon Antivipmyn AV
Agkistrodon spp. (Vc)	Copperheads and moccasins	Procoagulant coagulopathy, local necrosis/ blistering, shock	CroFab AV or Bioclon Antivipmyn AV
Micrurus spp. (E)	Coral snakes	Flaccid paralysis[3]	Bioclon Coralmyn AV
Latrodectus mactans	Widow spider	Neuroexcitation	MSD Widow spider AV
Centruroides sculpturatus	Arizona bark scorpion	Neuroexcitation	Bioclon Anascorp AV
Central and South America			
Crotalus spp. (Vc)	Rattlesnakes	Flaccid paralysis[2], myolysis, procoagulant coagulopathy, shock, renal failure	Specific AV from country
Bothrops spp. (Vc)	Lancehead vipers	Procoagulant coagulopathy, local necrosis/ blistering, shock, renal failure	Specific AV from country
Bothriechis spp. (Vc)	Eyelash pit vipers	Shock, pain and swelling	Specific AV from country
Lachesis spp. (Vc)	Bushmasters	Procoagulant coagulopathy, shock, renal failure, local necrosis/blistering	Specific AV from country
Micrurus spp. (E)	Coral snakes	Flaccid paralysis[2,3], myolysis, renal failure	Specific AV from country
Tityus serrulatus	Brazilian scorpion	Neuroexcitation, shock	Instituto Butantan scorpion AV
Loxosceles spp.	Recluse spiders	Local necrosis	Instituto Butantan spider AV
Phoneutria nigriventer	Banana spider	Neuroexcitation, shock	Instituto Butantan spider AV
Potamotrygon, *Dasyatis* spp.	Freshwater stingrays	Necrosis of bite area, shock, severe pain and oedema	No available AV; good wound care
Australia			
Pseudonaja spp. (E)	Brown snakes	Procoagulant coagulopathy, renal failure, flaccid paralysis[2] (rare)	CSL brown snake AV or PVAV
Notechis spp. (E)	Tiger snakes	Procoagulant coagulopathy, myolysis, flaccid paralysis[2,3], renal failure	CSL tiger snake AV or PVAV
Oxyuranus spp. (E)	Taipans	Procoagulant coagulopathy, flaccid paralysis[2,3], myolysis, renal failure	CSL taipan or PVAV
Acanthophis spp. (E)	Death adders	Flaccid paralysis[3]	CSL death adder or PVAV
Pseudechis spp.	Black and mulga snakes	Anticoagulant coagulopathy, myolysis, renal failure	CSL black snake AV or PVAV
Enhydrina schistosa	Sea snakes (all species globally)	Flaccid paralysis and/or myolysis	CSL sea snake AV
Atrax, *Hadronyche* spp.	Funnel web spiders	Neuroexcitation, shock	CSL funnel web spider AV
Latrodectus hasseltii	Red back spider	Neuroexcitation, pain and sweating	CSL red back spider AV
Chironex fleckeri	Box jellyfish	Neuroexcitation, cardiotoxicity, local necrosis	CSL box jellyfish AV
Synanceia spp.	Stonefish	Severe local pain	CSL stonefish AV

[1]For family name, see Box 8.4. [2]Pre-synaptic. [3]Post-synaptic.
(PVAV = polyvalent antivenom)

A significant proportion of venom is transported from the bite/ sting site via the lymphatic system, particularly for venoms with larger molecular weight toxins, such as many snake venoms. It is recommended that for most forms of envenoming, the patient should be kept still, the bitten limb immobilised with a splint and vital systems supported, where required. A patent upper airway should be specifically ensured and respiratory support provided, if required. For some animals, notably snakes in certain regions, the use of a local pressure pad bandage over the bite site (Myanmar) or a pressure immobilisation bandage (Australia, New Guinea) is recommended.

Ineffective or dangerous first aid, such as suction devices, 'cut and suck', local chemicals, snake stones (stones of some sort placed over the snakebite) and tourniquets, should not be used. Tourniquets, in particular, have the potential to cause catastrophic distal limb injuries in snakebite when applied too narrowly or too tightly, or left on too long.

Transporting patients

Where possible, transport should be brought to the patient. It is also vital to obtain medical assessment and intervention at the earliest opportunity, however, so any delay in transporting the patient to a medical facility should be avoided. Severely envenomed patients may develop life-threatening problems, such as shock or respiratory failure, during transport, so ideally the transport method used should allow for management of these problems en route.

In resource-poor environments, simple solutions for rapid transport have been successfully employed, such as motorbikes or similar with the patient supported between the driver in front and another person behind the patient. However, this method cannot cope with a patient developing airway compromise or respiratory failure, such as from developing neurotoxicity.

i 8.6 Selected important venomous animals in Africa and Europe

Scientific name[1]	Common name	Clinical effects	Antivenom/antidote/treatment
Africa			
Naja spp. (E)	Cobras		
	Non-spitters	Flaccid paralysis[3] ± local necrosis/blistering	South African PV or Sanofi Pasteur FavAfrica AV
	Spitters	Local necrosis/blistering (flaccid paralysis[3] uncommon)	South African PV or Sanofi Pasteur FavAfrica AV
Dendroaspis spp. (E)	Mambas	Mamba neurotoxic flaccid paralysis and muscle fasciculation, shock, necrosis (uncommon)	South African PV or Sanofi Pasteur FavAfrica AV
Hemachatus haemachatus (E)	Rinkhals	Flaccid paralysis[3], local necrosis, shock	South African PV
Atheris spp. (Vv)	Bush vipers	Procoagulant coagulopathy, shock, pain and swelling	No available AV (can try South African AV)
Bitis spp. (Vv)	Puff adders etc.	Procoagulant coagulopathy, shock, cardiotoxicity, local necrosis/blistering	South African PV or Sanofi Pasteur FavAfrica AV
Causus spp. (Vv)	Night adders	Pain and swelling	No available AV
Echis spp. (Vv)	Carpet vipers	Procoagulant coagulopathy, shock, renal failure, local necrosis/blistering	Specific anti-*Echis* AV for species/geographical region or Sanofi Pasteur FavAfrica AV
Cerastes spp. (Vv)	Horned desert vipers	Procoagulant coagulopathy, local necrosis, shock	Specific or polyspecific AV covering *Cerastes* from country of origin
Dispholidus typus (C)	Boomslang	Procoagulant coagulopathy, shock	Boomslang AV
Androctonus spp.	North African scorpions	Neuroexcitation	Specific scorpion AV (Algeria, Tunisia, Sanofi Pasteur Scorpifav)
Lelurus quinquestriatus	Yellow scorpion	Neuroexcitation, shock	Specific scorpion AV (Algeria, Tunisia, Sanofi Pasteur Scorpifav)
Europe			
Vipera spp. (Vv)	Vipers and adders	Shock, local necrosis/blistering, procoagulant coagulopathy (flaccid paralysis[2] rare)	ViperaTab AV or Zagreb AV or SanofiPasteur Viperfav AV

Assessment and management in hospital

On arrival at a health station or hospital, there are two immediate priorities:

- identifying and treating any life-threatening problems (e.g. circulatory shock, respiratory failure; see Ch. 16)
- determining whether envenoming is present and if that requires urgent treatment.

Assessment and management of life-threatening problems

Patients who are seriously envenomed must be identified early so that appropriate management is not delayed. Critically ill patients must be resuscitated (p. 202) and this takes precedence over administration of any antivenom. Clinicians should look for signs of:

- shock/hypotension
- airway and/or respiratory compromise (likely to be secondary to flaccid paralysis)
- major bleeding, including internal bleeding (especially intracranial)
- impending limb compromise from inappropriate first aid (e.g. a tourniquet) – though beware sudden envenoming on removal of a tourniquet.

In a patient with severe neurotoxic flaccid paralysis, who is still able to maintain sufficient respiratory function for survival, clinical assessment may suggest irretrievable brain injury (fixed dilated pupils, absent reflexes, no withdrawal response to painful stimuli, no movement of limbs, fixed forward gaze with gross ptosis; p. 152) when, in fact, the patient is conscious.

Assessment for evidence of envenoming

As in other areas of medicine, comprehensive assessment of a patient bitten/stung by a venomous animal requires a good history, a careful targeted examination and, where appropriate, 'laboratory' testing (though the latter may just consist of simple bedside tests performed by the doctor; p. 153). Animals that are unlikely to cause serious envenomation in humans should be identified so that inappropriate admission and intervention are avoided. Occasionally, patients may be unaware they have been bitten/stung and thus provide a misleading history. In regions of the world where keeping or handling venomous animals is illegal, patients may be reticent in giving a truthful history. Multiple bites or stings are more likely to cause major envenoming.

The following key questions should be asked:

- When was the patient exposed to the venomous bite/sting?
- Was the organism causing it seen and what did it look like (size, colour)?
- What were the circumstances (on land, in water etc.)?
- Was there more than one bite/sting?
- What first aid was used, when and for how long?
- What symptoms has the patient had (local and systemic)?
- Are there symptoms suggesting systemic envenoming (paralysis, rhabdomyolysis, coagulopathy etc.)?

- Is there any significant past medical history and medication use?
- Is there a past exposure to antivenom/venom and allergies?

If patients state that they have been bitten by a particular species, ensure this information is accurate. Private keepers of venomous animals may not have accurate knowledge of what they are keeping, and misidentification of a snake, scorpion or spider can have dire consequences if the wrong antivenom is used.

An outline of some principal findings on examination of the envenomed patient is shown on page 152. The patient may have a cluster of clinical features suggestive of a particular type of envenoming (see Box 8.1).

Even with dangerously venomous animals, some bites/stings will be dry bites and will not require antivenom. The time to onset of first symptoms and signs of envenomation is variable, depending on both animal and patient factors. It may range from a matter of minutes post-bite/sting to 24 hours later in some cases. Therefore, the initial assessment, if normal, must be repeated multiple times during the first 24 hours. Some types of envenomation will not cause symptoms or signs at all, or they may appear very late, long after the optimum time for treatment has passed. Evidence of envenomation may become apparent only through laboratory testing.

Laboratory investigations

Specific tests for venom are currently commercially available only for Australian snakebites but are likely to be developed for snakebites in other regions. They are not available for other types of envenomation, where venom concentrations are low. For snakebite, a screen for envenoming includes full blood count, coagulation screen, urea and electrolytes, creatinine, CK and electrocardiogram (ECG). Lung function tests, peripheral oximetry or arterial blood gases may be indicated in cases with potential or established respiratory failure. In areas without access to routine laboratory tests, the 20-minute whole-blood clotting test (20WBCT) is useful (p. 153).

Treatment

Once a diagnosis of likely envenoming has been made, the next and urgent decision is whether to give antivenom. Antivenom may not be the only crucial treatment, however. For a snakebite by a potentially lethal species such as Russell's viper, the patient might have local effects with oedema, blistering, necrosis, and resultant fluid shifts causing shock, and at the same time have systemic effects such as intractable vomiting, coagulopathy, paralysis and secondary renal failure. Specific treatment with antivenom will be required to reverse the coagulopathy and may prevent worsening of the paralysis and reduce the vomiting, but will not greatly affect the local tissue damage or the renal failure or shock. The latter will require intravenous fluid therapy, possibly respiratory support, renal dialysis and local wound care, perhaps including antibiotics.

Each venomous animal will cause a particular pattern of envenomation, requiring a tailored response. Listing all of these is beyond the scope of this chapter (see 'Further information' below).

Antivenom

Antivenom, sometimes inappropriately labelled as 'anti-snake venom' (ASV), is the most important tool in treating envenoming. It is made by hyperimmunising an animal, usually horses, to produce antibodies against venom. Once refined, these bind to venom toxins and render them inactive or allow their rapid clearance. Antivenom is available only for certain venomous animals and cannot reverse all types of envenoming. With a few exceptions, it should be given intravenously, with adrenaline (epinephrine) ready in case of anaphylaxis. It should be used only when clearly indicated, and indications will vary between venomous animals (Box 8.7). It is critical that the correct antivenom is used at the appropriate dose. Doses vary widely between antivenoms. In some situations (such as the Indian subcontinent), pre-treatment with subcutaneous adrenaline may reduce the chance of anaphylaxis to antivenom.

8.7 Indications for antivenom

General indications

- Shock/cardiac collapse
- Respiratory compromise
- Rapidly increasing swelling of the bitten limb
- Active bleeding
- Intractable non-specific symptoms, including recurrent vomiting

Specific indications

- Developing paralytic features (ptosis etc.)
- Developing rhabdomyolysis
- Developing coagulopathy
- Developing renal failure
- Developing neuroexcitatory envenoming

Antivenom can sometimes reverse post-synaptic neurotoxic paralysis (α-bungarotoxin-like neurotoxins) but will not usually reverse established pre-synaptic paralysis (β-bungarotoxin-like neurotoxins), so should be given before major paralysis has occurred (Fig. 8.2). Coagulopathy is best reversed by antivenom, but even after all venom is neutralised, there may be a delay of hours before normal coagulation is restored. More antivenom should not be given because coagulopathy has failed to normalise fully in the first 1–3 hours (except in very particular circumstances). Thrombocytopenia may persist for days, despite antivenom. The role of antivenom in reversing established rhabdomyolysis and renal failure is uncertain. Antivenom may help limit local tissue effects or injury in the bitten limb but this is quite variable and time-dependent. Neuroexcitatory envenoming can respond very well to antivenom (Australian funnel web spider bites and Mexican, South American and Indian scorpion stings) but there is controversy about the effectiveness of antivenom for some species (some North African and Middle Eastern scorpions). The role of antivenom in limiting local venom effects, including necrosis, is also controversial; it is most likely to be effective when given early.

All patients receiving antivenom are at risk of both early and late adverse reactions, including anaphylaxis (early; not always related to immunoglobulin E (IgE)) and serum sickness (late).

Non-antivenom treatments

Anticholinesterases are used as an adjunctive treatment for post-synaptic paralysis.

Prazosin (an α-adrenoceptor antagonist) is used in the management of hypertension or pulmonary oedema in scorpion sting cardiotoxicity, particularly for Indian red scorpion stings, though antivenom is now the preferred treatment.

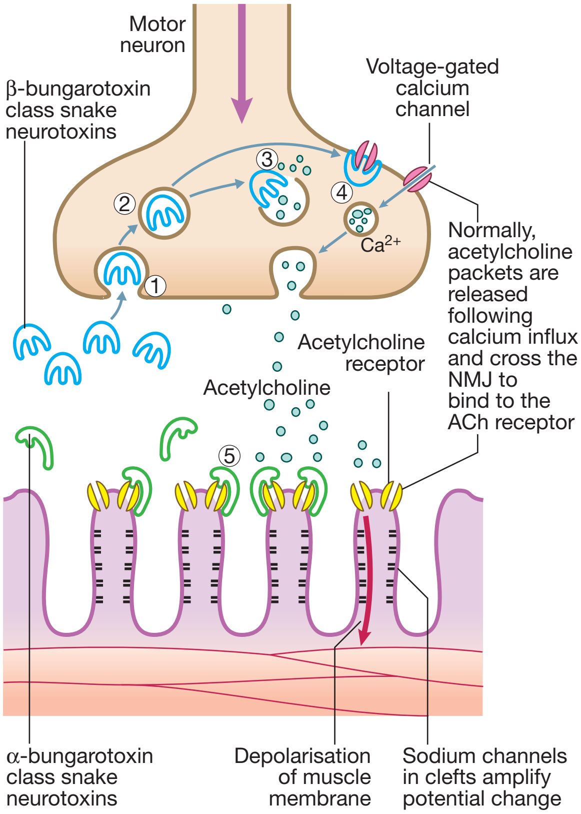

Fig. 8.2 Principal snake venom neurotoxins acting at the neuromuscular junction (NMJ). The pre-synaptic neurotoxins (β-bungarotoxin-like) bind to the cell membrane of the terminal axon (1), form a synaptosome (2) and enter the cell, where they disrupt acetylcholine (ACh) production (3) and damage intracellular structures, including ion channels (4). On initial entry, they cause release of excess ACh, followed by cessation of all ACh release, causing irreversible paralysis until the cell is repaired (days to weeks later). The post-synaptic neurotoxins (α-bungarotoxin-like) bind adjacent to the ACh receptor on the external surface of the muscle end plate and block ACh binding (5), thereby ceasing neurotransmission. Because this action is external to the cell and does not cause cell damage, it is potentially a reversible paralysis. *Copyright © Julian White.*

Antibiotics are not routinely required for most bites/stings, though a few animals, such as some South American pit vipers and stingrays, regularly cause significant wound infection or abscess. Tetanus is a risk in some types of bite or sting, such as snakebite, but intramuscular toxoid should not be given until any coagulopathy is reversed.

Mechanical ventilation (p. 202) is vital for established respiratory paralysis that will not reverse with antivenom and may be required for prolonged periods (up to several months in some cases).

Fasciotomy as a treatment for potential compartment syndrome or severe limb swelling is an overused and often disastrous surgical intervention in snakebite and is associated with poor functional outcomes. It should be reserved as a treatment of last resort and be used only in cases where compartment syndrome is confirmed by intracompartment pressure measurement and after first trying limb elevation and antivenom, and ensuring that any coagulopathy has resolved.

Follow-up

Cases with significant envenomation and those receiving antivenom should be followed up to ensure any complications have resolved and to identify any delayed envenoming.

Envenomation by specific animals

Venomous snakes

Venomous snakes represent the single most important cause of envenomation globally, affecting millions of humans annually and resulting in large numbers of deaths and patients left with long-term disability. Of the 3000-plus snake species, more than 1000 either are venomous or produce oral toxins. The most important venomous snake families are the Viperidae (vipers; includes typical vipers (subfamily Viperinae) and pit-vipers, with heat-sensing pit organs (subfamily Crotalinae)) and the Elapidae (cobras, kraits, mambas, coral snakes, sea snakes, Australian snakes). However, there are also dangerous species among the Atractaspididae (side-fanged burrowing vipers of Africa and the Middle East) and the non-front-fanged colubrids (NFFC snakes; several families, including the 'back-fanged' boomslang and vine snakes of Africa and the keelbacks of Asia).

A selection of important species is included in Boxes 8.4–8.6.

Clinical features and management

As with other forms of envenoming, the management of snakebite follows the standard assessment guidelines described previously (p. 152). The nature of the risks posed will depend on the specific snake fauna in a given region (p. 153). For example, in the Indian subcontinent, the major snakebite risks are claimed to come from the 'big four': cobras, kraits, Russell's viper and saw-scaled vipers. This list is misleading, though, as it omits other important snakes, including the hump-nosed vipers, king cobra and green pit vipers, all of which can cause severe or lethal envenoming and may not be covered by current Indian antivenoms. Even for those snakes recognised as causing envenoming, there may be major geographical variation in venom and features of envenoming. For Russell's viper (*Daboia* spp.), Sri Lankan specimens can cause rhabdomyolysis and flaccid paralysis, in addition to classic severe coagulopathy, haemorrhage, local bite site injury and acute kidney injury (AKI). Indian populations of the same snake are not associated with either rhabdomyolysis or paralysis, but in parts of Southern India may cause anterior pituitary haemorrhage and/or capillary leak syndrome (hypotensive shock plus vascular leakage resulting in pulmonary oedema). Capillary leak syndrome is also encountered with populations of Burmese Russell's viper (Myanmar), where AKI is especially common and severe.

Antivenom raised against venom from one population of these snakes is often poorly effective against bites from snakes from other regions. Similarly, each of the several species of saw-scaled vipers (*Echis* spp.) spread from West Africa across the Middle East to the Indian subcontinent, including Sri Lanka, has specific venoms that may not be neutralised by antivenoms raised against other species in the genus; Indian antivenoms are ineffective against African species. It follows that, in managing snakebite envenomation, it is critically important to choose the appropriate antivenom and to understand that

this may not include every antivenom claiming to cover a given species.

It is unwise to assume that everything is known about envenoming by snakes because new clinical information and syndromes are emerging as more detailed studies are carried out. For instance, krait bites (*Bungarus* spp.), long associated with 'painless' bites, later development of devastating flaccid paralysis and a high mortality rate, are now known to have some venom diversity. At least some species can cause rhabdomyolysis and/or severe hyponatraemia, and while bites may be painless, systemic envenomation can cause severe abdominal pain in at least some patients. Among cobra bites, the previous division into 'non-spitting', neurotoxic species and 'spitting', less neurotoxic species that cause local necrosis is less clear. Non-spitters are now known to spit in parts of their range (e.g. *Naja kaouthia* in West Bengal) and may cause local necrosis in addition to paralysis. Previously clear diagnostic indicators for envenomation by particular types of snakes, such as Russell's vipers and saw-scaled vipers causing coagulopathy, have also become less sure, as it is now known that other snakes, such as hump-nosed vipers (*Hypnale* spp.) and green pit vipers (*Trimeresurus* spp.), found in similar regions, can also cause marked coagulopathy and yet are often not covered by available antivenoms. The ability to cause life-threatening coagulopathy, associated with snakes previously considered harmless, such as the keelbacks in Asia (*Rhabdophis* spp.), can further complicate the diagnostic and management process, as antivenom against these snakes is currently available only in Japan.

Scorpions

Scorpions are second only to snakes in their venomous impact on humankind. Most medically important scorpions are in the family Buthidae and have complex neuroexcitatory venoms with highly specific ion-channel toxins. Classically, stings by these scorpions (some key genera listed in Boxes 8.4–8.6) cause moderate to severe local pain and rapid-onset systemic envenoming with development of a catecholamine storm-like syndrome as the toxins target the nervous system. There may be tachycardia or bradycardia, hyper- or hypotension, profuse sweating, salivation, cardiac dysfunction and pulmonary oedema. Cardiac collapse can occur, especially in children. Other clinical features may vary, depending on the scorpion species.

The Iranian scorpion, *Hemiscorpius lepturus* (principally south-west Iran), causes a quite different presentation, with an initial minor sting, followed by progressive development of bite site or limb necrosis and a potentially lethal systemic envenoming, characterised by intravascular haemolysis, disseminated intravascular coagulation (DIC), secondary renal failure and shock.

Clinical features and management

The approach to management varies with species and region. In Latin America, specific antivenoms are routinely used and associated with improved outcomes and dramatic falls in mortality rate. In India, the past reliance on prazosin has been replaced with use of specific antivenom, again with improved outcomes. In contrast, in parts of North Africa, past reliance on antivenom has been replaced with use of cardiac support and arguably poorer outcomes.

In Iran, *H. lepturus* stings are treated with antivenom, though as presentation is often delayed because the sting initially appears to be minor, the role of late antivenom is unclear.

Spiders

There are vast numbers and great species diversity of spiders, with two broad taxonomic groupings: the more 'primitive' Mygalomorphs (several medically important species, especially Australian funnel web spiders (*Atrax, Hadronyche* and *Illawarra*)) and the far more diverse Araneomorphs (main clinically important species in the genera *Latrodectus* (widow spiders), *Loxosceles* (brown recluse spiders) and *Phoneutria* (banana or wandering spiders)).

Clinical features and management

While spiders and spider bites are common, only those genera noted above commonly cause medically significant effects. In most cases this is a neuroexcitatory envenoming, sometimes similar to severe scorpion envenoming (notable from Australian funnel web spiders), but the recluse spiders cause an often painless bite that develops into local skin necrosis and sometimes a systemic illness similar to that caused by the Iranian scorpion, *H. lepturus*, and with similar lethal potential.

For most of these spiders, antivenom remains the key treatment and is life-saving in some cases. Recent studies suggesting that anti-*Latrodectus* antivenom is ineffective have not been confirmed by independent studies and are in contrast to decades of positive clinical experience.

Paralysis ticks

Most ticks are vectors for disease but a few species in Australia, North America and parts of Africa can cause flaccid paralysis. Toxins in the saliva act as potent pre-synaptic neurotoxins that can cause gradual-onset ascending flaccid paralysis.

There are no antivenoms for tick paralysis. Treatment is based on removal of all ticks and supportive care, including intubation/ventilation where required. The paralysis usually resolves by about 48 hours following removal of all ticks.

Venomous insects

A number of insects are venomous but very few cause significant envenoming in humans.

Venomous lepidopterans

The *Lonomia* caterpillars of South America, especially Brazil, have numerous protective venomous spines that, on contact with the skin, can discharge a potent procoagulant venom that can cause a progressive and sometimes fatal consumptive coagulopathy, with terminal haemorrhagic and/or organ failure events. Treatment includes use of a Brazilian specific antivenom and supportive care.

Venomous hymenopterans

Many bees, wasps, hornets and some ants have modified ovipositors in the abdomen that act as stings, attached to venom glands. The quantity of venom injected in a single sting is insufficient to cause significant envenomation, but as many of these venoms are potently allergenic, it can cause severe and sometimes fatal anaphylaxis in sensitised persons (p. 75). Massed stings by hundreds of these insects in a swarm, however, can cause life-threatening systemic envenoming, often with intravascular haemolysis, DIC, shock and multi-organ failure. 'Africanised' bees are a particular risk for such attacks in South

America and now in parts of North America. The giant wasps and hornets of Asia can similarly cause systemic envenoming with multiple attacks. Invasive ants, such as *Solenopsis* spp., are colonising new regions and can cause both allergic reactions and unpleasant local reactions.

Marine venomous and poisonous animals

The marine environment is dominated by animal life, and many species utilise toxins, either self-produced or taken up from the environment, to arm themselves for either defence or predation. Many of these animals can cause adverse effects in humans, either as a direct venom effect on bites/stings (venomous spiny fish, sea snakes, stingrays, jellyfish, sea urchins, some starfish, cone snails, selected octopuses etc.), or through poisoning if eaten (fugu, ciguatera, scombroid, several types of shellfish poisoning; p. 149).

For venomous marine animals, there is antivenom available only for sea snakes, which can cause rhabdomyolysis and/paralytic neurotoxicity; box jellyfish, which can cause very rapid cardiac collapse; and stonefish, which cause intense sting-site pain. In general, marine venoms respond to heat; thus a hot water immersion or shower (about 45°C) is effective at reducing local pain, particularly for jellyfish, stinging fish and stingray stings. For stingray stings, the venom may cause local tissue damage both through sting trauma and a venom effect; wounds penetrating the abdomen or chest are potentially lethal and wounds should be adequately explored, cleaned and allowed to heal by secondary intention. For bites by the blue-ringed octopus and stings by cone snails, rapid-acting venom can cause early cardiovascular collapse and flaccid paralysis. Supportive care is crucial in ensuring survival from these potentially lethal and seemingly trivial local wounds. Sea urchin and venomous starfish wounds can result in multiple penetrating spines, which cause pain and act as a nidus for secondary infection, but surgical removal of spines can be difficult and unrewarding.

Environmental medicine

Environmental medicine deals with the interactions between the environment and human health. While previously concerned mainly with controlling infectious diseases, the focus at present is predominantly on the multiple physical, chemical, biological and social factors that pose risks to human health. As the environment continually alters, whether through population growth, economic development or climate change, it plays an important role in disease causation – one that may increase over time. This chapter deals principally with acute effects of environmental hazards on individuals and should be read in conjunction with the chapters on Poisoning (Ch. 7) and Acute Medicine and Critical Illness (Ch. 10). Chapter 5 deals with more general effects of environmental factors on population health.

Radiation exposure

Radiation includes ionising (Fig. 9.1) and non-ionising radiations (ultraviolet (UV), visible light, laser, infrared and microwave). While global industrialisation and the generation of fluorocarbons have raised concerns about loss of the ozone layer, leading to an increased exposure to UV rays, and disasters such as the Chernobyl and Fukushima nuclear power station explosions have demonstrated the harm of ionising radiation, it is important to remember that it can be harnessed for medical benefit. Ionising radiation is used in X-rays, computed tomography (CT), radionuclide scans and radiotherapy, and non-ionising UV for therapy in skin diseases and laser therapy for diabetic retinopathy.

Types of ionising radiation

These include charged subatomic alpha and beta particles, uncharged neutrons or high-energy electromagnetic radiations such as X-rays and gamma rays. When they interact with atoms, energy is released and the resulting ionisation can lead to molecular damage. The clinical effects of different forms of radiation depend on their range in air and tissue penetration (Fig. 9.1).

Dosage and exposure

The dose of radiation is based on the energy absorbed by a unit mass of tissue and is measured in grays (Gy), with 1 Gy representing 1 J/kg. To take account of different types of radiation and variations in the sensitivity of various tissues, weighting factors are used to produce a unit of effective dose, measured in sieverts (Sv). This value reflects the absorbed dose weighted for the damaging effects of a particular form of radiation and is most valuable in evaluating the long-term effects of exposure.

'Background radiation' refers to our exposure to naturally occurring radioactivity (e.g. radon gas and cosmic radiation). This produces an average annual individual dose of approximately 2.6 mSv per year, although this figure varies according to local geology.

Effects of radiation exposure

Effects on the individual are classified as either deterministic or stochastic.

Deterministic effects

Deterministic (threshold) effects occur with increasing severity as the dose of radiation rises above a threshold level. Tissues with actively dividing cells, such as bone marrow and gastrointestinal mucosa, are particularly sensitive to ionising radiation. Lymphocyte depletion is the most sensitive marker of bone marrow injury, and after exposure to a fatal dose, marrow aplasia is a common cause of death. However, gastrointestinal mucosal toxicity may cause earlier death due to profound diarrhoea, vomiting, dehydration and sepsis. The gonads are highly radiosensitive and radiation may result in temporary or permanent sterility. Eye exposure can lead to cataracts and the skin is susceptible to radiation burns. Irradiation of the lung may induce acute inflammatory reactions or pulmonary fibrosis, and irradiation of the central nervous system may cause permanent neurological deficit. Bone necrosis and lymphatic fibrosis are characteristic following regional irradiation, particularly for breast cancer. The thyroid gland is not inherently sensitive but its ability to concentrate iodine makes it susceptible to damage after exposure to relatively low doses of radioactive iodine isotopes, such as those released from Chernobyl.

Stochastic effects

Stochastic (chance) effects occur with increasing probability as the dose of radiation increases. Carcinogenesis represents a stochastic effect. With acute exposures, leukaemias may arise after an interval of around 2–5 years and solid tumours after an

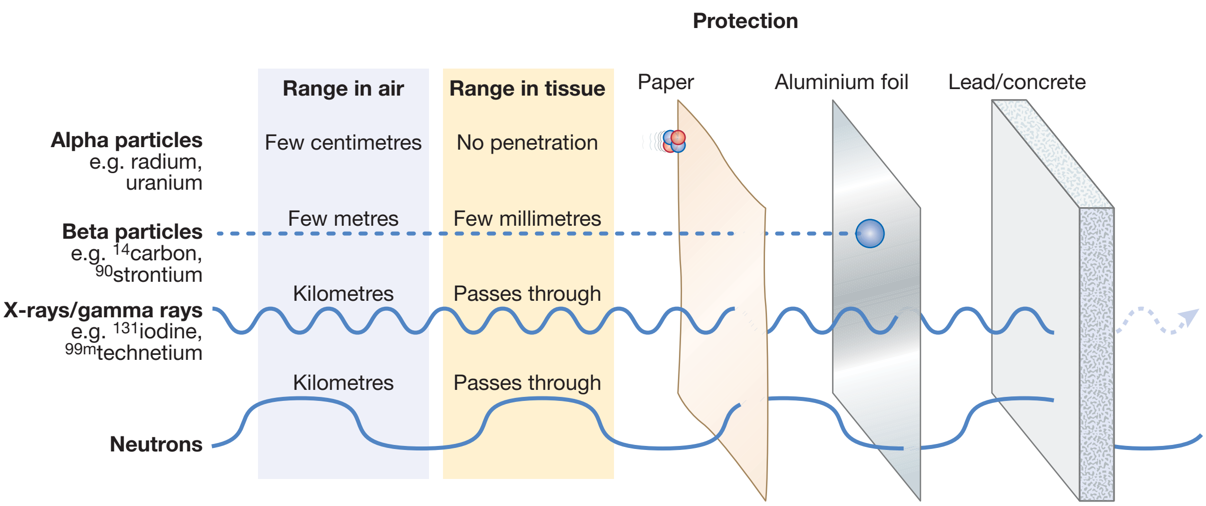

Fig. 9.1 Properties of different ionising radiations.

interval of about 10–20 years. Thereafter the incidence rises with time. An individual's risk of developing cancer depends on the dose received, the time to accumulate the total dose and the interval following exposure.

Management of radiation exposure

Exposed people should be removed from ongoing exposure ('get inside, stay inside'), and should take off affected clothing and shower to stop further contamination. If contamination of food and water supplies may have occurred, only bottled water and food in sealed containers should be consumed. The principal problems after large-dose exposures are maintenance of adequate hydration, control of sepsis and management of marrow aplasia. Associated injuries such as thermal burns need specialist management within 48 hours of active resuscitation. Internal exposure to radioisotopes should be treated with chelating agents (such as Prussian blue used to chelate ^{137}caesium after ingestion). White-cell colony stimulation and haematopoietic stem cell transplantation may need to be considered for marrow aplasia.

Extremes of temperature

Thermoregulation

Body heat is generated by basal metabolic activity and muscle movement, and lost by conduction (which is more effective in water than in air), convection, evaporation and radiation (most important at lower temperatures when other mechanisms conserve heat) (Box 9.1). Body temperature is controlled in the hypothalamus, which is directly sensitive to changes in core temperature and indirectly responds to temperature-sensitive neurons in the skin. The normal 'set-point' of core temperature is tightly regulated within the range 37±0.5°C, which is necessary to preserve the normal function of many enzymes and other metabolic processes. The temperature set-point is increased in response to infection (p. 218).

9.1 Thermoregulation: responses to hot and cold environments

	Mechanism	Hot environment	Cold environment
Heat production	Basal metabolic rate	→	↓ in hypothermia
	Muscle activity	↓ by lethargy	↑ by shivering ↓ in severe hypothermia
Heat loss	Conduction*	↑ by vasodilatation	↓ by vasoconstriction ↑↑ in water <31°C
	Convection*	↑ by vasodilatation ↓ by lethargy	↓ by vasoconstriction ↑ by wind and movement
	Evaporation*	↑↑ by sweating ↓ by high humidity	↑ by hyperventilation
	Radiation	↑ by vasodilatation	↓ by vasoconstriction (but is the major heat loss in dry cold)

*These losses are dependent on the relative ambient and skin temperatures.

In a cold environment, protective mechanisms include cutaneous vasoconstriction and shivering; however, any muscle activity that involves movement may promote heat loss by increasing convective loss from the skin, and respiratory heat loss by stimulating ventilation. In a hot environment, sweating is the main mechanism for increasing heat loss. This usually occurs when the ambient temperature rises above 32.5°C or during exercise.

Hypothermia

Hypothermia exists when the body's normal thermal regulatory mechanisms are unable to maintain heat in a cold environment and core temperature falls below 35°C (Fig. 9.2). Moderate hypothermia occurs below 32°C and severe hypothermia below 28°C. Other systems define hypothermia on the basis of symptoms rather than absolute temperature.

While infants are susceptible to hypothermia because of their poor thermoregulation and high body surface area to weight ratio, it is the elderly who are at highest risk (Box 9.2). Hypothyroidism is often a contributory factor in old age, while

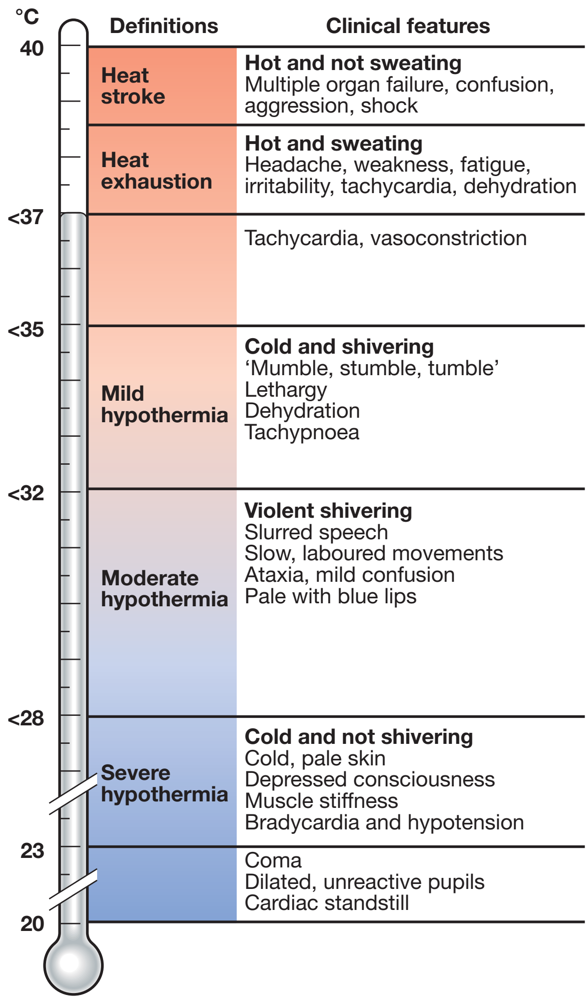

Fig. 9.2 Clinical features of abnormal core temperature. The hypothalamus normally maintains core temperature at 37°C, but this set-point is altered in, for example, fever (pyrexia, p. 218), and may be lost in hypothalamic disease (p. 679). In these circumstances, the clinical picture at a given core temperature may be different.

9.2 Thermoregulation in old age

- **Age-associated changes**: impairments in vasomotor function, skeletal muscle response and sweating mean that older people react more slowly to changes in temperature.
- **Increased comorbidity**: thermoregulatory problems are more likely in the presence of pathology such as atherosclerosis and hypothyroidism, and medication such as sedatives and hypnotics.
- **Hypothermia**: this may arise as a primary event, but more commonly complicates other acute illness, e.g. pneumonia, stroke or fracture.
- **Ambient temperature**: financial pressures and older equipment may result in inadequate heating during cold weather.

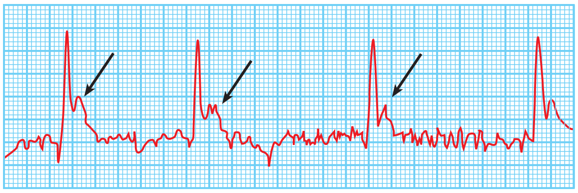

Fig. 9.3 Electrocardiogram showing J waves (arrows) in a hypothermic patient.

alcohol and other drugs (e.g. phenothiazines) commonly impede the thermoregulatory response in younger people. More rarely, hypothermia is secondary to hypothyroidism, glucocorticoid insufficiency, stroke, hepatic failure or hypoglycaemia.

Hypothermia also occurs in healthy individuals whose thermoregulatory mechanisms are intact but insufficient to cope with the intensity of the thermal stress. Typical examples include immersion in cold water, when core temperature may fall rapidly (acute hypothermia), exposure to extreme climates such as during hill walking (subacute hypothermia), and slow-onset hypothermia, as develops in an immobilised older individual (subchronic hypothermia). This classification is important, as it determines the method of rewarming.

Clinical features

Diagnosis is dependent on recognition of the environmental circumstances and measurement of core (rectal) body temperature. Clinical features depend on the degree of hypothermia (Fig. 9.2).

In a cold patient, it is very difficult to diagnose death reliably by clinical means. It has been suggested that, in extreme environmental conditions, irreversible hypothermia is probably present if there is asystole (no carotid pulse for 1 min), the chest and abdomen are rigid, the core temperature is <13°C and serum potassium is >12 mmol/L. However, in general, resuscitative measures should continue until the core temperature is normal and only then should a diagnosis of brain death be considered (p. 211).

Investigations

Blood gases, a full blood count, electrolytes, chest X-ray and electrocardiogram (ECG) are all essential investigations. Haemoconcentration and metabolic acidosis are common, and the ECG may show characteristic J waves, which occur at the junction of the QRS complex and the ST segment (Fig. 9.3). Cardiac arrhythmias, including ventricular fibrillation, may occur. Although the arterial oxygen tension may be normal when measured at room temperature, the arterial PO_2 in the blood falls by 7% for each 1°C fall in core temperature. Serum aspartate aminotransferase and creatine kinase may be elevated secondary to muscle damage and the serum amylase is often high due to subclinical pancreatitis. If the cause of hypothermia is not obvious, additional investigations for thyroid and pituitary–adrenal dysfunction (p. 633), hypoglycaemia (p. 725) and the possibility of drug intoxication (p. 134) should be performed.

Management

Following resuscitation, the objectives of management are to rewarm the patient in a controlled manner while treating associated hypoxia (by oxygenation and ventilation if necessary), fluid and electrolyte disturbance, and cardiovascular abnormalities, particularly arrhythmias. Careful handling is essential to avoid precipitating the latter. The method of rewarming is dependent not on the absolute core temperature, but on haemodynamic stability and the presence or absence of an effective cardiac output.

Mild hypothermia

Outdoors, continued heat loss is prevented by sheltering the patient from the cold, replacing wet clothing, covering the head and insulating him or her from the ground. Once in hospital, even in the presence of profound hypothermia, if there is an effective cardiac output then forced-air rewarming, heat packs placed in axillae and groins and around the abdomen, inhaled warmed air and correction of fluid and electrolyte disturbances are usually sufficient. Rewarming rates of 1–2°C per hour are effective in leading to a gradual and safe return to physiological normality. Underlying conditions should be treated promptly (e.g. hypothyroidism with triiodothyronine 10 μg IV 3 times daily; p. 640).

Severe hypothermia

In the case of severe hypothermia (<28°C), patients with cardiopulmonary arrest (non-perfusing rhythm), or those with cardiac instability (systolic blood pressure <90 mmHg or ventricular arrhythmias), the aim is to restore perfusion, and rapid rewarming at a rate of >2°C per hour is required. This is best achieved by cardiopulmonary bypass or extracorporeal membrane oxygenation (ECMO). If these are unavailable, then veno–veno haemofiltration, and pleural, peritoneal, thoracic or bladder lavage with warmed fluids are alternatives. Direct heat sources, such as hot water or heat pads, should be used with caution, as these can provoke cardiac arrhythmias or cause burns. Monitoring of cardiac rhythm and arterial blood gases, including H^+ (pH), is essential. Significant acidosis may require correction (p. 364).

Cold injury

Freezing cold injury (frostbite)

This represents the direct freezing of body tissues and usually affects the extremities: in particular, the fingers, toes, ears and face. Risk factors include smoking, peripheral vascular disease, dehydration and alcohol consumption. The tissues may become anaesthetised before freezing and, as a result, the injury often goes unrecognised at first. Frostbitten tissue is initially pale and doughy to the touch and insensitive to pain (Fig. 9.4). Once frozen, the tissue is hard.

Rewarming should not occur until it can be achieved rapidly in a water bath. Give oxygen and aspirin 300 mg as soon as possible. Frostbitten extremities should be rewarmed in warm water at 37–39°C, with antiseptic added. Adequate analgesia is necessary, as rewarming is very painful. Vasodilators such as

Fig. 9.4 Frostbite in a female Everest sherpa.

pentoxifylline (a phosphodiesterase inhibitor) have been shown to improve tissue survival. Once it has thawed, the injured part must not be re-exposed to the cold, and should be dressed and rested. While wound débridement may be necessary, amputations should be delayed for 60–90 days, as good recovery may occur over an extended period. As yet, the role of hyperbaric oxygen in the treatment of frostbite requires further research.

Non-freezing cold injury (trench or immersion foot)

This results from prolonged exposure to cold, damp conditions. The limb (usually the foot) appears cold, ischaemic and numb, but there is no freezing of the tissue. On rewarming, the limb appears mottled and thereafter becomes hyperaemic, swollen and painful. Recovery may take many months, during which period there may be chronic pain and sensitivity to cold. The pathology remains uncertain but probably involves endothelial injury. Gradual rewarming is associated with less pain than rapid rewarming. The pain and associated paraesthesia are difficult to control with conventional analgesia and may require amitriptyline (50 mg nocte), best instituted early. The patient is at risk of further damage on subsequent exposure to the cold.

Chilblains

Chilblains are tender, red or purplish skin lesions that occur in the cold and wet. They are often seen in horse riders, cyclists and swimmers, and are more common in women than men. They are short-lived and, although painful, not usually serious.

Heat-related illness

When generation of heat exceeds the body's capacity for heat loss, core temperature rises. Non-exertional heat illness (NEHI) occurs with a high environmental temperature in those with attenuated thermoregulatory control mechanisms: the elderly, the young, those with comorbidity or those taking drugs that affect thermoregulation (particularly phenothiazines, diuretics and alcohol). Exertional heat illness (EHI), on the other hand, typically develops in athletes when heat production exceeds the body's ability to dissipate it.

Acclimatisation mechanisms to environmental heat include stimulation of the sweat mechanism with increased sweat volume, reduced sweat sodium content and secondary hyperaldosteronism to maintain body sodium balance. The risk of heat-related illness falls as acclimatisation occurs. Heat illness can be prevented to a large extent by adequate replacement of salt and water, although excessive water intake alone should be avoided because of the risk of dilutional hyponatraemia (p. 357).

A spectrum of illnesses occurs in the heat (see Fig. 9.2). The cause is usually obvious but the differential diagnosis should be considered (Box 9.3).

i 9.3 Differential diagnosis in patients with elevated core body temperature

- Heat illness (heat exhaustion, heat stroke)
- Sepsis, including meningitis
- Malaria
- Drug overdose
- Serotonin syndrome (pp. 139 and 1199)
- Malignant hyperpyrexia
- Thyroid storm (p. 639)

Heat cramps

These painful muscle contractions occur following vigorous exercise and profuse sweating in hot weather. There is no elevation of core temperature. The mechanism is considered to be extracellular sodium depletion as a result of persistent sweating, exacerbated by replacement of water but not salt. Symptoms usually respond rapidly to rehydration with oral rehydration salts or intravenous saline.

Heat syncope

This is similar to a vasovagal faint (p. 181) and is related to peripheral vasodilatation in hot weather.

Heat exhaustion

Heat exhaustion occurs with prolonged exertion in hot and humid weather, profuse sweating and inadequate salt and water replacement. There is an elevation in core (rectal) temperature to between 37°C and 40°C, leading to the clinical features shown in Figure 9.2. Blood analyses may show evidence of dehydration with mild elevation of the blood urea, sodium and haematocrit. Treatment involves removal of the patient from the heat, and active evaporative cooling using tepid sprays and fanning ('strip–spray–fan'). Fluid losses are replaced with either oral rehydration mixtures or intravenous isotonic saline. Up to 5 L positive fluid balance may be required in the first 24 hours. Untreated, heat exhaustion may progress to heat stroke.

Heat stroke

Heat stroke occurs when the core body temperature rises above 40°C and is a life-threatening condition. The symptoms of heat exhaustion progress to include headache, nausea and vomiting. Neurological manifestations include a coarse muscle tremor and confusion, aggression or loss of consciousness. The patient's skin feels very hot, and sweating is often absent due to failure of thermoregulatory mechanisms. Complications include hypovolaemic shock, lactic acidosis, disseminated intravascular coagulation, rhabdomyolysis, hepatic and renal failure, and pulmonary and cerebral oedema.

Duration of hyperthermia is key to the outcome and immediate cooling should begin at the scene, before transfer to hospital. The aim should be to reduce core temperature by >0.2°C per minute to approximately 39°C, while avoiding overshooting and hypothermia. The patient should be resuscitated with evaporative or convective cooling. Fluid resuscitation with crystalloid intravenous fluids should be instituted but solutions containing potassium

should be avoided. Intravenous dextrose may be necessary, as hypoglycaemia can occur. Appropriate monitoring of fluid balance, including central venous pressure, is important, as over-aggressive fluid replacement may precipitate pulmonary oedema or further metabolic disturbance. Investigations for complications include routine haematology and biochemistry, coagulation screen, hepatic transaminases (aspartate aminotransferase and alanine aminotransferase), creatine kinase and chest X-ray. Once emergency treatment is established, heat stroke patients are best managed in intensive care.

Heat stroke is an emergency with a significant mortality. However, where temperatures can be reduced to <40°C within 30 minutes of collapse, death rates can approach zero. Patients who have had core temperatures of >40°C should be monitored carefully for later onset of rhabdomyolysis, renal damage and other complications before discharge from hospital. Clear advice to avoid heat and heavy exercise during recovery is important.

High altitude

The physiological effects of high altitude are significant. On Everest, the barometric pressure of the atmosphere falls from sea level by approximately 50% at base camp (5400 m) and approximately 70% at the summit (8848 m). The proportions of oxygen, nitrogen and carbon dioxide in air do not change with the fall in pressure but their partial pressure falls in proportion to barometric pressure (Fig. 9.5). Oxygen tension within the pulmonary alveoli is further reduced at altitude because the partial pressure of water vapour is related to body temperature and not barometric pressure, and so is proportionately greater at altitude, accounting for only 6% of barometric pressure at sea level but 19% at 8848 m.

Physiological effects of high altitude

Reduction in oxygen tension results in a fall in arterial oxygen saturation (Fig. 9.5). This varies widely between individuals, depending on the shape of the sigmoid oxygen–haemoglobin dissociation curve (see Fig. 23.5, p. 917) and the ventilatory response. Acclimatisation to hypoxaemia at high altitude involves a shift in this dissociation curve (dependent on 2,3-diphosphoglycerate (2,3-DPG)), erythropoiesis, haemoconcentration, and hyperventilation resulting from hypoxic drive, which is then sustained despite hypocapnia by restoration of cerebrospinal fluid pH to normal in prolonged hypoxia. This process takes several days, so travellers need to plan accordingly.

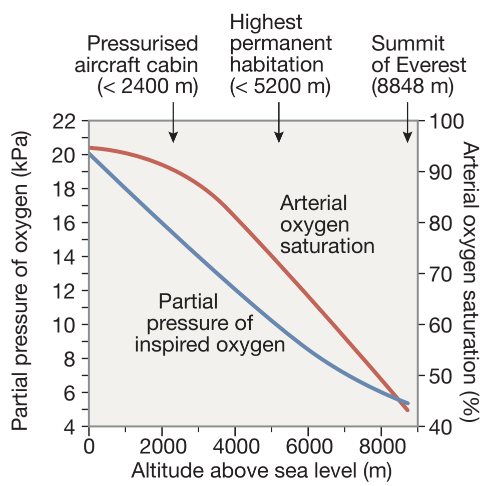

Fig. 9.5 Change in inspired oxygen tension and blood oxygen saturation at altitude. The blue curve shows changes in oxygen availability at altitude and the red curve shows the typical resultant changes in arterial oxygen saturation in a healthy person. Oxygen saturation varies between individuals according to the shape of the oxygen–haemoglobin dissociation curve and the ventilatory response to hypoxaemia. (To convert kPa to mmHg, multiply by 7.5.)

Illnesses at high altitude

Ascent to altitudes up to 2500 m or travel in a pressurised aircraft cabin is harmless to healthy people. Above 2500 m high-altitude illnesses may occur in previously healthy people, and above 3500 m these become common. Sudden ascent to altitudes above 6000 m, as experienced by aviators, balloonists and astronauts, may result in decompression illness with the same clinical features as seen in divers (see below), or even loss of consciousness. However, most altitude illness occurs in travellers and mountaineers.

Acute mountain sickness

Acute mountain sickness (AMS) is a syndrome comprised principally of headache, together with fatigue, anorexia, nausea and vomiting, difficulty sleeping or dizziness. Ataxia and peripheral oedema may be present. The aetiology of AMS is not fully understood but it is thought that hypoxaemia increases cerebral blood flow and hence intracranial pressure. Symptoms occur within 6–12 hours of an ascent and vary in severity from trivial to completely incapacitating. The incidence in travellers to 3000 m may be 40–50%, depending on the rate of ascent.

Treatment of mild cases consists of rest and simple analgesia; symptoms usually resolve after 1–3 days at a stable altitude, but may recur with further ascent. Occasionally, there is progression to cerebral oedema. Persistent symptoms indicate the need to descend but may respond to acetazolamide, a carbonic anhydrase inhibitor that induces a metabolic acidosis and stimulates ventilation; acetazolamide may also be used as prophylaxis if a rapid ascent is planned.

High-altitude cerebral oedema

The cardinal symptoms of high-altitude cerebral oedema (HACE) are ataxia and altered consciousness. HACE is rare, life-threatening and usually preceded by AMS. In addition to features of AMS, the patient suffers confusion, disorientation, visual disturbance, lethargy and ultimately loss of consciousness. Papilloedema and retinal haemorrhages are common and focal neurological signs may be found.

Treatment is directed at improving oxygenation. Descent is essential and dexamethasone (8 mg immediately and 4 mg 4 times daily) should be given. If descent is impossible, oxygen therapy in a portable pressurised bag may be helpful.

High-altitude pulmonary oedema

High-altitude pulmonary oedema (HAPE) is a life-threatening condition that usually occurs in the first 4 days after ascent above 2500 m. Unlike HACE, HAPE may occur de novo without the preceding signs of AMS. Presentation is with symptoms of dry cough, exertional dyspnoea and extreme fatigue. Later, the cough becomes wet and sputum may be blood-stained. Tachycardia and tachypnoea occur at rest and crepitations may often be heard in both lung fields. There may be profound hypoxaemia, pulmonary hypertension and radiological evidence

of diffuse alveolar oedema. It is not known whether the alveolar oedema is a result of mechanical stress on the pulmonary capillaries associated with the high pulmonary arterial pressure, or an effect of hypoxia on capillary permeability. Reduced arterial oxygen saturation is not diagnostic but is a marker for disease progression.

Treatment is directed at reversal of hypoxia with immediate descent and oxygen administration. Nifedipine (20 mg 4 times daily) should be given to reduce pulmonary arterial pressure, and oxygen therapy in a portable pressurised bag should be used if descent is delayed.

Chronic mountain sickness (Monge's disease)

This occurs on prolonged exposure to altitude and has been reported in residents of Colorado, South America and Tibet. Patients present with headache, poor concentration and other signs of polycythaemia. The haemoglobin concentration is high (>200 g/L) and the haematocrit raised (>65%). Affected individuals are cyanosed and often have finger clubbing.

High-altitude retinal haemorrhage

This occurs in over 30% of trekkers at 5000 m. The haemorrhages are usually asymptomatic and resolve spontaneously. Visual defects can occur with haemorrhage involving the macula but there is no specific treatment.

Venous thrombosis

This has been reported at altitudes of >6000 m. Risk factors include dehydration, inactivity and the cold. The use of the oral contraceptive pill at high altitude should be considered carefully, as this is an additional risk factor.

Refractory cough

A cough at high altitude is common and usually benign. It may be due to breathing dry, cold air and to increased mouth breathing, with consequent dry oral mucosa. This may be indistinguishable from the early signs of HAPE.

Air travel

Commercial aircraft usually cruise at 10 000–12 000 m, with the cabin pressurised to an equivalent of around 2400 m. At this altitude, the partial pressure of oxygen is 16 kPa (120 mmHg), leading to a PaO_2 in healthy people of 7.0–8.5 kPa (53–64 mmHg). Oxygen saturation is also reduced but to a lesser degree (see Fig. 9.5). Although well tolerated by healthy people, this degree of hypoxia may be dangerous in patients with respiratory disease.

Advice for patients with respiratory disease

The British Thoracic Society has published guidance on the management of patients with respiratory disease who want to fly. Specialist pre-flight assessment is advised for all patients who have hypoxaemia (oxygen saturation <95%) at sea level, and includes spirometry and a hypoxic challenge test with 15% oxygen (performed in hospital). Air travel may have to be avoided or undertaken only with inspired oxygen therapy during the flight. Asthmatic patients should be advised to carry their inhalers in their hand baggage. Following pneumothorax, flying should be avoided while air remains in the pleural cavity, but can be considered after proven resolution or definitive (surgical) treatment.

Advice for other patients

Other circumstances in which patients are more susceptible to hypoxia require individual assessment. These include cardiac arrhythmia, sickle-cell disease and ischaemic heart disease. Most airlines decline to carry pregnant women after the 36th week of gestation. In complicated pregnancies it may be advisable to avoid air travel at an earlier stage. Patients who have had recent abdominal surgery, including laparoscopy, should avoid flying until all intraperitoneal gas is reabsorbed. Divers should not fly for 24 hours after a dive requiring decompression stops.

Ear and sinus pain due to changes in gas volume are common but usually mild, although patients with chronic sinusitis and otitis media may need specialist assessment. A healthy mobile tympanic membrane visualised during a Valsalva manœuvre usually suggests a patent Eustachian tube.

On long-haul flights, patients with diabetes mellitus may need to adjust their insulin or oral hypoglycaemic dosing according to the timing of in-flight and subsequent meals (p. 750). Advice is available from Diabetes UK and other websites. Patients should be able to provide documentary evidence of the need to carry needles and insulin.

Deep venous thrombosis

Air travellers have an increased risk of venous thrombosis (p. 975), due to a combination of factors, including loss of venous emptying because of prolonged immobilisation (lack of muscular activity) and reduced barometric pressure on the tissues, together with haemoconcentration as a result of oedema and perhaps a degree of hypoxia-induced diuresis.

Venous thrombosis can probably be prevented by avoiding dehydration and excess alcohol, and by exercising muscles during the flight. Without a clear cost–benefit analysis, prophylaxis with aspirin or heparin cannot be recommended routinely, but may be considered in high-risk cases.

Under water

Drowning and near-drowning

Drowning is defined as death due to asphyxiation following immersion in a fluid, while near-drowning is defined as survival for longer than 24 hours after suffocation by immersion. Drowning remains a common cause of accidental death throughout the world and is particularly common in young children (Box 9.4). In about 10% of cases, no water enters the lungs and death follows intense laryngospasm ('dry' drowning). Prolonged immersion in cold water, with or without water inhalation, results in a rapid fall in core body temperature and hypothermia (p. 165).

Following inhalation of water, there is a rapid onset of ventilation–perfusion imbalance with hypoxaemia, and the development

9.4 Most common causes of drowning by age

of diffuse pulmonary oedema. Fresh water is hypotonic and, although rapidly absorbed across alveolar membranes, impairs surfactant function, which leads to alveolar collapse and right-to-left shunting of unoxygenated blood. Absorption of large amounts of hypotonic fluid can result in haemolysis. Salt water is hypertonic and inhalation provokes alveolar oedema, but the overall clinical effect is similar to that of freshwater drowning.

Clinical features

Those rescued alive (near-drowning) are often unconscious and not breathing. Hypoxaemia and metabolic acidosis are inevitable features. Acute lung injury usually resolves rapidly over 48–72 hours, unless infection occurs (Fig. 9.6). Complications include dehydration, hypotension, haemoptysis, rhabdomyolysis, renal failure and cardiac arrhythmias. A small number of patients, mainly the more severely ill, progress to develop the acute respiratory distress syndrome (ARDS; p. 198).

Survival is possible after immersion for up to 30 minutes in very cold water, as the rapid development of hypothermia after immersion may be protective, particularly in children. Long-term outcome depends on the severity of the cerebral hypoxic injury and is predicted by the duration of immersion, delay in resuscitation, intensity of acidosis and the presence of cardiac arrest.

Management

Initial management requires cardiopulmonary resuscitation with administration of oxygen and maintenance of the circulation (p. 456). It is important to clear the airway of foreign bodies and protect the cervical spine. Continuous positive airways pressure (CPAP; p. 202) should be considered for spontaneously breathing patients with oxygen saturations of <94%. Observation is required for a minimum of 24 hours. Prophylactic antibiotics are only required if exposure was to obviously contaminated water.

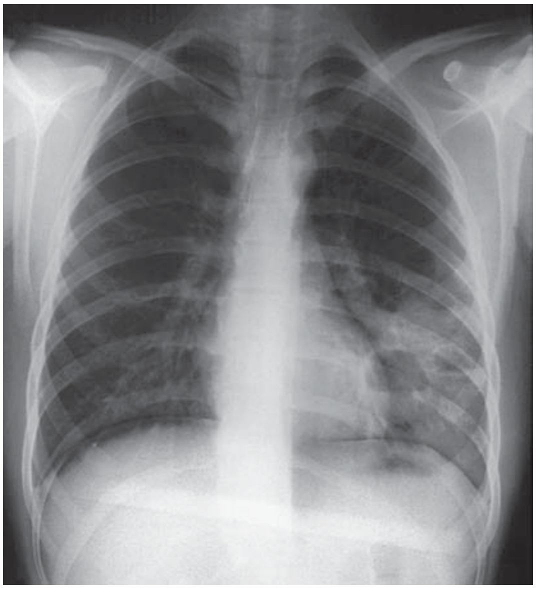

Fig. 9.6 Near-drowning. Chest X-ray of a 39-year-old farmer, 2 weeks after immersion in a polluted freshwater ditch for 5 min before rescue. Airspace consolidation and cavities in the left lower lobe reflect secondary staphylococcal pneumonia and abscess formation.

Diving-related illness

The underwater environment is extremely hostile. Other than drowning, most diving illness is related to changes in barometric pressure and its effect on gas behaviour.

Ambient pressure under water increases by 101 kPa (1 atmosphere, 1 ata) for every 10 metres of seawater (msw) or 33 eet of seawater (fsw) depth. As divers descend, the partial pressures of the gases they are breathing increase (Box 9.5), and the blood and tissue concentrations of dissolved gases rise accordingly. Nitrogen is a weak anaesthetic agent, and if the inspiratory pressure of nitrogen is allowed to increase above 320 kPa (3.2 ata; i.e. a depth of approximately 30 msw), it produces 'narcosis', resulting in impairment of cognitive function and manual dexterity, not unlike alcohol intoxication. For this reason, compressed air can be used only for shallow diving. Oxygen is also toxic at inspired pressures above approximately 40 kPa (0.4 ata; inducing apprehension, muscle twitching, euphoria, sweating, tinnitus, nausea and vertigo), so 100% oxygen cannot be used as an alternative. For dives deeper than approximately 30 msw, mixtures of oxygen with nitrogen and/or helium are used.

While drowning remains the most common diving-related cause of death, another important group of disorders usually present once the diver returns to the surface: decompression illness (DCI) and barotrauma.

Clinical features

Decompression illness

This includes decompression sickness (DCS) and arterial gas embolism (AGE). While the vast majority of symptoms of DCI present within 6 hours of a dive, they can also be provoked by flying (further decompression), and thus patients may present to medical services at sites far removed from the dive.

Exposure of individuals to increased partial pressures of nitrogen results in additional nitrogen being dissolved in body tissues; the amount dissolved depends on the depth/pressure and on the duration of the dive. On ascent, the tissues become supersaturated with nitrogen, and this places the diver at risk of producing a critical quantity of gas (bubbles) in tissues if the ascent is too fast. The gas so formed may cause symptoms locally, peripherally due to bubbles passing through the pulmonary vascular bed (Box 9.6) or by embolisation elsewhere. Arterial embolisation may occur if the gas load in the venous system exceeds the lungs' abilities to excrete nitrogen, or when bubbles pass through a patent foramen ovale (present asymptomatically

9.5 Physics of breathing compressed air while diving in sea water

Depth	Lung volume	Barometric pressure	PiO_2	PiN_2
Surface	100%	101 kPa (1 ata)	21 kPa (0.21 ata)	79 kPa (0.78 ata)
10 m	50%	202 kPa (2 ata)	42 kPa (0.42 ata)	159 kPa (1.58 ata)
20 m	33%	303 kPa (3 ata)	63 kPa (0.63 ata)	239 kPa (2.34 ata)
30 m	25%	404 kPa (4 ata)	84 kPa (0.84 ata)	319 kPa (3.12 ata)

i 9.6 Assessment of a patient with decompression illness*

Evolution
• Progressive • Static • Relapsing • Spontaneously improving
Manifestations
• Pain: often large joints, e.g. shoulder ('the bends') • Neurological: any deficit is possible • Audiovestibular: vertigo, tinnitus, nystagmus; may mimic inner ear barotrauma • Pulmonary: chest pain, cough, haemoptysis, dyspnoea; may be due to arterial gas embolism (AGE) • Cutaneous: itching, erythematous rash • Lymphatic: tender lymph nodes, oedema • Constitutional: headache, fatigue, general malaise
Dive profile
• Depth • Type of gas used • Duration of dive
*Information required by diving specialists to decide appropriate treatment. See contact details on page 172.

in 25–30% of adults; p. 531). Although DCS and AGE can be indistinguishable, their early treatment is the same.

Barotrauma

During the ascent phase of a dive, the gas in the diver's lungs expands due to the decreasing pressure. The diver must therefore ascend slowly and breathe regularly; if ascent is rapid or the diver holds his/her breath, the expanding gas may cause lung rupture (pulmonary barotrauma). This can result in pneumomediastinum, pneumothorax or AGE as a result of gas passing directly into the pulmonary venous system. Other air-filled body cavities may be subject to barotrauma, including the ear and sinuses.

Management

The patient is nursed horizontally and airway, breathing and circulation are assessed. Treatment includes the following:

- *High-flow oxygen* is given by a tight-fitting mask using a rebreathing bag. This assists in the washout of excess inert gas (nitrogen) and may reduce the extent of local tissue hypoxia resulting from focal embolic injury.
- *Fluid replacement* (oral or intravenous) corrects the intravascular fluid loss from endothelial bubble injury and dehydration associated with immersion. Maintenance of an adequate peripheral circulation is important for the excretion of excess dissolved gas.
- *Recompression* is the definitive therapy. Transfer to a recompression facility may be by surface or air, provided that the altitude remains low (<300 m) and the patient continues to breathe 100% oxygen. Recompression reduces the volume of gas within tissues (Boyle's law), forces nitrogen back into solution and is followed by slow decompression, allowing the nitrogen load to be excreted.

The majority of patients make a complete recovery with treatment, although a small but significant proportion are left with neurological disability.

Humanitarian crisis

Humanitarian crises are common. If the medical profession is to help, it must understand that the emergency treatment of a few sick and injured people is not always the priority and that there is a set of basic needs that must be addressed in order to do the most for the most.

A humanitarian crisis can take many forms: an environmental disaster, mass emigration due to drought, conflict or famine, a disease outbreak or any number of natural or man-made events. When this event overwhelms the resources of the affected country's government, then the international community will often step in to help. Although a full examination of the subject is beyond the scope of this book, there are a few basic principles for managing a humanitarian crisis.

The response is broken down into four phases:

1. recognition (first week)
2. emergency response (first month)
3. consolidation phase (to crisis resolution or crisis containment)
4. handover and withdrawal.

Recognition

Recognition of a disaster may be obvious in a sudden event such as an earthquake or a tidal wave, but less obvious in a disease outbreak or when it stems from internal conflict. The recognition phase is for the host nation rather than the international community, and requests for support will come from the affected country's government.

Emergency response

During the emergency phase, responders (whether international, governmental or the charity sector) will undertake an initial assessment of need, set objectives, mobilise resources, coordinate with other agencies and deploy to the crisis in order to deliver an initial response.

Consolidation phase

The consolidation phase involves matching resources to need, dealing with the crisis, building resilience, supporting infrastructure (human and physical) and instituting systems to manage the ongoing health needs of the population.

Handover and withdrawal

Once the crisis is under control and the country is able to manage within resources, a phased withdrawal can occur.

Health-care priorities

When the normal infrastructure of a country or area fails, then populations are at risk, whether they shelter in place or flee, leading to mass migration. For health-care teams, rather than logisticians, rescue teams or security forces, there are well-defined priorities, which must be in place (Box 9.7). This must all occur during the emergency phase and is followed by the

9.7 Priorities in a humanitarian crisis

1. Assessment of population need
2. Safe water and sanitation
3. Food and nutrition
4. Shelter and warmth
5. Emergency health care
6. Immunisation of risk groups
7. Control of communicable diseases
8. Ongoing health surveillance and reporting
9. Training and deployment of indigenous health-care workers
10. Handover of responsibility to local authorities

implementation of a public health surveillance and reporting system and the mobilisation of local human resources, and their training and deployment during the consolidation phase in order to prepare for handover to the local competent authority and withdrawal.

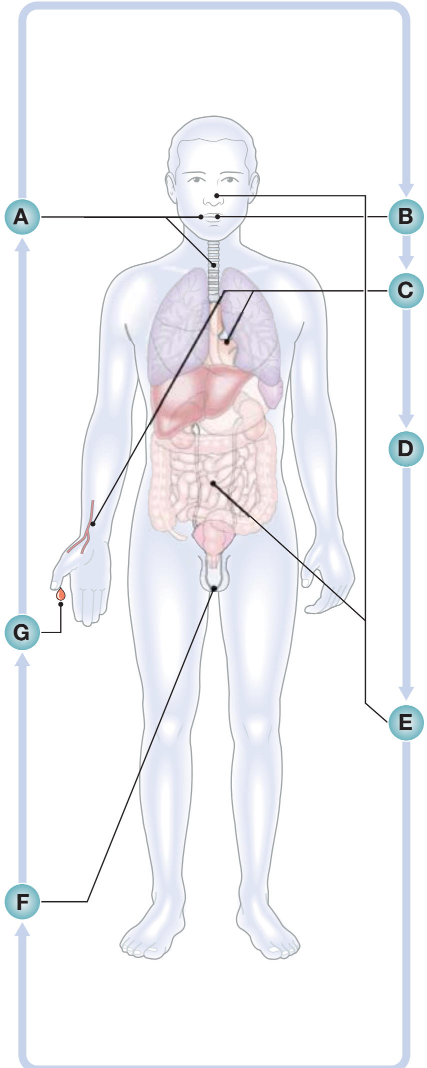
Acute medicine and critical illness

Clinical examination in critical care

A Airway
Is the airway patent?
Is the end-tidal CO_2 trace normal?
Are there any signs of airway obstruction?

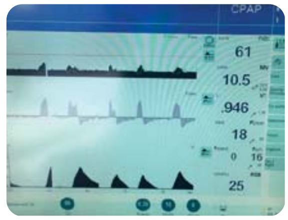


I Infection
What is the temperature?
Review recent infective markers and trend
What antibiotics are being given and what is the duration of treatment?

H Haematology
What are the haemoglobin/platelet levels?
Are there any signs of bleeding?

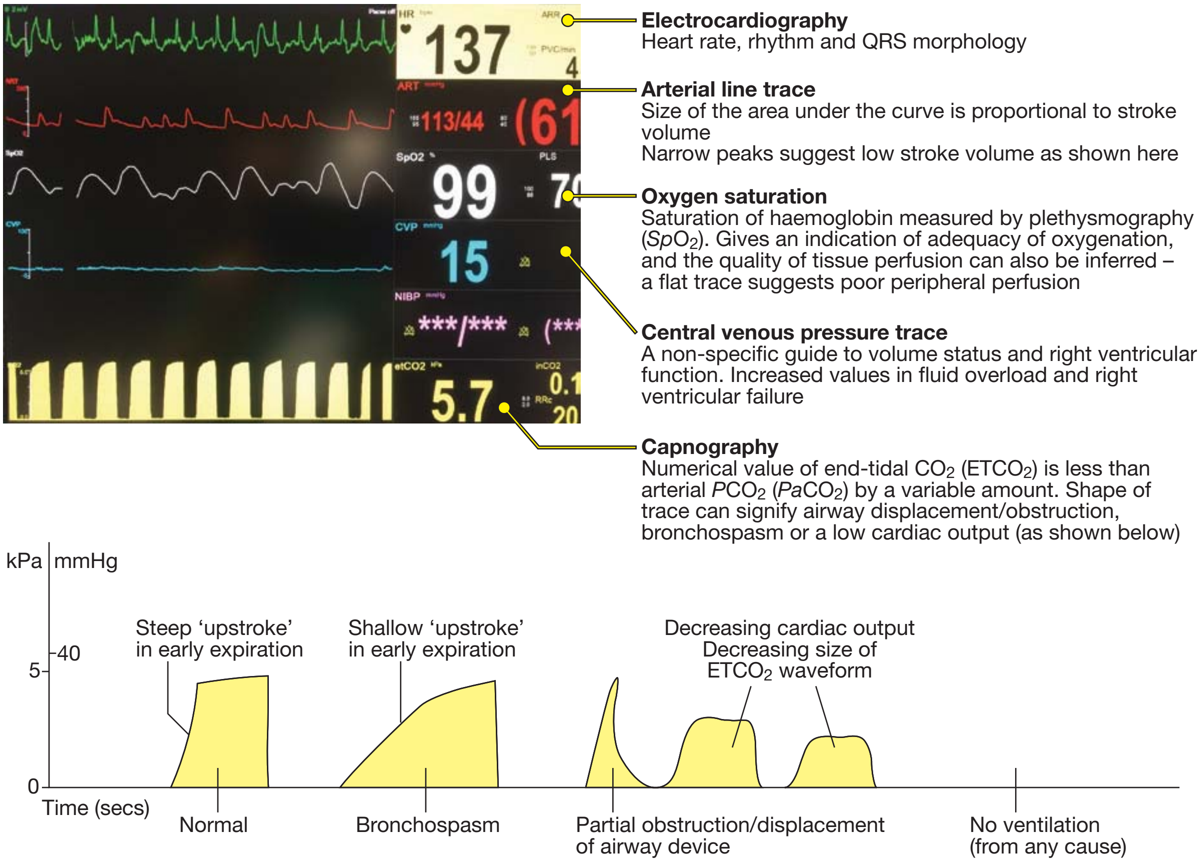
G Glucose
What is the glucose level?
Is insulin being administered?

F Fluids, electrolytes and renal system
What is the fluid balance?
Urine volume and colour?
Is there any oedema?
Review the renal biochemistry and electrolyte levels



E Enteral/exposure
Feeding regime
Stool frequency
Abdominal tenderness/bowel sounds present?

B Breathing
Is the physiology normal (SpO_2, respiratory rate, tidal volume)?
What is the level of support?
Are there any abnormal signs on chest examination?
Review the ventilator settings, arterial blood gases and recent chest X-ray

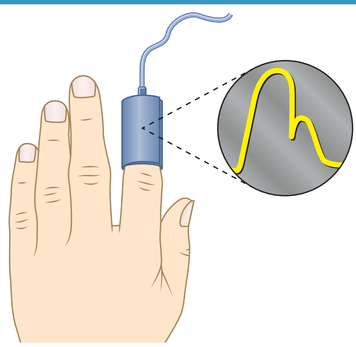


C Circulation
Is the physiology normal (heart rate, blood pressure, peripheral temperature, lactate, urine output)?
How much support is required (inotrope,vasopressor)?

D Disability
Level of responsiveness
Delirium screen
Pupillary responses
Doses of sedative drugs

Monitoring

Bedside physiological data commonly monitored in an intensive care unit setting.



i Plethysmography (SpO_2)

Basic principles

- Uses the different red and infrared absorption profiles of oxyhaemoglobin and deoxyhaemoglobin to estimate arterial oxyhaemoglobin saturation (SaO_2)
- Only pulsatile absorption is measured
- A poor trace correlates with poor perfusion

Sources of error

- Carboxyhaemoglobin – absorption profile is the same as oxyhaemoglobin: falsely elevated SpO_2
- Methaemoglobinaemia – SpO_2 will tend towards 85%
- Ambient light/poor application of probe/ severe tricuspid regurgitation (pulsatile venous flow): falsely depressed SpO_2
- Reduced accuracy below 80% saturation
- Hyperbilirubinaemia does not affect SpO_2

Hospital medicine is becoming ever more specialised and people are living longer while accruing increasing numbers of chronic disease diagnoses. Rather than diminishing the role of the generalist, these factors paradoxically create a need for experts in the undifferentiated presentation. In the UK such physicians are known as 'general physicians', while in the US they are referred to as 'hospitalists'.

Acute illness can present in a large variety of ways, depending on the nature of the illness, the underlying health of the individual, and their cultural and religious background. The skills of prompt diagnosis formation and provision of appropriate treatment rely on the integration of information from all the available sources, along with careful consideration of underlying chronic health problems.

Patients who deteriorate while in hospital make up a small but important cohort. If they are well managed, in-hospital cardiac arrest rates will be low. This can be achieved through the combined effects of prompt resuscitation and appropriate end-of-life decision-making. Early recognition of deterioration by ward teams and initial management by health-care professionals operating within a functioning rapid response system are the central tenets of any system designed to improve the outcomes of deteriorating ward patients.

Intensive care medicine has developed into a prominent specialty, central to the safe functioning of a modern acute hospital. Scientific endeavour has resulted in a much better understanding of the molecular pathophysiology of processes such as sepsis and acute respiratory distress syndrome, which account for much premature death worldwide.

Acute medicine

Acute medicine is the part of general medicine that is concerned with the immediate and early management of medical patients who require urgent care. As a specialty, it is closely aligned with emergency medicine and intensive care medicine, but is firmly rooted within general medicine. Acute physicians manage the adult medical take and lead the development of acute care pathways that aim to reduce variability, improve care and cut down hospital admissions.

The decision to admit to hospital

Every patient presenting to hospital should be assessed by a clinician who is able to determine whether or not admission is required. The requirement for admission is determined by many factors, including the severity of illness, the patient's physiological reserve, the need for urgent investigations, the nature of proposed treatments and the patient's social circumstances. In many cases, it is clear early in the assessment process that a patient requires admission. In such cases, a move into a medical receiving unit – often termed a medical admissions unit (MAU) or acute medical unit (AMU) – should be facilitated as soon as the initial assessment has been completed and urgent investigations and/or treatments have been instigated. In hospitals where such units do not exist, patients will need to be moved to a downstream ward once treatment has been commenced and they have been deemed sufficiently stable. Following the initial assessment, it may be possible to discharge stable patients home with a plan for early follow-up (such as a rapid-access specialist clinic appointment).

Ambulatory care

In some hospitals, it is increasingly possible for patient care to be coordinated in an ambulatory setting, negating the need for a patient to remain in hospital overnight. In the context of acute medicine, ambulatory care can be employed for conditions that are perceived by either the patient or the referring practitioner as requiring prompt clinical assessment by a competent decision-maker with access to appropriate diagnostic resources. The patient may return on several occasions for investigation, observation, consultation or treatment. Some presentations, such as a unilateral swollen leg (p. 186), lend themselves to this type of management (Box 10.1). If indicated, a Doppler ultrasound can be arranged, and patients with confirmed deep vein thromboses can be anticoagulated on an outpatient basis. Successful ambulatory care requires careful patient selection; while many patients may cherish the opportunity to sleep at home, others may find frequent trips to hospital or clinic too difficult due to frailty, poor mobility or transport difficulties.

Presenting problems in acute medicine

Chest pain

Chest pain is a common symptom in patients presenting to hospital. The differential diagnosis is wide (Box 10.2), and a

10.1 Groups of patients who are potentially suitable for ambulatory care

Group	Example(s)	Quality and safety issues
Diagnostic exclusion group	Chest pain – possible myocardial infarction; breathlessness – possible pulmonary embolism	Even when a specific condition has been excluded, there is still a need to explain the patient's symptoms through the diagnostic process
Low-risk stratification group	Non-variceal upper gastrointestinal bleed with low Blatchford score (p. 780); community-acquired pneumonia with low CURB-65 score (p. 583)	Appropriate treatment plans should be in place
Specific procedure group	Replacement of percutaneous endoscopic gastrostomy (PEG) tube; drainage of pleural effusion/ascites	The key to implementation is how ambulatory care for this group of patients can be delivered when they present out of hours
Outpatient group with supporting infrastructure	Deep vein thrombosis (DVT); cellulitis	These are distinct from the conditions listed above because the infrastructure required to manage them is quite different

i 10.2 Differential diagnosis of chest pain

Central

Cardiac
- Myocardial ischaemia (angina)
- Myocardial infarction
- Myocarditis
- Pericarditis
- Mitral valve prolapse syndrome

Aortic
- Aortic dissection
- Aortic aneurysm

Oesophageal
- Oesophagitis
- Oesophageal spasm
- Mallory–Weiss syndrome
- Oesophageal perforation (Boerhaave's syndrome)

Pulmonary embolus

Mediastinal
- Malignancy

Anxiety/emotion[1]

Peripheral

Lungs/pleura
- Pulmonary infarct
- Pneumonia
- Pneumothorax
- Malignancy
- Tuberculosis
- Connective tissue disorders

Musculoskeletal[2]
- Osteoarthritis
- Rib fracture/injury
- Acute vertebral fracture
- Costochondritis (Tietze's syndrome)
- Intercostal muscle injury
- Epidemic myalgia (Bornholm disease)

Neurological
- Prolapsed intervertebral disc
- Herpes zoster
- Thoracic outlet syndrome

[1]May also cause peripheral chest pain. [2]Can sometimes cause central chest pain.

detailed history and thorough clinical examination are paramount to ensure that the subsequent investigative pathway is appropriate.

Presentation

Chest 'pain' is clearly a subjective phenomenon and may be described by patients in a variety of different ways. Whether the patient describes 'pain', 'discomfort' or 'pressure' in the chest, there are some key features that must be elicited from the history.

Site and radiation

Pain secondary to myocardial ischaemia is typically located in the centre of the chest. It may radiate to the neck, jaw, and upper or even lower arms. Occasionally, it may be experienced only at the sites of radiation or in the back. The pain of myocarditis or pericarditis is characteristically felt retrosternally, to the left of the sternum, or in the left or right shoulder. The severe pain of aortic dissection is typically central with radiation through to the back. Central chest pain may also occur with tumours affecting the mediastinum, oesophageal disease (p. 791) or disease of the thoracic aorta (p. 505). Pain situated over the left anterior chest and radiating laterally is unlikely to be due to cardiac ischaemia and may have many causes, including pleural or lung disorders, musculoskeletal problems or anxiety. Rarely, sharp, left-sided chest pain that is suggestive of a musculoskeletal problem may be a feature of mitral valve prolapse (p. 520).

Characteristics

Pleurisy, a sharp or 'catching' chest pain aggravated by deep breathing or coughing, is indicative of respiratory pathology, particularly pulmonary infection or infarction. However, the pain associated with myocarditis or pericarditis is often also described as 'sharp' and may 'catch' during inspiration, coughing or lying flat. It typically varies in intensity with movement and the phase of respiration. A malignant tumour invading the chest wall or ribs can cause gnawing, continuous local pain. The pain of myocardial ischaemia is typically dull, constricting, choking or 'heavy', and is usually described as squeezing, crushing, burning or aching. Patients often emphasise that it is a discomfort rather than a pain. Angina occurs during (not after) exertion and is promptly relieved (in less than 5 minutes) by rest. It may also be precipitated or exacerbated by emotion but tends to occur more readily during exertion, after a large meal or in a cold wind. In crescendo or unstable angina, similar pain may be precipitated by minimal exertion or at rest. The increase in venous return or preload induced by lying down may also be sufficient to provoke pain in vulnerable patients (decubitus angina). Patients with reversible airways obstruction, such as asthma, may also describe exertional chest tightness that is relieved by rest. This may be difficult to distinguish from myocardial ischaemia. Bronchospasm may be associated with wheeze, atopy and cough (p. 556). Musculoskeletal chest pain is variable in site and intensity but does not usually fall into any of the patterns described above. The pain may vary with posture or movement of the upper body, or be associated with a specific movement (bending, stretching, turning). Many minor soft tissue injuries are related to everyday activities, such as driving, manual work and sport.

Onset

The pain associated with myocardial infarction (MI) typically takes several minutes or even longer to develop to its maximal intensity; similarly, angina builds up gradually in proportion to the intensity of exertion. Pain that occurs after, rather than during, exertion is usually musculoskeletal or psychological in origin. The pain of aortic dissection (severe and 'tearing'), massive pulmonary embolism (PE) or pneumothorax is usually very sudden in onset. Other causes of chest pain tend to develop more gradually, over hours or even days.

Associated features

The pain of MI, massive PE or aortic dissection is often accompanied by autonomic disturbance, including sweating, nausea and vomiting. Some patients describe a feeling of impending death, referred to as 'angor animi'. Breathlessness, due to pulmonary congestion arising from transient ischaemic left ventricular dysfunction, is often a prominent feature of myocardial ischemia. Breathlessness may also accompany any of the respiratory causes of chest pain and can be associated with cough, wheeze or other respiratory symptoms. Patients with myocarditis or pericarditis may describe a prodromal viral illness. Gastrointestinal disorders, such as gastro-oesophageal reflux or peptic ulceration, may present with chest pain that is hard to distinguish from myocardial ischaemia; it may even be precipitated by exercise and be relieved by nitrates. However, it is usually possible to elicit a history relating chest pain to supine posture or eating, drinking or oesophageal reflux. The pain of gastro-oesophageal reflux often radiates to the interscapular region and dysphagia may be present. Severe chest pain arising after retching or vomiting, or following oesophageal instrumentation, should raise the possibility of oesophageal perforation.

10

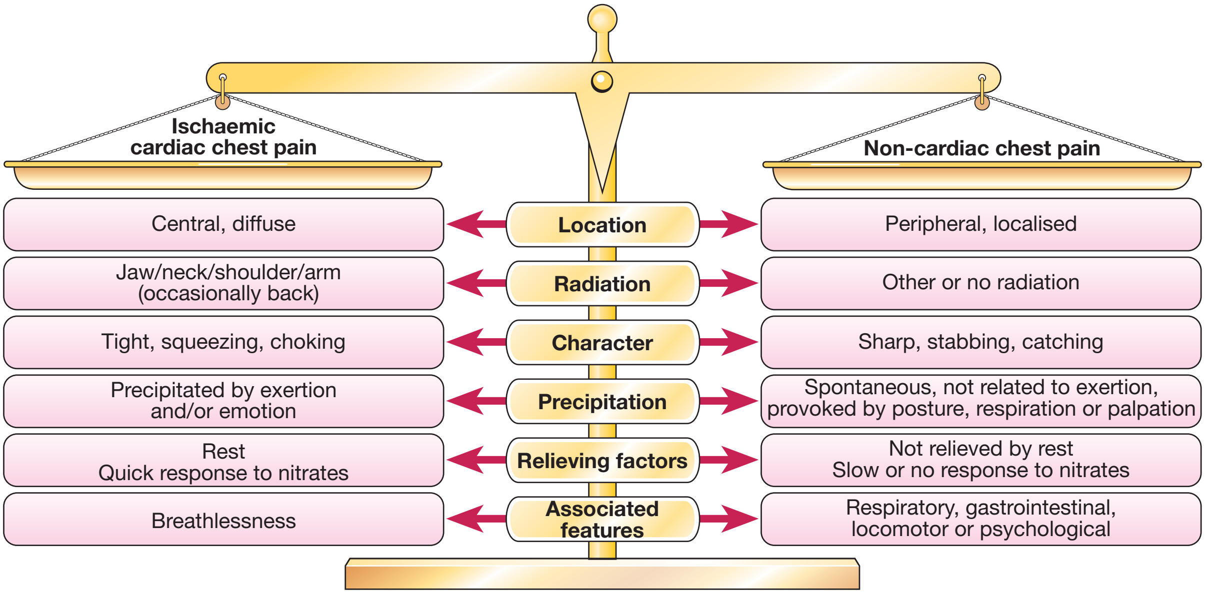


Fig. 10.1 Identifying ischaemic cardiac pain: the 'balance' of evidence.

Anxiety-induced chest pain may be associated with breathlessness (without hypoxaemia), throat tightness, perioral tingling and other evidence of emotional distress. It is important to remember, however, that chest pain itself can be an extremely frightening experience, and so psychological and organic features often coexist. Anxiety may amplify the effects of organic disease and a confusing clinical picture may result.

A detailed and clear history is key to narrowing the differential diagnosis of chest pain. Figure 10.1 shows how certain features of the history, particularly when combined, can tip the balance of evidence towards or away from ischaemic cardiac chest pain.

Clinical assessment

Cardiorespiratory examination may detect clinical signs that help guide ongoing investigation. Patients with a history compatible with myocardial ischaemia should have a 12-lead electrocardiogram (ECG) performed while clinical examination proceeds. Ongoing chest pain with clinical features of shock or pulmonary oedema, or ECG evidence of ventricular arrhythmia or complete heart block should prompt urgent cardiology review and referral to a higher level of care.

Chest pain that is accompanied by clinical evidence of increased intracardiac pressure (especially a raised jugular venous pressure) increases the likelihood of myocardial ischaemia or massive PE. The legs should be examined for clinical evidence of deep vein thrombosis.

A large pneumothorax should be evident on clinical examination, with absent breath sounds and a hyper-resonant percussion note on the affected side. Other unilateral chest signs, such as bronchial breathing or crackles, are most likely to indicate a respiratory tract infection, and a chest X-ray should be expedited.

Pericarditis may be accompanied by a pericardial friction rub. In aortic dissection, syncope or neurological deficit may occur. Examination may reveal asymmetrical pulses, features of undiagnosed Marfan's syndrome (p. 508) or a new early diastolic murmur representing aortic regurgitation.

Any disease process involving the pleura may restrict rib movement and a pleural rub may be audible on the affected side. Local tenderness of the chest wall is likely to indicate musculoskeletal pain but can also be found in pulmonary infarction.

Subdiaphragmatic inflammatory pathology, such as a liver abscess, cholecystitis or ascending cholangitis, can mimic pneumonia by causing fever, pleuritic chest pain and a small sympathetic pleural effusion, usually on the right. Likewise, acute pancreatitis can present with thoracic symptoms, and an amylase or lipase level should be requested where appropriate. It is imperative that the abdomen is examined routinely in all patients presenting with pleuritic chest pain.

Initial investigations

Chest X-ray, ECG and biomarkers (e.g. troponin, D-dimer) play a pivotal role in the evaluation of chest pain. However, indiscriminate ordering of such investigations may result in diagnostic confusion and over-investigation. The choice of investigation(s) is intimately linked to the history and examination findings. A chest X-ray and 12-lead ECG should be performed in the vast majority of patients presenting to hospital with chest pain. Pregnancy is not a contraindication to chest X-ray, but particular consideration should be given to whether the additional diagnostic information justifies breast irradiation.

The chest X-ray may confirm the suspected diagnosis, particularly in the case of pneumonia. Small pneumothoraces are easily missed, as are rib fractures or small metastatic deposits, and all should be considered individually during chest X-ray review. A widened mediastinum suggests acute aortic dissection but a normal chest X-ray does not exclude the diagnosis. Provided it has been more than 1 hour since the onset of pain, chest X-ray in oesophageal rupture may reveal subcutaneous emphysema, pneumomediastinum or a pleural effusion.

Patients with a history compatible with myocardial ischaemia require an urgent 12-lead ECG. Acute chest pain with ECG changes indicating a ST segment elevation myocardial infarction (STEMI) suggests that the patient is likely to benefit from immediate reperfusion therapy. Specific information relating to cocaine or amphetamine use should be sought, particularly in younger

i 10.3 Causes of elevated serum troponin other than acute coronary syndrome

Cardiorespiratory causes

- Pulmonary embolism
- Acute pulmonary oedema
- Tachyarrhythmias
- Myocarditis/myopericarditis
- Aortic dissection
- Cardiac trauma
- Cardiac surgery/ablation

Non-cardiorespiratory causes

- Prolonged hypotension
- Severe sepsis
- Severe burns
- Stroke
- Subarachnoid haemorrhage
- End-stage renal failure

patients. In the context of a compatible history, an ECG showing ischaemic changes that do not meet STEMI criteria should prompt regular repeat ECGs and treatment for non-ST segment elevation myocardial infarction (NSTEMI)/unstable angina. Measurement of serum troponin concentration on admission is often helpful in cases where there is diagnostic doubt, but a negative result should always prompt a repeat sample 6–12 hours after maximal pain. Acute coronary syndrome may be diagnosed with confidence in patients with a convincing history of ischaemic pain (Fig. 10.1) and either ECG evidence of ischaemia or an elevated serum troponin. If an elevated serum troponin is found in a patient who has an atypical history or is at low risk of ischaemic heart disease, then alternative causes of raised troponin should be considered (Box 10.3). Further management of acute coronary syndromes is discussed on page 498.

In the absence of convincing ECG evidence of myocardial ischaemia, other life-threatening causes of chest pain, such as aortic dissection, massive PE and oesophageal rupture, should be considered. Suspicion of aortic dissection (background of hypertension, trauma, pregnancy or previous aortic surgery) should prompt urgent thoracic computed tomography (CT) or transoesophageal echocardiography. An ECG in the context of massive PE most commonly reveals only a sinus tachycardia, but may show new right axis deviation, right bundle branch block or a dominant R wave in V_1. The classical finding of $S_1Q_3T_3$ (a deep S wave in lead I, with a Q wave and T wave inversion in lead III) is rare. If massive PE is suspected and the patient is haemodynamically unstable, a transthoracic echocardiogram, to seek evidence of right heart strain and exclude alternative diagnoses such as tamponade, is extremely useful.

If the patient is deemed to be at low risk of PE, a D-dimer test can be informative, as a negative result effectively excludes the diagnosis. The D-dimer test should be performed only if there is clinical suspicion of PE, as false-positive results can lead to unnecessary investigations. If the D-dimer is positive, there is high clinical suspicion, or there is other convincing evidence of PE (such as features of right heart strain on the ECG), prompt imaging should be arranged (p. 619 and Fig. 17.67).

Acute breathlessness

In acute breathlessness, the history, along with a rapid but careful examination, will usually suggest a diagnosis that can be confirmed by routine investigations including chest X-ray, 12-lead ECG and arterial blood gas (ABG) sampling.

Presentation

A key feature of the history is the speed of onset of breathlessness. Acute severe breathlessness (over minutes or hours) has a distinct

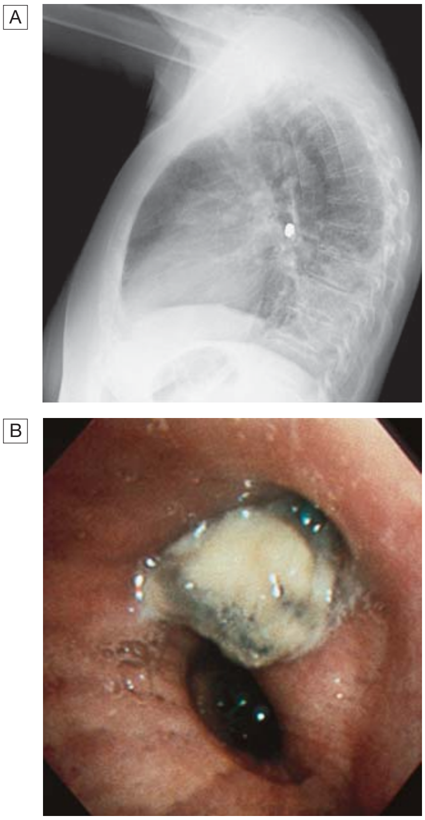

Fig. 10.2 Inhaled foreign body. **A** Chest X-ray showing a tooth lodged in a main bronchus. **B** Bronchoscopic appearance of inhaled foreign body (tooth) with a covering mucous film.

differential diagnosis list to chronic exertional breathlessness. The presence of associated cardiovascular (chest pain, palpitations, sweating and nausea) or respiratory symptoms (cough, wheeze, haemoptysis, stridor) can narrow the differential diagnosis yet further. A previous history of left ventricular dysfunction, asthma or exacerbations of chronic obstructive pulmonary disease (COPD) is important. In the severely ill patient, it may be necessary to obtain the history from accompanying witnesses. In children, the possibility of inhalation of a foreign body (Fig. 10.2) or acute epiglottitis should always be considered. There is often more than one underlying diagnosis; a thorough assessment should continue, even after a possible diagnosis has been reached, particularly if the severity of symptoms does not seem to be adequately explained. The causes of acute severe breathlessness are covered here; chronic exertional dyspnoea is discussed further on page 557.

Clinical assessment

Airway obstruction, anaphylaxis and tension pneumothorax require immediate identification and treatment. If any of these is suspected, treatment should not be delayed while additional investigations are performed, and anaesthetic support is likely to be required. In the absence of an immediately life-threatening cause, the following should be assessed and documented:

- level of consciousness
- degree of central cyanosis
- work of breathing (rate, depth, pattern, use of accessory muscles)
- adequacy of oxygenation (SpO_2)

- ability to speak (in single words or sentences)
- cardiovascular status (heart rate and rhythm, blood pressure (BP) and peripheral perfusion).

Pulmonary oedema is suggested by a raised jugular venous pressure and bi-basal crackles or diffuse wheeze, while asthma or COPD is characterised by wheeze and prolonged expiration. A hyper-resonant hemithorax with absent breath sounds raises the possibility of pneumothorax, while severe breathlessness with normal breath sounds may indicate PE. Leg swelling may suggest cardiac failure or, if asymmetrical, venous thrombosis.

The presence of wheeze is not always indicative of bronchospasm. In acute left heart failure, an increase in the left ventricular diastolic pressure causes the pressure in the left atrium, pulmonary veins and pulmonary capillaries to rise. When the hydrostatic pressure of the pulmonary capillaries exceeds the oncotic pressure of plasma (about 25–30 mmHg), fluid moves from the capillaries into the interstitium. This stimulates respiration through a series of autonomic reflexes, producing rapid, shallow respiration, and congestion of the bronchial mucosa may cause wheeze (sometimes known as cardiac asthma). Sitting upright or standing may provide some relief by helping to reduce congestion at the apices of the lungs. The patient may be unable to speak and is typically distressed, agitated, sweaty and pale. Respiration is rapid, with recruitment of accessory muscles, coughing and wheezing. Sputum may be profuse, frothy and blood-streaked or pink. Extensive crepitations and rhonchi are usually audible in the chest and there may also be signs of right heart failure.

Any arrhythmia may cause breathlessness, but usually does so only if the heart is structurally abnormal, such as with the onset of atrial fibrillation in a patient with mitral stenosis. In such cases, the classic mid-diastolic rumbling murmur with pre-systolic accentuation may be heard. Patients sometimes describe chest tightness as 'breathlessness'. However, myocardial ischaemia may also induce true breathlessness by provoking transient left ventricular dysfunction. When breathlessness is the dominant or sole feature of myocardial ischaemia, it is known as 'angina equivalent'. A history of chest tightness or close correlation with exercise should be sought.

Initial investigations

As shown in Box 10.4, amalgamation of a clear history and thorough clinical examination with chest X-ray, ECG and ABG findings will usually indicate the primary cause of breathlessness. If bronchospasm is suspected, measurement of peak expiratory flow will assist in the assessment of severity and should be performed whenever possible. An ABG will often provide additional information to SpO_2 measurement alone, particularly if there is clinical evidence (drowsiness, delirium, asterixis) or a strong likelihood of hypercapnia. An acute rise in $PaCO_2$ will increase the HCO_3^- by only a small amount, resulting in inadequate buffering and acidaemia. Renal compensation and a large rise in HCO_3^- will take at least 12 hours. In acute type II respiratory failure (p. 565), the rate of rise of $PaCO_2$ is a better indicator of severity than the absolute value.

An ABG is essential in the context of smoke inhalation to measure carboxyhaemoglobin level, and is central to the identification of metabolic acidosis or the diagnosis of psychogenic hyperventilation (Box 10.4). If 'angina equivalent' is suspected,

10.4 Clinical features in acute breathlessness

Condition	History	Signs	Chest X-ray	ABG	ECG
Pulmonary oedema	Chest pain, palpitations, orthopnoea, cardiac history*	Central cyanosis, ↑JVP, sweating, cool extremities, basal crackles*	Cardiomegaly, oedema/pleural effusions*	↓PaO_2 ↓$PaCO_2$	Sinus tachycardia, ischaemia*, arrhythmia
Massive pulmonary embolus	Risk factors, chest pain, pleurisy, syncope*, dizziness*	Central cyanosis, ↑JVP*, absence of signs in the lung*, shock (tachycardia, hypotension)	Often normal Prominent hilar vessels, oligaemic lung fields*	↓PaO_2 ↓$PaCO_2$	Sinus tachycardia, RBBB, $S_1Q_3T_3$ pattern ↑T(V_1–V_4)
Acute severe asthma	History of asthma, asthma medications, wheeze*	Tachycardia, pulsus paradoxus, cyanosis (late), →JVP*, ↓peak flow, wheeze*	Hyperinflation only (unless complicated by pneumothorax)*	↓PaO_2 ↓$PaCO_2$ (↑$PaCO_2$ in extremis)	Sinus tachycardia (bradycardia in extremis)
Acute exacerbation of COPD	Previous episodes*, smoker. If in type II respiratory failure, may be drowsy	Cyanosis, hyperinflation*, signs of CO_2 retention (flapping tremor, bounding pulses)*	Hyperinflation*, bullae, complicating pneumothorax	↓ or ↓↓PaO_2 ↑$PaCO_2$ in type II failure ± ↑H^+, ↑HCO_3^- in chronic type II failure	Normal, or signs of right ventricular strain
Pneumonia	Prodromal illness*, fever*, rigors*, pleurisy*	Fever, delirium, pleural rub*, consolidation*, cyanosis (if severe)	Pneumonic consolidation*	↓PaO_2 ↓$PaCO_2$ (↑ in extremis)	Tachycardia
Metabolic acidosis	Evidence of diabetes mellitus or renal disease, aspirin or ethylene glycol overdose	Fetor (ketones), hyperventilation without heart or lung signs*, dehydration*, air hunger	Normal	PaO_2 normal ↓↓$PaCO_2$, ↑H^+ ↓HCO_3^-	
Psychogenic	Previous episodes, digital or perioral dysaesthesia	No cyanosis, no heart or lung signs, carpopedal spasm	Normal	PaO_2 normal* ↓↓$PaCO_2$, ↓H^+*	

*Valuable discriminatory feature.
(ABG = arterial blood gas; COPD = chronic obstructive pulmonary disease; JVP = jugular venous pressure; RBBB = right bundle branch block)

objective evidence of myocardial ischaemia from stress testing may help to establish the diagnosis.

Syncope/presyncope

The term 'syncope' refers to sudden loss of consciousness due to reduced cerebral perfusion. 'Presyncope' refers to lightheadedness, in which the individual thinks he or she may 'black out'. Dizziness and presyncope are particularly common in old age (Box 10.5). Symptoms are disabling, undermine confidence and independence, and can affect a person's ability to work or to drive.

There are three principal mechanisms that underlie recurrent presyncope or syncope:

- *cardiac syncope* due to mechanical cardiac dysfunction or arrhythmia
- *neurocardiogenic syncope (also known as vasovagal or reflex syncope)*, in which an abnormal autonomic reflex causes bradycardia and/or hypotension
- *postural hypotension*, in which physiological peripheral vasoconstriction on standing is impaired, leading to hypotension.

There are, however, other causes of loss of consciousness, and differentiating syncope from seizure is a particular challenge. Psychogenic blackouts (also known as non-epileptic seizures or pseudoseizures) also need to be considered in the differential diagnosis.

10.5 Dizziness in old age

- **Prevalence**: common, affecting up to 30% of people aged >65 years.
- **Symptoms**: most frequently described as a combination of unsteadiness and lightheadedness.
- **Most common causes**: postural hypotension and cardiovascular disease. Many patients have more than one underlying cause.
- **Arrhythmia**: can present with lightheadedness either at rest or on activity.
- **Anxiety**: frequently associated with dizziness but rarely the only cause.
- **Falls**: multidisciplinary workup is required if dizziness is associated with falls.

Presentation

The history from the patient *and* a witness is the key to establishing a diagnosis. The terms used for describing the symptoms associated with syncope vary so much among patients that they should not be taken for granted. Some patients use the term 'blackout' to describe a purely visual symptom, rather than loss of consciousness. Some may understand 'dizziness' to mean an abnormal perception of movement (vertigo), some will consider this a feeling of faintness, and others will regard it as unsteadiness. The clinician thus needs to elucidate the exact nature of the symptoms that the patient experiences. The potential differential diagnoses of syncope and presyncope, on the basis of the symptoms described, is shown in Figure 10.3.

The history should always be supplemented by a direct eyewitness account if available. Careful history with corroboration will usually establish whether there has been full consciousness, altered consciousness, vertigo, transient amnesia or something else. Attention should be paid to potential triggers (e.g. medication, micturition, exertion, prolonged standing), the patient's appearance (e.g. colour, seizure activity), the duration of the episode, and the speed of recovery (Box 10.6). Cardiac syncope is usually sudden but can be associated with premonitory lightheadedness, palpitation or chest discomfort. The blackout is usually brief and recovery rapid. Exercise-induced syncope can be the presenting feature of a number of serious pathologies (such as hypertrophic obstructive cardiomyopathy or exercise-induced arrhythmia) and always requires further investigation. Neurocardiogenic syncope will often be associated with a situational trigger (such as pain or emotion), and the patient may experience flushing, nausea, malaise and clamminess for several minutes afterwards. Recovery is usually quick and without subsequent delirium, provided the patient has assumed a supine position. There is often some brief stiffening and limb-twitching, which requires differentiation from seizure-like movements. It is rare for syncope to cause injury or to cause amnesia after regaining awareness. Patients with seizures do not exhibit pallor, may have abnormal movements, usually take more than 5 minutes to recover and are often confused. Aspects of the history that can help to differentiate seizure from syncope are shown in Box 10.7.

A diagnosis of psychogenic blackout (also known as non-epileptic seizure, pseudoseizure or psychogenic seizure) may be suggested by specific emotional triggers, dramatic movements

10.6 Typical features of cardiac syncope, neurocardiogenic syncope and seizures

	Cardiac syncope	Neurocardiogenic syncope	Seizures
Premonitory symptoms	Often none Lightheadedness Palpitation Chest pain Breathlessness	Nausea Lightheadedness Sweating	Delirium Hyperexcitability Olfactory hallucinations 'Aura'
Unconscious period	Extreme 'death-like' pallor	Pallor	Prolonged (>1 min) unconsciousness Motor seizure activity* Tongue-biting Urinary incontinence
Recovery	Rapid (<1 min) Flushing	Slow Nausea Lightheadedness	Prolonged delirium (>5 mins) Headache Focal neurological signs

*N.B. Cardiac syncope can also cause convulsions by inducing cerebral anoxia.

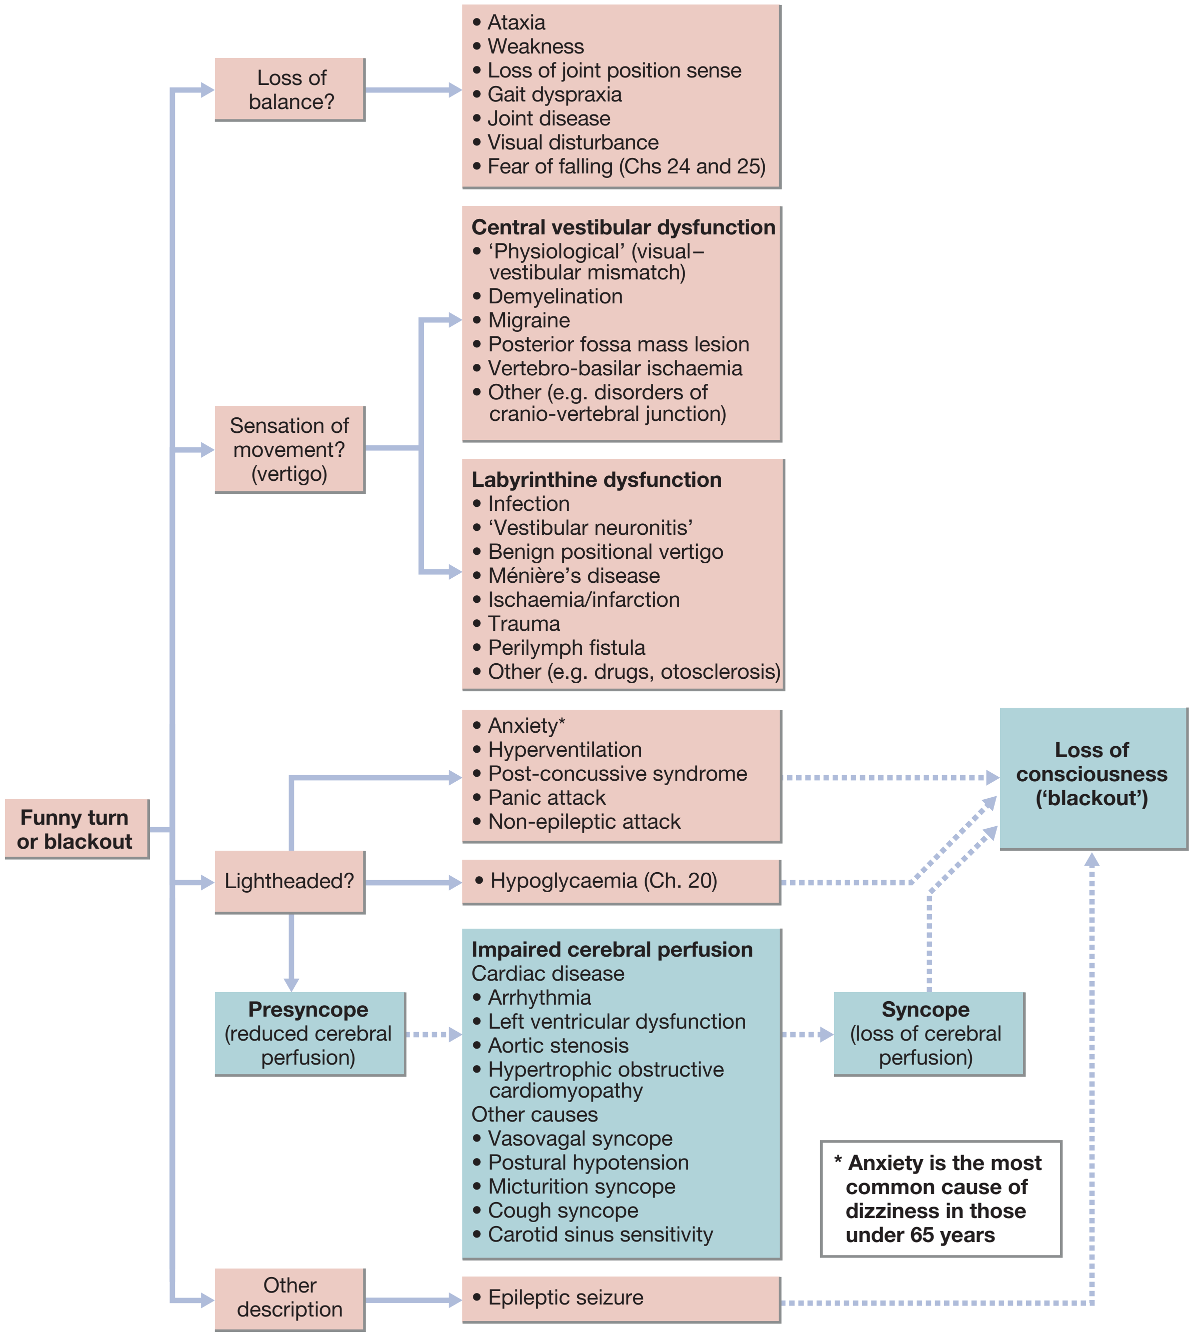

Fig. 10.3 The differential diagnosis of syncope and presyncope.

10.7 How to differentiate seizures from syncope

	Seizure	Syncope
Aura (e.g. olfactory)	+	–
Cyanosis	+	–
Lateral tongue-biting	+	–/+
Post-ictal delirium	+	–
Post-ictal amnesia	+	–
Post-ictal headache	+	–
Rapid recovery	–	+

or vocalisation, or by very prolonged duration (hours). A history of rotational vertigo is suggestive of a labyrinthine or vestibular disorder (p. 1086). Postural hypotension is normally obvious from the history, with presyncope or, less commonly, syncope occurring within a few seconds of standing. The history should include enquiry about predisposing medications (diuretics, vasodilators, antidepressants) and conditions (such as diabetes mellitus and Parkinson's disease).

Clinical assessment

Examination of the patient may be entirely normal, but may reveal clinical signs that favour one form of syncope. The systolic murmurs of aortic stenosis or hypertrophic obstructive

cardiomyopathy are important findings, particularly if paired with a history of lightheadedness or syncope on exertion. BP taken when supine and then after 1 and 3 minutes of standing may, when combined with symptoms, provide robust evidence of symptomatic postural hypotension.

Clinical suspicion of hypersensitive carotid sinus syndrome (sensitivity of carotid baroreceptors to external pressure such as a tight collar) should prompt monitoring of the ECG and BP during carotid sinus pressure, provided there is no carotid bruit or history of cerebrovascular disease. A positive cardio-inhibitory response is defined as a sinus pause of 3 seconds or more; a positive vasodepressor response is defined as a fall in systolic BP of more than 50 mmHg. Carotid sinus pressure will produce positive findings in about 10% of elderly individuals, but fewer than 25% of these experience spontaneous syncope. Symptoms should not, therefore, be attributed to hypersensitive carotid sinus syndrome unless they are reproduced by carotid sinus pressure.

Initial investigations

A 12-lead ECG is essential in all patients presenting with syncope or presyncope. Lightheadedness may occur with many arrhythmias, but blackouts (Stokes–Adams attacks, p. 477) are usually due to profound bradycardia or malignant ventricular tachyarrhythmias. The ECG may show evidence of conducting system disease (e.g. sinus bradycardia, atrioventricular block, bundle branch block), which would predispose a patient to bradycardia, but the key to establishing a diagnosis is to obtain an ECG recording *while symptoms are present*. Since minor rhythm disturbances are common, especially in the elderly, symptoms must occur at the same time as a recorded arrhythmia before a diagnosis can be made. Ambulatory ECG recordings are helpful only if symptoms occur several times per week. Patient-activated ECG recorders are useful for examining the rhythm in patients with recurrent dizziness but are not helpful in assessing sudden blackouts. When these investigations fail to establish a cause in patients with presyncope or syncope, an implantable ECG recorder can be sited subcutaneously over the upper left chest. This device continuously records the cardiac rhythm and will activate automatically if extreme bradycardia or tachycardia occurs. The ECG memory can also be tagged by the patient, using a hand-held activator as a form of 'symptom diary'. Stored ECGs can be accessed by the implanting centre, using a telemetry device in a clinic, or using a home monitoring system via an online link.

Head-up tilt-table testing is a provocation test used to establish the diagnosis of vasovagal syncope. It involves positioning the patient supine on a padded table that is then tilted to an angle of 60–70° for up to 45 minutes, while the ECG and BP responses are monitored. A positive test is characterised by bradycardia (cardio-inhibitory response) and/or hypotension (vasodepressor response), associated with typical symptoms.

Delirium

Delirium is a syndrome of transient, reversible cognitive dysfunction that is more common in old age. It is associated with high rates of mortality, complications and institutionalisation, and with longer lengths of stay. The recognised risk factors for delirium are shown in Box 10.8.

Presentation

Delirium manifests as a disturbance of arousal with global impairment of mental function, causing drowsiness with disorientation, perceptual errors and muddled thinking. The three broad subtypes of delirium – hypoactive, hyperactive and mixed – can be differentiated on the basis of psychomotor changes. Patients with hyperactive delirium are often agitated and restless, whereas hypoactive delirium can present as lethargy and sedation, and is frequently misdiagnosed as depression or dementia. Fluctuation is typical and delirium is often worse at

10.8 Risk factors for delirium

Predisposing factors

- Old age
- Dementia
- Frailty
- Sensory impairment
- Polypharmacy
- Renal impairment

Precipitating factors

- Intercurrent illness
- Surgery
- Change of environment or ward
- Sensory deprivation (e.g. darkness) or overload (e.g. noise)
- Medications (e.g. opioids, psychotropics)
- Dehydration
- Pain
- Constipation
- Urinary catheterisation
- Acute urinary retention
- Hypoxia
- Fever
- Alcohol withdrawal

10.9 How to make a diagnosis of delirium: the 4AT

1. Alertness

This includes patients who may be markedly drowsy (e.g. difficult to rouse and/or obviously sleepy during assessment) or agitated/hyperactive. Observe the patient. If asleep, attempt to wake with speech or gentle touch on shoulder. Ask the patient to state their name and address to assist rating:

• Normal (fully alert, but not agitated, throughout assessment)	**0**
• Mild sleepiness for <10 secs after waking, then normal	**0**
• Clearly abnormal	**4**

2. AMT4

Age, date of birth, place (name of the hospital or building), current year:

• No mistakes	**0**
• 1 mistake	**1**
• ≥2 mistakes/untestable	**2**

3. Attention

Say to the patient: 'Please tell me the months of the year in backwards order, starting at December.' To assist initial understanding, one prompt of 'What is the month before December?' is permitted:

• Achieves ≥7 months correctly	**0**
• Starts but scores <7 months/refuses to start	**1**
• Untestable (cannot start because unwell, drowsy, inattentive)	**2**

4. Acute change or fluctuating course

Evidence of significant change or fluctuation in: alertness, cognition, other mental function (e.g. paranoia, hallucinations) arising over the last 2 weeks and still evident in last 24 hrs:

• No	**0**
• Yes	**4**

Total 4AT score (maximum possible score 12)

≥4: possible delirium ± cognitive impairment
1–3: possible cognitive impairment
0: delirium or severe cognitive impairment unlikely (but delirium still possible if information in 4 incomplete)

(AMT4 = Abbreviated Mental Test 4)

night, when delirious patients can present significant management difficulties. Emotional disturbance (anxiety, irritability or depression) is common. History-taking from a delirious patient is frequently impossible, and every effort should be made to obtain a collateral history from a close friend or relative. As delirium is particularly common in patients with dementia, the collateral history should ask specifically about onset and course of delirium, along with any functional consequences in comparison to the patient's norm.

Clinical assessment

In order to manage delirium effectively, the first step is to make a diagnosis. Tools such as the 4AT (Box 10.9) or the Confusion Assessment Method (CAM) can be used to detect delirium and differentiate it from dementia; such screening tools should be applied to all older patients admitted to hospital. Once a diagnosis of delirium has been established, attempts should be made to identify all of the reversible precipitating factors. Symptoms suggestive of a physical illness, such as an infection or stroke, should be elicited. An accurate drug and alcohol history is required, especially to ascertain whether any drugs have been recently stopped or started (see Fig. 10.4 for commonly implicated drugs). Although not always possible in its entirety, a full physical examination of all delirious patients should be attempted, noting in particular:

- pyrexia and any signs of infection in the chest, skin, abdomen or urine (on dipstick testing)
- oxygen saturation and signs of CO_2 retention
- signs of alcohol withdrawal or psychoactive drug use, such as tremor or sweating
- any focal neurological signs.

Certain psychiatric conditions, such as depressive pseudo-dementia and dissociative disorder, can easily be mistaken for delirium. Mental state examination is necessary to seek evidence of associated mood disorder, hallucinations, delusions or behavioural abnormalities. Examination should also include cognitive testing with a tool such as the Mini-Mental State Examination (MMSE) or the Montreal Cognitive Assessment (MoCA) (p. 1181).

Investigations and management

Common causes of delirium, along with appropriate investigative pathways, are shown in Figure 10.4. Alongside investigation and treatment of underlying causes, delirium and disorientation should be minimised by a well-lit and quiet environment, with hearing aids and glasses readily available. Good nursing is needed to preserve orientation, prevent pressure sores and falls, and maintain hydration, nutrition and continence. Sedatives may worsen delirium and should be used as a last resort. Resolution of delirium, particularly in the elderly, may be slow and incomplete. Many patients fail to recover to their pre-morbid level of cognition.

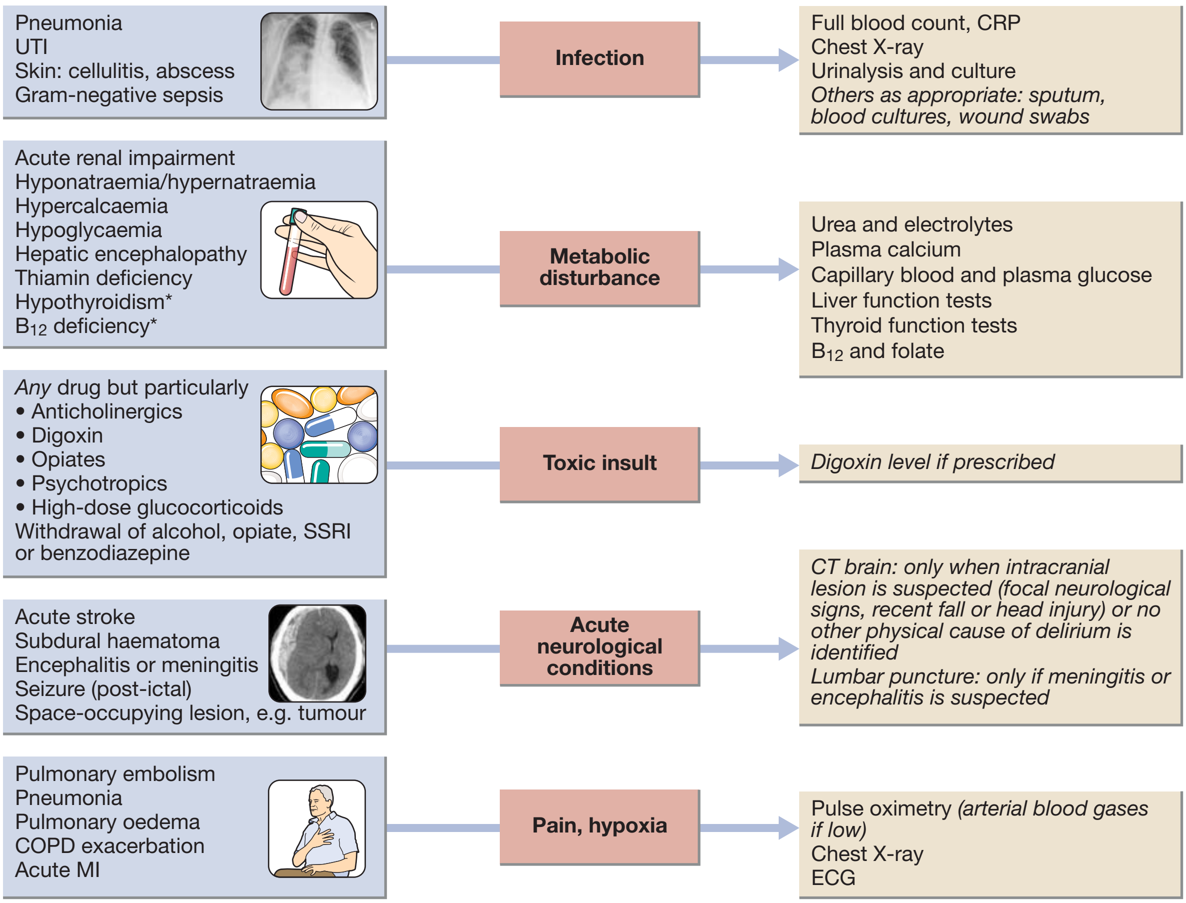

Fig. 10.4 Common causes and investigation of delirium. All investigations are performed routinely, except those in italics. *Tend to present over weeks to months rather than hours to days. The chest X-ray shows right mid- and lower zone consolidation. The CT scan shows a subdural haematoma. (COPD = chronic obstructive pulmonary disease; CRP = C-reactive protein; MI = myocardial infarction; SSRI = selective serotonin re-uptake inhibitor; UTI = urinary tract infection)

Headache

Headache is common and causes considerable worry amongst both patients and clinicians, but rarely represents sinister disease. The causes may be divided into primary or secondary, with primary headache syndromes being vastly more common (Box 10.10).

Presentation

The primary purpose of the history and clinical examination in patients presenting with headache is to identify the small minority of patients with serious underlying pathology. Key features of the history include the temporal evolution of a headache; a headache that reached maximal intensity immediately or within 5 minutes of onset requires rapid assessment for possible subarachnoid haemorrhage. Other 'red flag' symptoms are shown in Box 10.11.

It is important to establish whether the headache comes and goes, with periods of no headache in between (usually migraine), or whether it is present all or almost all of the time. Associated features, such as preceding visual symptoms, nausea/vomiting or photophobia/phonophobia, may support a diagnosis of migraine but others, such as progressive focal symptoms or constitutional upset like weight loss, may suggest a more sinister cause. The headache of cerebral venous thrombosis may be 'throbbing' or 'band-like' and associated with nausea, vomiting or hemiparesis. Raised intracranial pressure (ICP) headache tends to be worse in the morning and when lying flat or coughing, and associated with nausea and/or vomiting.

A description of neck stiffness along with headache and photophobia should raise the suspicion of meningitis (Box 10.12), although this may present in atypical ways in immunosuppressed, alcoholic or pregnant patients. The behaviour of the patient during headache is often instructive; migraine patients typically retire to bed to sleep in a dark room, whereas cluster headache often induces agitated and restless behaviour. The pain of a subarachnoid haemorrhage frequently causes significant distress.

Headache duration is also important to elicit; headaches that have been present for months or years are almost never sinister, whereas new-onset headache, especially in the elderly, is more of a concern. In a patient over 60 years with head pain localised to one or both temples, scalp tenderness or jaw claudication, temporal arteritis (p. 1042) should be considered.

Clinical assessment

An assessment of conscious level (using the Glasgow Coma Scale (GCS); Fig. 10.5) should be performed early and constantly reassessed. A decreased conscious level suggests raised ICP and urgent CT scanning (with airway protection if necessary) is indicated. A full neurological examination may provide clues as to the pathology involved; for example, brainstem signs in the context of acute-onset occipital headache may indicate vertebrobasilar dissection. Neurological signs may, however, be 'falsely localising', as in large subarachnoid haemorrhage or bacterial meningitis. Care should be taken to examine for other evidence of meningitis such as a rash (not always petechial), fever or signs of shock.

Unilateral headache with agitation, ipsilateral lacrimation, facial sweating and conjunctival injection is typical of cluster headache. Conjunctival injection may also be seen in acute glaucoma, accompanied by peri- or retro-orbital pain, clouding of the cornea, decreased visual acuity and, often, systemic upset. Temporal headaches in patients over 60 should prompt examination for enlarged or tender temporal arteries and palpation of temporal pulses (often absent in temporal arteritis). Visual acuity should be assessed promptly, as visual loss is an important complication of temporal arteritis.

Initial investigations

If there is any alteration of conscious level, focal neurological signs, new-onset seizures or a history of head injury, then CT scanning of the head is indicated. The urgency of scanning will depend on the clinical picture and trajectory but in many circumstances

10.10 Primary and secondary headache syndromes

Primary headache syndromes

- Migraine (with or without aura)
- Tension-type headache
- Trigeminal autonomic cephalalgia (including cluster headache)
- Primary stabbing/coughing/exertional/sex-related headache
- Thunderclap headache
- New daily persistent headache syndrome

Secondary causes of headache

- Medication overuse headache (chronic daily headache)
- Intracranial bleeding (subdural haematoma, subarachnoid or intracerebral haemorrhage)
- Raised intracranial pressure (brain tumour, idiopathic intracranial hypertension)
- Infection (meningitis, encephalitis, brain abscess)
- Inflammatory disease (temporal arteritis, other vasculitis, arthritis)
- Referred pain from other structures (orbit, temporomandibular joint, neck)

10.11 'Red flag' symptoms in headache

Symptom	Possible explanation
Sudden onset (maximal immediately or within 5 mins)	Subarachnoid haemorrhage Cerebral venous sinus thrombosis Pituitary apoplexy Meningitis
Focal neurological symptoms (other than for typically migrainous)	Intracranial mass lesion: Vascular Neoplastic Infection
Constitutional symptoms: Weight loss General malaise Pyrexia Meningism Rash	Meningitis Encephalitis Neoplasm (lymphoma or metastases) Inflammation (vasculitis)
Raised intracranial pressure (worse on waking/lying down, associated vomiting)	Intracranial mass lesion
New onset aged >60 years	Temporal arteritis

10.12 Identification of bacterial meningitis

In patients presenting with headache, identification of those with bacterial meningitis is a top priority to facilitate rapid antibiotic treatment. In almost all cases there will be one of the following features:

- meningism (neck stiffness, photophobia, positive Kernig's sign)
- fever >38°C
- signs of shock (tachycardia, hypotension, elevated serum lactate)
- rash (not always petechial)

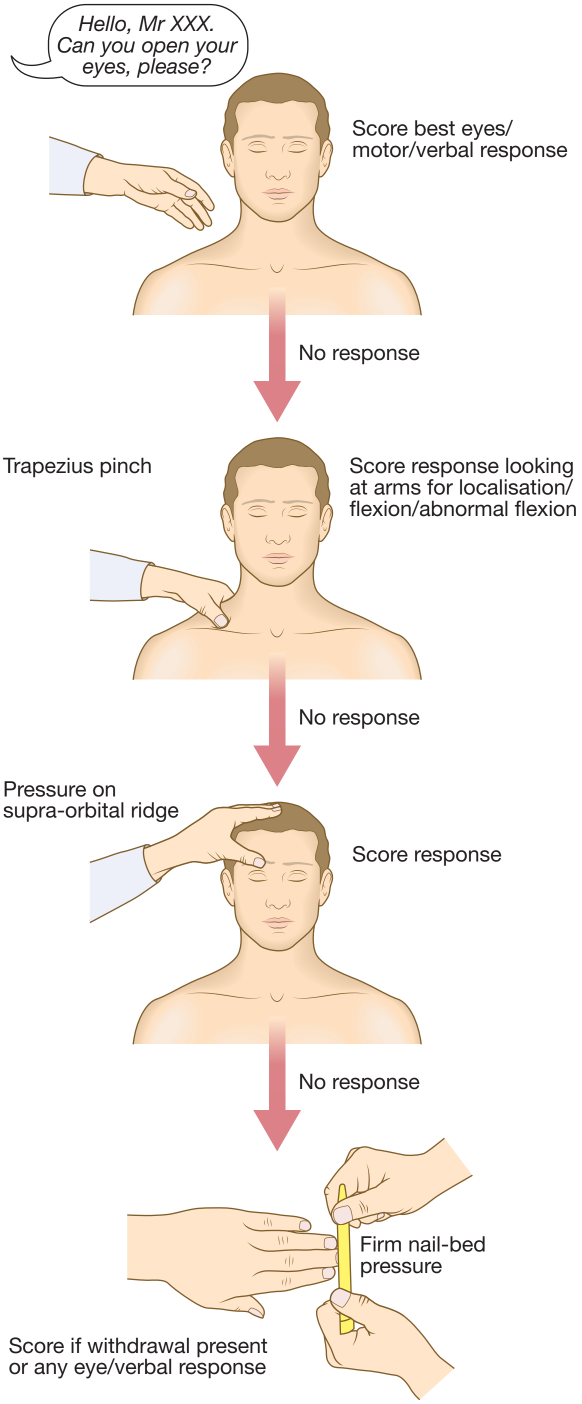

Fig. 10.5 Assessment of the Glasgow Coma Scale (GCS) score in an obtunded patient. Avoid using a sternal rub, as it causes bruising.

will be immediately required. Intracranial haemorrhage or a space-occupying lesion with mass effect should prompt urgent neurosurgical referral. If bacterial meningitis is suspected (Box 10.12), cerebrospinal fluid (CSF) analysis is required to make a definite diagnosis. Antibiotics should not be delayed for lumbar puncture (LP), which needs to be preceded by CT scanning only if raised ICP is suspected. In cases of thunderclap headache (peak intensity within 5 minutes and lasting over an hour), a normal CT scan should be followed by an LP performed more than 12 hours after headache onset, to look for evidence of xanthochromia. It is increasingly accepted, however, that a negative CT scan within 6 hours of headache onset has such a high degree of sensitivity for excluding subarachnoid haemorrhage that an LP is not necessary. In such circumstances, a CT angiogram should be considered to exclude other pathology, such as arterial dissection. Many headaches require prompt involvement of specialists. Features of acute glaucoma, for example, require immediate ophthalmological review for measurement of intraocular pressures. Suspected temporal arteritis with an erythrocyte sedimentation rate (ESR) of >50 mm/hr should prompt immediate glucocorticoid therapy and rheumatological referral (see p. 1042 for management). Features of raised ICP in the absence of a mass lesion on neuroimaging may indicate idiopathic intracranial hypertension; CSF opening pressure is likely to be informative.

Unilateral leg swelling

Most leg swelling is caused by oedema, the accumulation of fluid within the interstitial space. There are three explanatory mechanisms for development of oedema that are described in Box 10.13. Unilateral swelling usually indicates a localised pathology in either the venous or the lymphatic system, while bilateral oedema often represents generalised fluid overload combined with the effects of gravity. However, all causes of unilateral leg swelling may present bilaterally, and generalised fluid overload may present with asymmetrical (and therefore apparently unilateral) oedema. Fluid overload may be the result of cardiac failure, pulmonary hypertension (even in the absence of right ventricular failure), renal failure, hypoalbuminaemia or drugs (calcium channel blockers, glucocorticoids, mineralocorticoids, non-steroidal anti-inflammatory drugs (NSAIDs) and others); see Box 16.14 (p. 463) for other causes. The remainder of this section focuses on the causes of 'unilateral' oedema.

Presentation

Any patient who presents with unilateral leg swelling should be assessed with the possibility of deep vein thrombosis (DVT) in mind. The pain and swelling of a DVT is often fairly gradual in onset, over hours or even days. Sudden-onset pain in the posterior aspect of the leg is more consistent with gastrocnemius muscle tear (which may be traumatic or spontaneous) or a ruptured Baker's cyst. Leg swelling and pain associated with paraesthesia or paresis, or in the context of lower limb injury or reduced conscious level, should always prompt concern regarding the possibility of compartment syndrome (Box 10.14).

Clinical assessment

Lower limb DVT characteristically starts in the distal veins, causing an increase in temperature of the limb and dilatation of the superficial veins. Often, however, symptoms and signs are minimal.

i 10.13 Mechanisms of oedema

There are three explanatory mechanisms for the development of oedema that may occur in isolation or combination:

- increased hydrostatic pressure in the venous system due to increased intravascular volume or venous obstruction
- decreased oncotic pressure secondary to a decrease in the plasma proteins that retain fluid within the circulation
- obstruction to lymphatic drainage ('lymphoedema')

10.14 Identification of compartment syndrome

- Compartment syndrome classically occurs following extrinsic compression of a limb due to trauma or reduced conscious level (especially when caused by drugs or alcohol)
- It usually presents with a tense, firm and exquisitely painful limb
- The pain is characteristically exacerbated by passive muscle stretching or squeezing the compartment
- Altered sensation may be evident distally
- Absent peripheral pulses are a late sign and their presence does not exclude the diagnosis
- Clinical suspicion of compartment syndrome should prompt measurement of creatine kinase and urgent surgical review

Cellulitis is usually characterised by erythema and skin warmth localised to a well-demarcated area of the leg and may be associated with an obvious source of entry of infection (e.g. leg ulcer or insect bite). The patient may be febrile and systemically unwell. Superficial thrombophlebitis is more localised; erythema and tenderness occur along the course of a firm, palpable vein.

Examination of any patient presenting with leg swelling should include assessment for malignancy (evidence of weight loss, a palpable mass or lymphadenopathy). Malignancy is a risk factor for DVT, but pelvic or lower abdominal masses can also produce leg swelling by compressing the pelvic veins or lymphatics. Early lymphoedema is indistinguishable from other causes of oedema. More chronic lymphoedema is firm and non-pitting, often with thickening of the overlying skin, which may develop a 'cobblestone' appearance.

Chronic venous insufficiency is a cause of long-standing oedema that, particularly when combined with another cause of leg swelling, may acutely worsen. Characteristic skin changes (haemosiderin deposition, hair loss, varicose eczema, ulceration) and prominent varicosities are common, and sometimes cause diagnostic confusion with cellulitis. See Box 10.14 for the examination findings associated with compartment syndrome.

Initial investigations

Clinical criteria can be used to rank patients according to their likelihood of DVT, by using scoring systems such as the Wells score (Box 10.15). Figure 10.6 gives an algorithm for investigation of suspected DVT based on initial Wells score. In patients with a low ('unlikely') pre-test probability of DVT, D-dimer levels can be measured; if these are normal, further investigation for DVT is unnecessary. In those with a moderate or high ('likely') probability of DVT or with elevated D-dimer levels, objective diagnosis of DVT should be obtained using appropriate imaging, usually a Doppler ultrasound scan. The investigative pathway for DVT, therefore, differs according to the pre-test probability (p. 11) of DVT. For low-probability DVT, the negative predictive value of the D-dimer test (the most important parameter in this context) is over 99%; if the test is negative, the clinician can discharge the patient with confidence. In patients with a high probability of DVT, the negative predictive value of a D-dimer test falls to somewhere in the region of 97–98%. While this may initially appear to be a high figure, to discharge 2 or 3 patients in every 100 incorrectly would generally be considered an unacceptable error rate. Hence, with the exception of pregnancy (Box 10.16), a combination of clinical probability and blood test results should be used in the diagnosis of venous thromboembolism.

If cellulitis is suspected, serum inflammatory markers, skin swabs and blood cultures should be sent, ideally before antibiotics

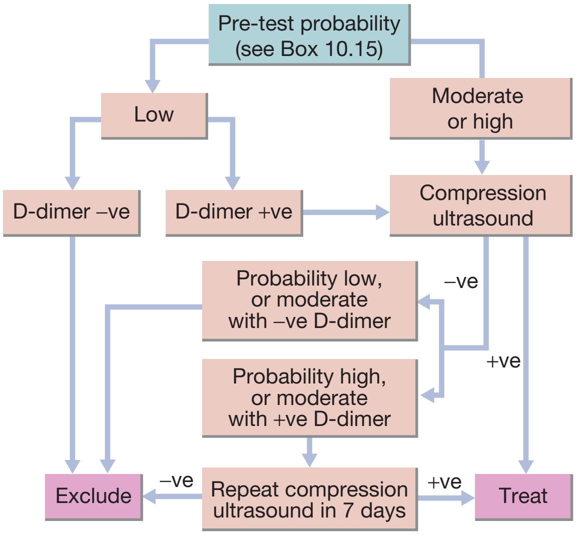

Fig. 10.6 Investigation of suspected deep vein thrombosis. Pre-test probability is calculated in Box 10.15. See also page 11.

10.15 Predicting the pre-test probability of deep vein thrombosis (DVT) using the Wells score*

Clinical characteristic	Score
Previous documented DVT	1
Active cancer (patient receiving treatment for cancer within previous 6 months or currently receiving palliative treatment)	1
Paralysis, paresis or recent plaster immobilisation of lower extremities	1
Recently bedridden for ≥3 days, or major surgery within previous 4 weeks	1
Localised tenderness along distribution of deep venous system	1
Entire leg swollen	1
Calf swelling at least 3 cm larger than that on asymptomatic side (measured 10 cm below tibial tuberosity)	1
Pitting oedema confined to symptomatic leg	1
Collateral superficial veins (non-varicose)	1
Alternative diagnosis at least as likely as DVT	–2
Clinical probability	**Total score**
DVT low probability	<1
DVT moderate probability	1–2
DVT high probability	>2

*A dichotomised revised Wells score, which classifies patients as 'unlikely' or 'likely', may also be used.
From Wells PS. Evaluation of D-dimer in the diagnosis of suspected deep-vein thrombosis. N Engl J Med 2003; 349:1227; copyright © 2003 Massachusetts Medical Society.

are given. Ruptured Baker's cyst and calf muscle tear can both be readily diagnosed on ultrasound. If pelvic or lower abdominal malignancy is suspected, a prostate-specific antigen (PSA) level should be measured in males and appropriate imaging with ultrasound (transabdominal or transvaginal) or CT should be undertaken.

10.16 Swollen legs in pregnancy

- **Benign swollen legs**: common in pregnancy; this is usually benign.
- **DVT**: pregnancy is a significant risk factor, however.
- **D-dimer**: should not be measured in pregnancy; it has not been validated in this group.
- **Imaging**: should be arranged on the basis of clinical suspicion alone, and the threshold for undertaking a definite diagnostic test should be low.

Identification and assessment of deterioration

Early warning scores and the role of the medical emergency team

There are many systems that have been developed with the aim of rapidly identifying and managing physiological deterioration. These are referred to as 'rapid response systems'. One popular example of a rapid response system is a medical emergency team (MET). A MET system operates on the basis that when a patient meets certain physiological criteria, the team is alerted. The team is expected to make a rapid assessment and institute immediate management. This may include escalation to critical care or, following liaison with the parent clinical team, ongoing ward-based care.

The trigger for a 'MET' call may be a single parameter – such as a low BP or tachycardia – or may consist of a composite early warning score. Early warning score systems function by the observer allocating a value between 0 and 3 for abnormalities in respiratory rate, SpO_2, temperature, BP, heart rate, neurological response and urine output (Fig. 10.7). The values are summed and the composite score gives an indication of the severity of physiological derangement. Early warning systems can be automated into an electronic format that calculates the score and even alerts the responsible clinician(s) by email or text message.

There are advantages and disadvantages to having a separate MET system, compared with allowing the responsible clinical team to manage deterioration, and to having a composite score or a single parameter detection system. These are outlined in Box 10.17.

Immediate assessment of the deteriorating patient

An approach to assessment of the deteriorating patient can be summarised by the mnemonic 'C-A-B-C-D-E'.

C – Control of obvious problem

For example, if the patient has ventricular tachycardia on the monitor or significant blood loss is apparent, immediate action is required.

A and B – Airway and breathing

If the patient is talking in full sentences, then the airway is clear and breathing is adequate. A rapid history should be obtained while the initial assessment is undertaken. Breathing should be assessed with a focused respiratory examination. Oxygen saturations and ABGs should be checked early (p. 190).

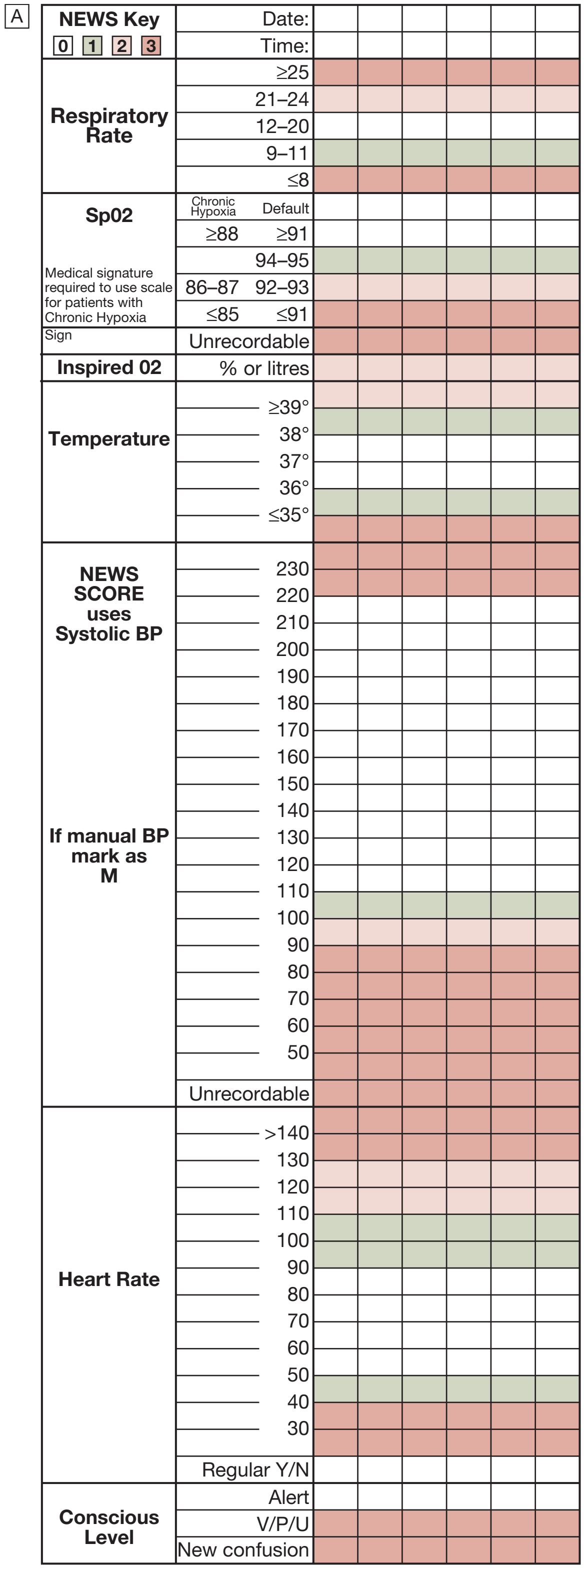

Fig. 10.7 Identifying and responding to physiological deterioration. A An example of an early warning score chart. (NEWS = National Early Warning Score; V/P/U = Verbal/Pain/Unresponsive)

B

*Regardless of NEWS always escalate if concerned about a patient's condition

NEWS Score	Frequency of Observations	Clinical Response
Total 0*	**Minimum 12 hourly/4 hourly in admission areas**	• Continue routine NEWS monitoring with every set of observations
Total 1–4*	**Minimum 4 hourly** Consider Structured Response Tool Consider Fluid Balance Chart	• Inform registered nurse • Registered nurse assessment using ABCDE • Review frequency of observations • Inform Nurse in Charge • **If ongoing concern, escalate to Medical Team**
Total 5–6* or 3 in one parameter	**Increase frequency to a minimum of 1 hourly** Start Structured Response Tool Start Fluid Balance Chart	• Registered nurse assessment • Inform Nurse in Charge • Escalate to Medical Team as per local escalation • Urgent medical assessment • Management plan to be discussed with Senior Trainee or above • Consider level of monitoring required in relation to clinical care
Total 7* or more	**Continuous monitoring of vital signs** Start Structured Response Tool Start Fluid Balance Chart	• Registered nurse to assess immediately • Inform Nurse in Charge • Request immediate assessment by Senior Trainee or above • Case to be discussed with supervising Consultant • If appropriate contact Critical Care for review

Fig. 10.7, cont'd B Responses to physiological deterioration. *A and B, From Royal College of Physicians. National Early Warning Score (NEWS): standardising the assessment of acute-illness severity in the NHS. Report of a working party. London: RCP, 2012.*

i 10.17 Advantages and disadvantages of different rapid response systems

System	Advantages	Disadvantages
Single parameter trigger	High sensitivity. Probably picks up subclinical deterioration and allows optimisation	Low specificity. Much time will be spent with patients who are not deteriorating
Composite early warning scoring system, e.g. NEWS or MEWS score	Combines good sensitivity with improved specificity	May miss single parameter deterioration that is still significant, e.g. a drop of 2 GCS points may not trigger an alert
MET system	Brings expertise in deteriorating patients immediately to the bedside	Expensive to have well-trained individuals who are free from other clinical duties. May deskill the ward-based teams in acute care. May not have expertise in highly specific areas of medicine
Clinical team review	Patient is seen by clinicians familiar with the patient and condition	Clinical team may be busy with other urgent duties. There may not be expertise in acute care within the ward-based team

(GCS = Glasgow Coma Scale; MET = Medical Emergency Team; MEWS = Modified Early Warning Score; NEWS = National Early Warning Score)

C – Circulation

A focused cardiovascular examination should include heart rate and rhythm, jugular venous pressure, evidence of bleeding, signs of shock and abnormal heart sounds. The carotid pulse should be palpated in the collapsed or unconscious patient, but peripheral pulses also should be checked in conscious patients. The radial, brachial, foot and femoral pulses may disappear as shock progresses, and this indicates the severity of circulatory compromise.

D – Disability

Conscious level should be assessed using the GCS (see Fig. 10.5 and Box 10.24, pp. 186 and 194). A brief neurological examination looking for focal signs should be performed. Capillary blood glucose should always be measured to exclude hypoglycaemia or severe hyperglycaemia.

E – Exposure and evidence

'Exposure' indicates the need for targeted clinical examination of the remaining body systems, particularly the abdomen and lower limbs. 'Evidence' may be gathered via a collateral history from other health-care professionals or family members, recent investigations, prescriptions or monitoring charts.

Selecting the appropriate location for ongoing management

Any patient who will gain benefit from a critical care area should be admitted. Such patients generally fall into two groups: those with organ dysfunction severe enough to require organ support and those in whom the disease process is clearly setting them on a downward trajectory and in whom early, aggressive management may alter the outcome. Whether an individual patient should be

10.18 Levels of care and the corresponding admission criteria for intensive care unit (ICU) and high-dependency unit (HDU)

Level of care	Criteria	Appropriate location
3	Patients requiring/likely to require endotracheal intubation and invasive mechanical ventilatory support Patients requiring support of two or more organ systems (e.g. inotropes and haemofiltration) Patients with chronic impairment of one or more organ systems (e.g. COPD or severe ischaemic heart disease) who require support for acute reversible failure of another organ	ICU
2	Patients requiring detailed observation or monitoring that cannot be provided at ward level: Direct arterial BP monitoring CVP monitoring Fluid balance Neurological observations, regular GCS recording Patients requiring support for a single failing organ system, excluding invasive ventilatory support (IPPV): Non-invasive respiratory support (p. 202) Moderate inotropic or vasopressor support Renal replacement therapy in an otherwise stable patient Step-down from intensive care requiring additional monitoring or single organ support	HDU
1	Patients in whom frequent but intermittent observations and medical review are sufficient	General ward setting

(BP = blood pressure; COPD = chronic obstructive pulmonary disease; CVP = central venous pressure; GCS = Glasgow Coma Scale; IPPV = intermittent positive pressure ventilation)

admitted to the intensive care or high-dependency unit (ICU/HDU) will depend on local arrangements. A useful tool to assist with the decision regarding location is the 'level of care' required (Box 10.18). Many intensive care units are a mix of level 2 and level 3 beds, which streamlines the admission process.

Common presentations of deterioration

As patients become critically unwell, they usually manifest physiological derangement. The principle underpinning critical care is the simultaneous assessment of illness severity and the stabilisation of life-threatening physiological abnormalities. The goal is to prevent deterioration and effect improvements, as the diagnosis is established and treatment of the underlying disease process is initiated.

It can be useful to consider the physiological changes as a starting point to help delineate urgent investigations and supportive treatment, which should proceed alongside the search for a definitive diagnosis.

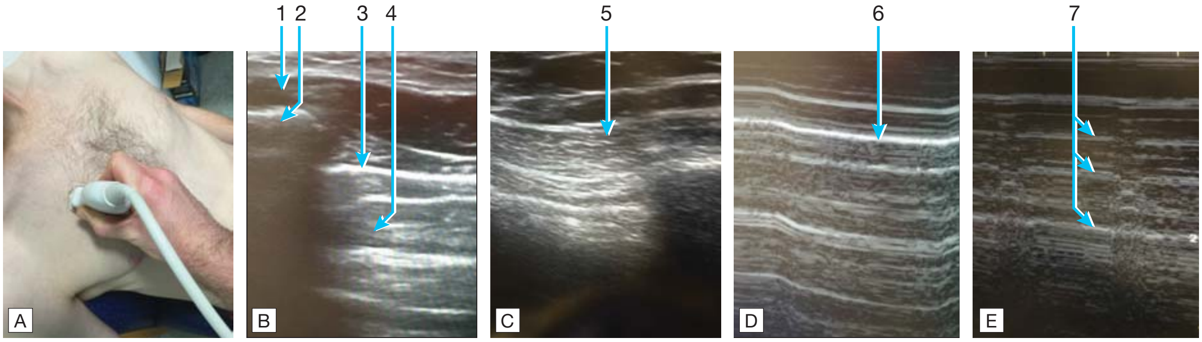
Tachypnoea

Pathophysiology

A raised respiratory rate (tachypnoea) is the earliest and most sensitive sign of clinical deterioration. Tachypnoea may be primary (i.e. a problem within the respiratory system) or secondary to pathology elsewhere in the body. Cardiopulmonary causes of tachypnoea have been covered on page 179. Secondary tachypnoea is usually due to a metabolic acidosis, most commonly observed in the context of sepsis, haemorrhage, ketoacidosis or visceral ischaemia. More detailed information on metabolic acidosis can be found on page 364.

Assessment and management

A simple assessment of a patient's clinical status and basic physiology will usually indicate whether urgent intervention is required. In the examination, attention should be paid to the adequacy of chest expansion, air entry and the presence of added sounds such as wheeze.



Analysis of an arterial blood sample is especially helpful in narrowing the differential diagnosis and confirming clinical suspicion of severity. The 'base excess' provides rapid quantification of the component of disease that is metabolic in origin. A base excess lower than –2 mEq/L (or, put another way, a 'base deficit' of more than 2 mEq/L) is likely to represent a metabolic acidosis. A simple rule of thumb is that a lactate of more than 4 mmol/L or a base deficit of more than 10 mEq/L should cause concern and trigger escalation to a higher level of care. In addition to clinical examination, chest radiography and bedside ultrasound can help to distinguish the cause of poor air entry; consolidation and effusion can be readily identified and a significant pneumothorax can be excluded (as shown in Fig. 10.8).

Hypoxaemia

Pathophysiology

Low arterial partial pressure of oxygen (PaO_2) is termed hypoxaemia. It is a common presenting feature of deterioration. Hypoxia is defined as an inadequate amount of oxygen in tissues (or the inability of cells to use the available oxygen for cellular respiration). Hypoxia may be due to hypoxaemia, or may be secondary to impaired cardiac output, the presence of inadequate or dysfunctional haemoglobin, or intracellular dysfunction (such as in cyanide poisoning, where oxygen utilisation at the cellular level is impaired).

Over 97% of oxygen carried in the blood is bound to haemoglobin. The haemoglobin–oxygen dissociation curve delineates the relationship between the percentage saturation of haemoglobin with oxygen (SO_2) and the partial pressure (PO_2) of oxygen in the blood. A shift in the curve will influence the uptake and release of oxygen by the haemoglobin molecule. As capillary PCO_2 rises, the curve moves to the right, increasing the offloading of oxygen in the tissues (the Bohr effect). This increases capillary PO_2 and hence cellular oxygen supply. Shifts of the oxyhaemoglobin dissociation curve can have significant implications in certain disease processes (Fig. 10.9).

Normal (no pneumothorax) | Abnormal (pneumothorax cannot be excluded) | Normal (no pneumothorax) | Abnormal (pneumothorax cannot be excluded)

Fig. 10.8 Using ultrasound to rule out an anterior pneumothorax. A Probe position and orientation. B and C Two-dimensional (2D) ultrasound images. D and E M-mode ultrasound images. Key: (1) Intercostal muscle. (2) Rib. (3) Normal bright pleural line –'shimmering appearance' of sliding pleura. (4) Lung. (5) Absent 'shimmering' in pneumothorax and lung not visible. (6) Normal – 'sea shore' sign excludes pneumothorax at that location. The 'sea shore' is represented by the bright granular line with lung (sea) deeper to the bright line. (7) Absent granular pleural line and a repeating linear pattern or 'barcode' sign suggest the presence of pneumothorax.

10

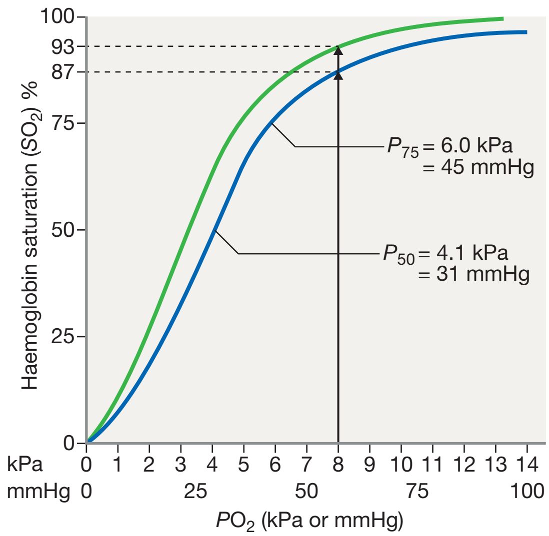


Fig. 10.9 The haemoglobin–oxygen dissociation curve and the effect of CO_2 on oxygen saturations. In pulmonary embolism, compensatory hyperventilation often occurs. $PaCO_2$ decreases, shifting the oxyhaemoglobin saturation curve to the left (green line). Therefore, despite a low PaO_2 (8 kPa/60 mmHg), the saturation reading is 93%.

Due to the shape of the curve, a small drop in arterial PO_2 (PaO_2) below 8 kPa (60 mmHg) will cause a marked fall in SaO_2.

Relative hypoxaemia refers to the comparison between the observed PaO_2 and that which might be expected for a given fraction of inspired oxygen (FiO_2). With the patient breathing air, PaO_2 of 12–14 kPa (90–105 mmHg) would be expected; with the patient breathing 100% oxygen, a PaO_2 of >60 kPa (450 mmHg) would be normal.

Assessment and management

Oxygen therapy should be titrated to avoid hyperoxia (too high a PaO_2; Box 10.19). Hyperoxia is theoretically harmful via a number of mechanisms. This has a clinically significant effect in patients with acute stroke, those with MI and those who chronically retain CO_2. Adverse effects of hyperoxia include:

- free radical-induced tissue damage
- less efficient buffering of carbon dioxide by oxyhaemoglobin (compared to deoxyhaemoglobin)
- less efficient ventilation–perfusion matching in lung units (due to loss of hypoxic vasoconstriction of under-ventilated lung units)
- decreased hypoxic respiratory drive in individuals with chronic hypercapnia.

When attempting to determine the cause of hypoxaemia, it is useful to consider whether the primary physiological mechanism is a type of shunt, or one of the many causes of ventilation–perfusion mismatch, such as alveolar or central hypoventilation (Fig. 10.10). A classification of common causes of hypoxaemia in hospitalised patients is shown in Box 10.20. In reality, the observed physiological abnormality may represent a combination of inter-related processes, such as severe pulmonary oedema leading to exhaustion, which in turn causes hypoventilation.

Evaluation of risk factors, history and examination will help to differentiate the likely aetiology and guide specific management. Further management of respiratory failure is discussed on page 202.

10.19 Prescribing oxygen in critical illness

- Oxygen should be prescribed to achieve a target saturation of 94–98% for most critically unwell patients.
- 88–92% is a more appropriate target range for those at risk of hypercapnic respiratory failure.

Tachycardia

Pathophysiology

A heart rate of >110 beats/min in an adult should always be considered abnormal and not attributed to anxiety until other causes have been excluded. Intrinsic cardiac causes (atrial fibrillation (AF), atrial flutter, supraventricular tachycardia and

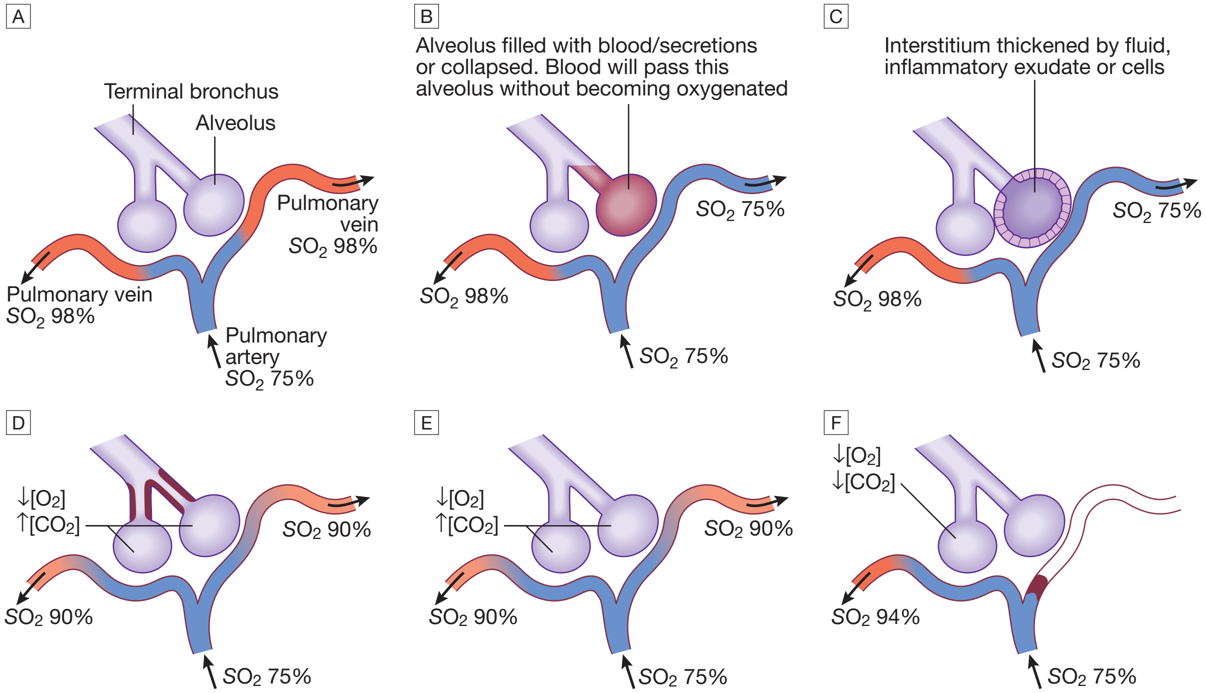

Fig. 10.10 Theoretical mechanisms of hypoxaemia. A Normal physiology. B Shunt caused by alveolar filling, e.g. in pneumonia or alveolar haemorrhage. The mixture of oxygenated and deoxygenated blood causes arterial desaturation. C Shunt caused by interstitial pathology, e.g. pulmonary oedema or fibrosis. Interstitial thickening causes inadequate transfer of oxygen from the alveolus to the blood, leading to shunting and arterial desaturation. Because minute volume is usually maintained, this causes type I respiratory failure. D Ventilation–perfusion ($\dot{V}/\dot{Q}$) mismatch caused by alveolar hypoventilation, e.g. in chronic obstructive pulmonary disease (COPD)/asthma. Alveoli are under-ventilated relative to perfusion. Alveolar PO_2 falls and PCO_2 rises, causing type II respiratory failure. E $\dot{V}/\dot{Q}$ mismatch caused by central hypoventilation, e.g. in neuromuscular disease or narcotic use. The alveoli are relatively over-perfused, causing type II respiratory failure. F $\dot{V}/\dot{Q}$ mismatch caused by a perfusion defect, e.g. a small pulmonary embolism. Pulmonary blood flow is diverted to other alveoli, causing them to be relatively over-perfused and thus reducing alveolar PO_2. Minute volume is increased, so PCO_2 is not elevated.

i 10.20 Common causes of hypoxaemia in hospitalised patients

Hypoxaemia due to shunt

- Lung collapse
- Consolidation/alveolar haemorrhage
- Interstitial oedema or interstitial infiltration (e.g. fibrosis)
- Silent aspiration of gastric contents

Hypoxaemia due to ventilation–perfusion mismatch

- Pulmonary embolism
- Acute exacerbation of asthma
- COPD (with high minute volume)

Hypoxaemia from hypoventilation

- Effects of opiates
- Severe COPD (with low minute volume)
- Neuromuscular disease/general weakness from other illness

(COPD = chronic obstructive pulmonary disease)

ventricular dysrhythmias) are less common in the general inpatient population than secondary causes of tachycardia.

A cardiac monitor or 12-lead ECG early in the examination will help both determine severity (heart rate > 160 beats/min should prompt urgent escalation to a higher level of care) and narrow the differential diagnosis. AF with a rapid ventricular response should usually be regarded as secondary to another insult (mostly commonly, infection) until other diagnoses have been excluded.

Hypovolaemia should not be missed. Concealed bleeding (e.g. into the pleura, gastrointestinal tract or retroperitoneum) may not be apparent initially and assessment of haemoglobin in an acute haemorrhage, when <30 mL/kg of fluid has been administered, can be misleadingly high. Sepsis and other hyper-metabolic conditions may present with a tachycardia that is accompanied by tachypnoea, peripheral vasodilatation and a raised temperature. Other organ dysfunction should be noted from a brief general examination and salient points from the history.

Assessment and management

The management of a tachycardic patient should focus on treating the cause. Treating the rate alone with beta-blockade in an unwell or deteriorating patient should be done only under specialist guidance, in controlled conditions, and when a clear evaluation of the risk–benefit ratio has been undertaken.

The recognition and management of primary cardiac dysrhythmias are discussed on page 468. The most appropriate method of rate control in AF depends primarily on the degree of haemodynamic compromise. An intravenous loading dose of amiodarone is well tolerated and efficacious in the majority of critically ill patients with AF and a very rapid ventricular rate. There are thromboembolic concerns regarding chemical cardioversion of AF of unknown duration. However, in deteriorating patients, the low incidence of embolic events makes this concern of secondary importance to achieving haemodynamic stability.

Digoxin continues to have a role in the treatment of AF in critically unwell but haemodynamically stable patients, when

its inotropic properties can be helpful. Electrical cardioversion is reserved for dysrhythmias with extremely high heart rates, following failure of pharmacological management, and/or for those of ventricular origin. It is rarely successful in dysrhythmias secondary to systemic illness.

Hypotension

Pathophysiology

Low BP (hypotension) should always be defined in relation to a patient's usual BP. The calculation of mean arterial pressure (MAP) is shown in Box 10.21; it unifies the systolic and diastolic BPs into a single reference value. A MAP of >65 mmHg will maintain renal perfusion in the majority of patients, although a MAP of up to 80 mmHg may be required in patients with chronic hypertension.

Assessment and management

The first stage of assessment is to decide if the hypotension is physiological or pathological. The MAP is useful as, despite low systolic pressures, it is rare to see a physiological MAP of <65 mmHg. Urine output is particularly useful in the determination of the desirable MAP for an individual patient; oliguria suggests that measures to increase the MAP should be sought (p. 204). If the hypotension is pathological, an assessment of severity should look at whether it is causing physiological harm to the patient (i.e. the patient is shocked).

Shock

Shock means 'circulatory failure'. It can be defined as a level of oxygen delivery (DO_2) that fails to meet the metabolic requirements of the tissues (Box 10.22). Hypotension is a common presentation of shock but the terms are not synonymous. Patients can be hypotensive but not shocked, and oxygen delivery can be critically low in the context of a 'normal' BP. Along with the signs of low cardiac output (Box 10.23), objective markers of inadequate tissue oxygen delivery, such as increasing base deficit, elevated blood lactate and reduced urine output, can aid early identification. If shock is suspected, resuscitation should be commenced (p. 204).

Hypotensive patients who do not have any evidence of shock are still at significant risk of organ dysfunction. Hypotension should serve as a 'red flag' that there may be serious underlying pathology. Organ failure occurs despite normal or elevated oxygen delivery, so a full assessment of the patient is indicated. A review of the drug chart is essential, as many inpatients will be on antihypertensive medications that are contributing to hypotension. Non-cardiac medications may also have a negative influence on BP; for example, some drugs used for urine outflow tract obstruction, such as tamsulosin, have an α-adrenoceptor-blocking effect.

i 10.21 Calculation of mean arterial pressure (MAP)

$$\text{MAP} = \text{Diastolic blood pressure} + \frac{(\text{systolic} - \text{diastolic})}{3}$$

At normal heart rates, the heart, on average, spends two-thirds of the cycle in diastole. The MAP reflects this by weighting the value towards the diastolic blood pressure

i 10.22 Oxygen content and delivery

- Oxygen content of blood = *Haemoglobin level × oxygen saturation × constant
- Cardiac output = Heart rate × stroke volume
- Stroke volume is dependent on cardiac filling (preload) and contractility
- In shock, the most productive measures to improve oxygen delivery are optimising the haemoglobin level and the cardiac output

*Oxygen is almost exclusively bound to haemoglobin; only tiny amounts are dissolved in blood at atmospheric pressure.

i 10.23 Hypotension in relation to cardiac output: clinical signs and possible causes

	High cardiac output	Low cardiac output
Signs	Warm hands Pulsatile head movement High-volume/strong pulse Low venous pressure	Cold/clammy peripheries Peripheral cyanosis Raised venous pressure
Causes	Sepsis Allergy Drug overdose (e.g. antihypertensive) Acidosis (e.g. diabetic ketoacidosis) Thyrotoxicosis Beri-beri	Bleeding Aortic stenosis and failed compensation Dysrhythmia Obstructive (pulmonary embolism/tamponade/ dynamic hyperinflation as in severe asthma) Chronic heart failure

Hypertension

Pathophysiology

High BP (hypertension) is common and is usually benign in a critical care context. However, it can be the presenting feature of a number of serious disease processes. Furthermore, acute hypertension can result in an acute rise in vascular tone that increases left ventricular end-systolic pressure (afterload). The left ventricle may be unable to eject blood against the increased aortic pressure, and acute pulmonary oedema can result (referred to as 'flash' pulmonary oedema.)

Assessment and management

Before treating an acute rise in BP, it is worth considering a few important diagnoses that may impact on the immediate management:

- *Intracranial event*. Ischaemia of the brainstem (commonly via a pressure effect) will cause acute increases in BP. A neurological examination and CT scan of the head should be considered.
- *Fluid overload*. Once the capacity of the venous blood reservoir becomes saturated, increases in fluid volume will lead to increases in BP. This can occur in younger patients without the onset of peripheral oedema and originate from myocardial dysfunction or impaired renal clearance.
- *Underlying medical problems*. A brief search for a history of renal disease, spinal injury and less common metabolic causes such as phaeochromocytoma can be worthwhile. In women of child-bearing age, pregnancy-induced

hypertension and pre-eclampsia must always be considered.
- *Primary cardiac problems*. Myocardial ischaemia, acute heart failure and aortic dissection can all present with hypertension.
- *Drug-related problems*. Most commonly, these involve a missed antihypertensive medication, but sympathomimetic drugs such as cocaine and amphetamines can be implicated.

The management of hypertension is discussed further on page 510.

Decreased conscious level

Assessment

A reduction in conscious level should prompt an urgent assessment of the patient, a search for the likely cause and an evaluation of the risk of airway loss. The GCS was developed to risk-stratify head injury, but it has become the most widely recognised assessment tool for conscious level (see Box 10.24 for breakdown of GCS assessment, Box 10.25 for how to communicate the findings and Fig. 10.5 for how to assess GCS). While disorders that affect language or limb function (e.g. left hemisphere stroke, locked-in syndrome) may reduce its usefulness, evaluation of the GCS usually provides helpful prognostic information, and serial recordings can plot improvement or deterioration. It is not possible to define a total score below which a patient is unlikely to be able to protect the airway (from aspiration or obstruction), but a motor score of less than 5 would suggest significant risk.

Coma is defined as a persisting state of deep unconsciousness. In practice, this means a sustained GCS of 8 or less. There are many causes of coma (Box 10.26), including neurological (structural or non-structural brain disease) and non-neurological (e.g. type II respiratory failure) ones. The mode of onset of coma and any precipitating event is crucial to establishing the cause, and should be obtained from witnesses. Failure to obtain an adequate history for patients in coma is a common cause of diagnostic delay.

Once the patient is stable from a cardiorespiratory perspective, examination should include accurate assessment of conscious level and a thorough general medical examination, looking for clues such as needle tracks indicating drug abuse, rashes, fever and focal signs of infection, including neck stiffness or evidence of head injury. Focal neurological signs may suggest a structural explanation (stroke or tumour) or may be falsely localising (for example, 6th nerve palsy can occur as a consequence of raised intracerebral pressure). It is vital to exclude non-neurological causes of coma. Sodium and glucose should be measured urgently as part of the initial assessment, as acute hyponatraemia (p. 358) and hypoglycaemia (p. 738) are easily corrected and can cause irreversible brain injury if missed.

10.24 Glasgow Coma Scale (GCS)*

Eye-opening (E)	
• Spontaneous	4
• To speech	3
• To pain	2
• Nil	1
Best motor response (M)	
• Obeys commands	6
• Localises to painful stimulus	5
• Flexion to painful stimulus or withdraws hand from pain	4
• Abnormal flexion (internal rotation of shoulder, flexion of wrist)	3
• Extensor response (external rotation of shoulder, extension of wrist)	2
• Nil	1
Verbal response (V)	
• Orientated	5
• Confused conversation	4
• Inappropriate words	3
• Incomprehensible sounds	2
• Nil	1
Coma score = E + M + V	
Always present GCS as breakdown, not a sum score (unless 3 or 15)	
• Minimum sum	3
• Maximum sum	15

*Record the best score observed. When the patient is intubated, there can be no verbal response. The suffix 'T' should replace the verbal component of the score, and the remainder of the score is therefore a maximum of 10.

10.25 How to communicate conscious level to other health-care professionals

- It is best to state the physical response along with the numerical score
- For example, 'a patient who doesn't open his eyes, withdraws to pain and makes groaning noises, having a GCS of E1, M4, V2, making a total of 7' is preferable to 'a male with a GCS of 7'

10.26 Causes of coma

Metabolic disturbance	
• Drug overdose • Diabetes mellitus: Hypoglycaemia Ketoacidosis Hyperosmolar coma • Hyponatraemia • Uraemia • Hepatic failure (hyperammonaemia)	• Inborn errors of metabolism causing hyperammonaemia • Hyperammonaemia on refeeding following profound anorexia • Respiratory failure • Hypothermia • Hypothyroidism
Trauma	
• Cerebral contusion • Extradural haematoma	• Subdural haematoma • Diffuse axonal injury
Vascular disease	
• Subarachnoid haemorrhage • Brainstem infarction/haemorrhage	• Intracerebral haemorrhage • Cerebral venous sinus thrombosis
Infections	
• Meningitis • Encephalitis	• Cerebral abscess • Systemic sepsis
Others	
• Epilepsy • Brain tumour	• Functional ('pseudo-coma')

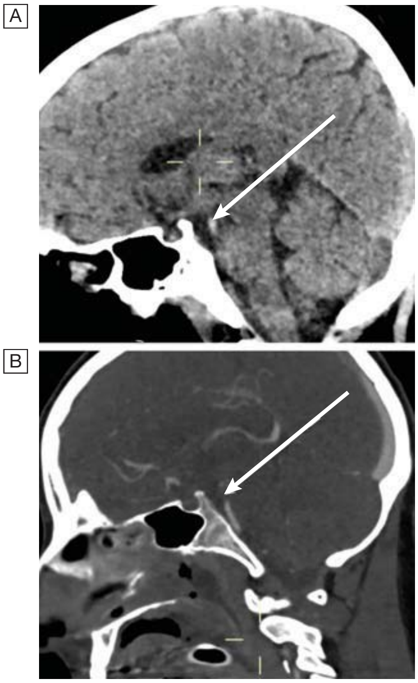

Fig. 10.11 Hyperacute changes in conscious state are commonly of vascular origin. CT of the brain is unlikely to identify many vascular causes but a CT angiogram of the circle of Willis is a high-yield investigation in this context. **A** Non-contrast CT of the head showing hyperdense thrombus in the basilar artery (arrow). This is a specific, but not sensitive, sign. **B** CT angiogram of the circle of Willis demonstrating thrombosis in the basilar artery (arrow). This has better sensitivity for acute vascular occlusion.

Further investigations should be guided by the clinical presentation and examination findings; a sudden onset suggests a vascular cause. An early CT scan of the brain may demonstrate any gross pathology but if a brainstem stroke is suspected (Fig. 10.11), a CT angiogram of the circle of Willis will provide more useful information, as a non-contrast CT is frequently negative in this context. If there are features suggestive of cerebral venous thrombosis, such as thrombophilia or sinus infection, a CT venogram should be performed. Meningitis or encephalitis may be suggested by the history, signs of infection or subtle radiological findings. If these diagnoses are considered, it is best to commence treatment with broad-spectrum antibiotics and antivirals while awaiting more definitive diagnostic information.

Other drug, metabolic and hepatic causes of reduced conscious level are dealt with in the relevant chapters. An ammonia level (sent on ice) can narrow the differential diagnosis to a metabolic or hepatic cause if there is diagnostic doubt; levels >100 μmol/L (140 μg/dL) are significantly abnormal. Psychiatric conditions such as catatonic depression or neurological conditions such as the autoimmune encephalitides can cause a reduced level of consciousness, but they are diagnoses of exclusion and will require specialist input.

Management

Moving an unconscious patient into the recovery position is best for airway protection while preparations are made for escalation to a higher level of care. The decision regarding intubation for airway protection is always difficult. Length of stay in intensive care is significantly reduced if there is no secondary organ dysfunction. Therefore, early intubation and the prevention of lung injury constitute the safer option if there is any doubt about a patient's ability to protect the airway from obstruction or aspiration.

Decreased urine output/deteriorating renal function

Assessment

A urine output of 0.5 mL/kg/hr is a commonly quoted, though admittedly arbitrary target. Although some patients can produce urine volumes below this level with no change in their renal biochemistry, such low volumes should alert the clinician to the possibility of suboptimal renal perfusion.

Oliguria in association with hypotension or an increase in serum creatinine level (even if small) should prompt examination for the underlying cause. Pre-renal causes predominate in the general inpatient population, so optimising the MAP by administration of intravenous fluids (and possibly vasopressors) is the first priority. In the majority of inpatients there is no role for high volumes (i.e. >30 mL/kg) of intravenous fluid if the MAP is normal. Exceptions to this rule include patients with clinical dehydration or high fluid losses such as in burns, diabetes emergencies (pp. 735 and 738) and diabetes insipidus (p. 687), where fluid management should be guided by local protocols.

Diagnosis and management

Further assessment and management of oliguria are explained on page 391. Two other important causes of renal failure in the inpatient population are abdominal compartment syndrome and rhabdomyolysis.

Abdominal compartment syndrome

Abdominal compartment syndrome occurs when raised pressure within the abdomen reduces perfusion to the abdominal organs. It is most commonly seen in surgical patients, but can occur in medical conditions with extreme fluid retention such as liver cirrhosis. When it is suspected, intra-abdominal pressure can be monitored via a pressure transducer connected to a urinary catheter (following instillation of 25 mL of 0.9% saline into the bladder). Values over 20 mmHg suggest abdominal compartment syndrome is present. Urgent measures should be taken to reduce the pressure, such as decompression of the stomach, bladder and peritoneum if ascites is present. If conservative measures fail, a laparostomy should be considered.

Rhabdomyolysis

Rhabdomyolysis occurs when there is an injury to a large volume of skeletal muscle, usually because a single limb or muscle compartment has been ischaemic for a prolonged period. It can also occur following trauma and crush injury or after over-exertion of muscles. Over-exertion can occur after intense physical exercise or as part of a medical condition that causes widespread muscular activity, such as malignant hyperpyrexia or neuroleptic malignant syndrome. A creatine kinase (CK) level of >1000 U/L is highly suggestive, although it can rise to tens of thousands in severe cases. Management should focus on identification and correction of the underlying cause and support for multi-organ dysfunction. Forced alkaline diuresis (using intravenous bicarbonate infusion and furosemide) can be used to maintain a good flow of less acidic fluid within the renal tubules and reduce myoglobin precipitation.

Disorders causing critical illness

Sepsis and the systemic inflammatory response

Sepsis is one of the most common causes of multi-organ failure. Sepsis requires the presence of infection with a resultant systemic inflammatory state; organ dysfunction occurs from a combination of the two processes. The definition of sepsis has undergone various iterations and there is still a lack of consensus as to the exact wording that best reflects this complex, multisystem process (Box 10.27).

Aetiology and pathogenesis

To understand how an infection can lead to progressive multi-organ failure, it is essential to have a grasp of the pathophysiology.

Initiation of the inflammatory response

The process begins with infection in one part of the body that triggers a localised inflammatory response. Appropriate source control and a competent immune system will, in most cases, contain the infection at this stage. However, if certain factors are present, the infection may become systemic. The causative factors are not fully elucidated but probably include:

- a genetic predisposition to sepsis
- a large microbiological load
- high virulence of the organism
- delay in source control (either surgical or antimicrobial)
- resistance of the organism to treatment
- patient factors (immune status, nutrition, frailty).

Mediators are released from damaged cells (called 'alarmins') and these, coupled with direct stimulation of immune cells by the molecular patterns of the microorganism, trigger the inflammatory response. An example of such direct stimulation is that of lipopolysaccharide, which is found on the surface of Gram-negative bacteria. It strongly stimulates an immune response and is commonly used in research settings to initiate a septic cascade.

Viral and fungal infections can cause a syndrome that is clinically indistinguishable from bacterial sepsis. Likewise, numerous non-infective processes, such as pancreatitis, burns, trauma, major surgery and drug reactions, can cause alarmins to be released and initiate the process of systemic inflammation.

i 10.27 Definitions of sepsis and septic shock*

Sepsis

Patients with suspected infection who have 2 or more of:
- *Hypotension* – systolic blood pressure <100 mmHg
- *Altered mental status* – Glasgow Coma Scale score ≤14
- *Tachypnoea* – respiratory rate ≥22 breaths/min

Sepsis can also be diagnosed by suspected infection and an increase of ≥2 points on the Sequential Organ Failure Assessment (SOFA) score (p. 214)

Septic shock

A subset of sepsis with underlying circulatory or cellular/metabolic abnormalities associated with a substantially increased mortality:
- Sepsis and both of (after fluid resuscitation):
  1. Persistent hypotension requiring vasopressors to maintain a MAP >65 mmHg
  2. Serum lactate >2 mmol/L (18 mg/dL)

*From the Third International Consensus Definitions for Sepsis and Septic Shock (Sepsis-3).

Propagation of the inflammatory response

Once activated, immune cells such as macrophages release the inflammatory cytokines interleukin-2 (IL-2), IL-6 and tumour necrosis factor alpha, which, in turn, activate neutrophils. Activated neutrophils express adhesion factors and release various other inflammatory and toxic substances; the net effects are vasodilatation (via activation of inducible nitric oxide synthase enzymes) and damage to the endothelium. Neutrophils migrate into the interstitial space; fluid and plasma proteins will also leak through the damaged endothelium, leading to oedema and intravascular fluid depletion.

Activation of the coagulation system

Damaged endothelium triggers the coagulation cascade (via tissue factor, factor VII, and reduced activity of proteins C and S) and thrombus forms within the microvasculature. A vicious circle of endothelial injury, intravascular coagulation and microvascular occlusion develops, causing more tissue damage and further release of inflammatory mediators. In severe sepsis, intravascular coagulation can become widespread. This is referred to as disseminated intravascular coagulation (DIC) and usually heralds the onset of multi-organ failure. Specific aspects of the diagnosis and management of DIC are discussed on page 978.

Organ damage from sepsis

Any and all organs may be injured by severe sepsis. The pathological mechanisms are shown in Figure 10.12.

Lactate physiology

Lactate is an excellent biomarker for the severity of sepsis. Hyperlactataemia (serum lactate >2.4 mmol/L or 22 mg/dL) is used as a marker of severity. Figure 10.13 explains the physiology of hyperlactataemia; it is caused by all types of shock and therefore is not specific to sepsis. A lactate level of >8 mmol/L (>73 mg/dL) is associated with an extremely high mortality and should trigger immediate escalation. Measures to optimise oxygen delivery should be sought, and the adequacy of resuscitation measured by lactate clearance.

The anti-inflammatory cascade

As the inflammatory state develops, a compensatory anti-inflammatory system is activated involving the release of anti-inflammatory cytokines such as IL-4 and IL-10 from immune cells. While such mechanisms are necessary to keep the inflammatory response in check, they may lead to a period of immunosuppression after the initial septic episode. Patients recovering from severe sepsis are prone to developing secondary infections due to a combination of this immunosuppression and the presence of indwelling devices.

Management

The most important action is to consider sepsis as the cause of a patient's deterioration. Aligned to this is the requirement to consider other diagnoses that could be causing the presentation, such as haemorrhage, PE, anaphylaxis or a low cardiac output state.

Resuscitation in sepsis

General resuscitative measures are discussed on page 204. Early resuscitation can be aided by following the requirements of the

'Sepsis Six' (Box 10.28). Red cell transfusion should be used to target a haemoglobin concentration of 70–90 g/L (7–9 g/dL). Albumin 4% can be used as colloid solution and has the theoretical benefit of remaining in the intravascular space for longer than crystalloid. Early intubation is recommended in severe cases to facilitate further management and reduce oxygen demand.

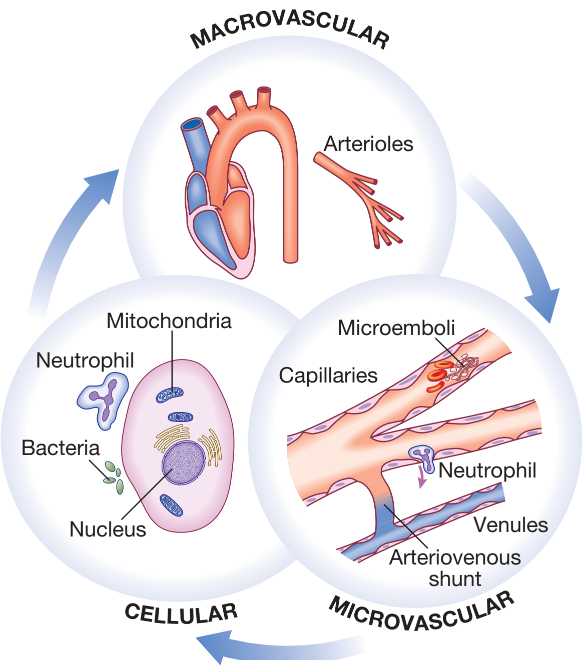

Fig. 10.12 Pathophysiology of organ damage in sepsis. *Macrovascular.* Severe hypovolaemia, vasodilatation or septic cardiomyopathy can reduce oxygen delivery, causing tissue hypoxia. Paradoxically, most patients with sepsis have an increased cardiac output and oxygen delivery. *Microvascular.* Tissue injury can occur from hypoxia secondary to microvascular injury and thrombosis. Damaged epithelium permits neutrophils, proteins and fluid to leak out. *Shunting.* Organs fail in sepsis despite supranormal blood flow. It is likely that arteriovenous shunt pathways exist within vascular beds; these shunts open up in septic shock. *Cellular.* Cells are damaged by a number of mechanisms in sepsis: (1) direct injury by microorganisms; (2) injury from toxins produced by immune cells, e.g. oxygen free radicals; (3) mitochondrial injury causing cytopathic hypoxia – cells are unable to metabolise oxygen; (4) apoptosis – if the cell injury is sufficient, capsase enzymes are activated within the nucleus and programmed cell death occurs; (5) hypoxia from micro- and macrovascular pathology.

Appropriate antibiotics should be administered as early as possible (Box 10.29). The antibiotic choice will depend on local patterns of resistance, patient risk factors and the likely source of infection. Information on likely organisms and appropriate antibiotics can be found on pages 117 and 226. Microbiological samples (such as blood cultures, urine or CSF) should be taken, but this should not delay antibiotic administration, if obtaining samples is difficult.

Early source control

Source control requires an accurate diagnosis; urgent investigations should be performed as soon as physiological stability has been established. A CT scan of the chest and abdomen with contrast is a high-yield test in this context. Specific points in the history should be reviewed, such as risk factors for human immunodeficiency virus (HIV), contacts with tuberculosis and underlying immune status. Immunocompromised patients will be susceptible to a far broader spectrum of infectious microorganisms (p. 223).

10.28 The 'Sepsis Six'*

1. Deliver high-flow oxygen
2. Take blood cultures
3. Administer intravenous antibiotics
4. Measure serum lactate and send full blood count
5. Start intravenous fluid replacement
6. Commence accurate measurement of urine output

*International recommendations for the immediate management of suspected sepsis from the Surviving Sepsis Campaign (all to be delivered within 1 hr of the initial diagnosis of sepsis).

10.29 Early administration of antibiotics in suspected sepsis

- Broad-spectrum antibiotics should be administered as soon as possible after sepsis is suspected
- Every hour of delayed treatment is associated with a 5–10% increase in mortality

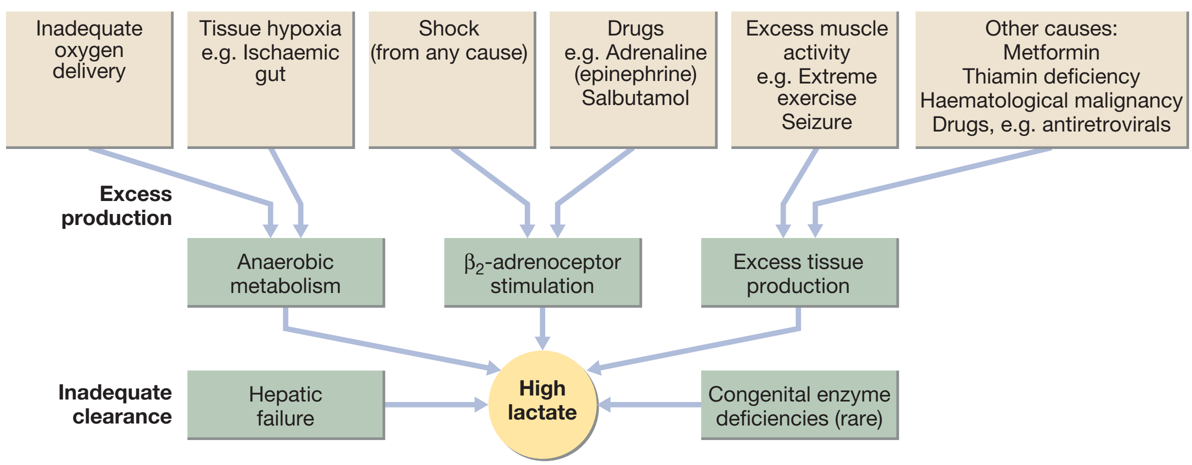

Fig. 10.13 Physiology of hyperlactataemia.

i 10.30 Central and mixed venous oxygen saturations

- Saturation of venous blood sampled from the right atrium or superior vena cava (central) or pulmonary artery (mixed venous)
- Both values reflect the balance of supply and demand of oxygen to the tissues
- Mixed venous oxygen saturation is a measure of whole-body supply and demand of oxygen; central venous oxygen saturation measures the supply and demand of oxygen from the upper body. Normal mixed venous oxygen saturation is 70%. Lower values than this suggest inadequate oxygen delivery
- Central venous oxygen saturation is more variable, depending on whether the patient is awake or anaesthetised, but a value of 70% is considered normal
- Where cytopathic hypoxia occurs, oxygen extraction is impaired and the central and mixed venous oxygen saturations may be >80%. This is often a poor prognostic sign

Noradrenaline (norepinephrine) for refractory hypotension

Central venous access should be established early in the resuscitation process and a noradrenaline infusion commenced. If there is severe hypotension, it is not necessary to wait until 30 mL/kg of fluid has been administered before commencing noradrenaline; early vasopressor use may improve the outcome from acute kidney injury. Measurement of central and mixed venous oxygen saturations may provide additional prognostic information (Box 10.30).

Other therapies for refractory hypotension

Refractory hypotension is due to either inadequate cardiac output or inadequate systemic vascular resistance (vasoplegia). When vasoplegia is suspected, it may be necessary to add vasopressin (antidiuretic hormone, ADH). This is a potent vasoconstrictor that may be used to augment noradrenaline (norepinephrine) in achieving an acceptable MAP. Intravenous glucocorticoids are also commonly used in refractory hypotension. There is little evidence that they improve the overall outcome, but they do lead to a more rapid reversal of the shocked state. There is a small increased risk of secondary infection following glucocorticoid use.

Septic cardiomyopathy

The myocardium can be affected by the septic process, presenting as either acute left or right ventricular dysfunction. A bedside echocardiogram is particularly useful to confirm the diagnosis, as ECG changes are usually non-specific. Dobutamine or adrenaline (epinephrine) can be used to augment cardiac output, and intravenous calcium should be replaced if ionised calcium is low.

Other interventions such as intravenous bicarbonate in profound metabolic acidosis, high-volume haemofiltration/haemodialysis and extracorporeal support are sometimes used, but currently lack evidence of benefit.

Review of the underlying pathology

While sepsis is the most common cause of acute systemic inflammation, up to 20% of patients initially treated for sepsis will have a non-infectious cause: that is, a sepsis mimic (Box 10.31). These conditions should be considered where the clinical picture is not typical, no source of sepsis can be found, or the inflammatory response seems excessive in the context of local infection. Early reconsideration of the diagnosis of sepsis is crucial, as many of the 'sepsis mimics' offer a finite time window for specific intervention, after which irreversible organ damage will have occurred.

i 10.31 Sepsis mimics

- Pancreatitis
- Drug reactions
- Widespread vasculitis – catastrophic antiphospholipid syndrome, Goodpasture's syndrome
- Autoimmune diseases – inflammatory bowel disease, rheumatoid arthritis, systemic lupus erythematosus
- Malignancy – carcinoid syndrome
- Haematological conditions – haemophagocytic syndrome, diffuse lymphoma, thrombotic thrombocytopenic purpura

Acute respiratory distress syndrome

Aetiology and pathogenesis

Acute respiratory distress syndrome (ARDS) is a diffuse neutrophilic alveolitis caused by a range of conditions and characterised by bilateral radiographic infiltrates and hypoxaemia (Box 10.32). Activated neutrophils are sequestered into the lungs and capillary permeability is increased, with damage to cells within the alveoli. The pathophysiology is part of the inflammatory spectrum described in 'Sepsis' above, and the triggers are similar: infective and non-infective inflammatory processes. These processes result in exudation and accumulation of protein-rich cellular fluid within alveoli and the formation of characteristic 'hyaline membranes'. Local release of cytokines and chemokines by activated macrophages and neutrophils results in progressive recruitment of inflammatory cells. Secondary effects include loss of surfactant and impaired surfactant production. The net effect is alveolar collapse and reduced lung compliance, most marked in dependent regions of the lung (mainly dorsal in supine patients). The affected airspaces become fluid-filled and can no longer contribute to ventilation, resulting in hypoxaemia (due to increased pulmonary shunt) and hypercapnia (due to inadequate ventilation in some areas of the lung): that is, ventilation–perfusion mismatch.

Diagnosis and management

ARDS can be difficult to distinguish from fluid overload or cardiac failure. Classic chest X-ray and CT appearances are shown in Figures 10.14 and 10.15, respectively. Occasionally, conditions may present in a similar way to ARDS but respond to alternative treatments; an example of this might be a glucocorticoid-responsive interstitial pneumonia (p. 605). Management of ARDS is supportive, including use of lung-protective mechanical ventilation, inducing a negative fluid balance and treating the underlying cause. Establishing the severity of ARDS (Box 10.33) is useful, as severe disease will require more proactive management such as prone positioning or extracorporeal membrane oxygenation (ECMO; p. 204).

i 10.32 Berlin definition of ARDS

- Onset within 1 week of a known clinical insult, or new or worsening respiratory symptoms
- Bilateral opacities on chest X-ray, not fully explained by effusions, lobar/lung collapse or nodules
- Respiratory failure not fully explained by cardiac failure or fluid overload. Objective assessment (e.g. by echocardiography) must exclude hydrostatic oedema if no risk factor is present
- Impaired oxygenation (see Box 10.33)

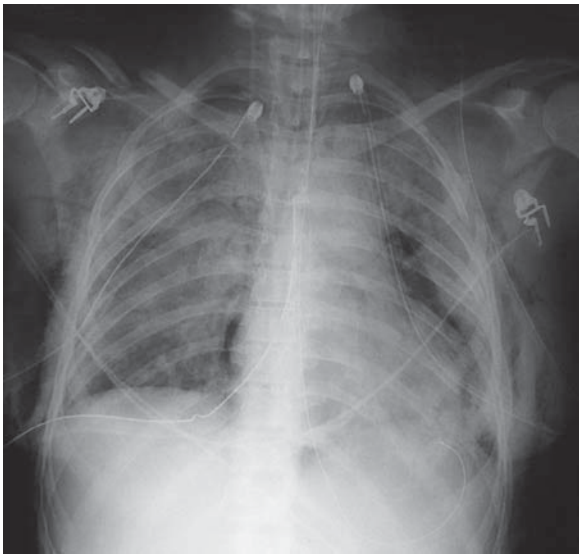

Fig. 10.14 Chest X-ray in acute respiratory distress syndrome (ARDS). Note bilateral lung infiltrates, pneumomediastinum, pneumothoraces with bilateral chest drains, surgical emphysema, and fractures of the ribs, right clavicle and left scapula.

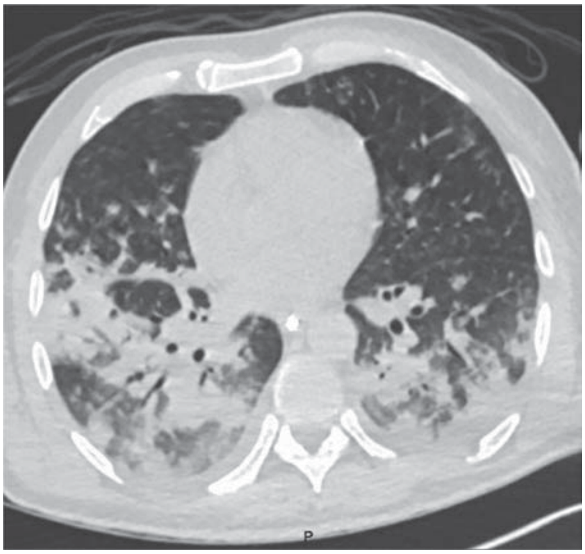

Fig. 10.15 CT scan of the thorax in a patient with severe ARDS. Note the pathology is mainly in the dorsal (dependent) parts of the lung.

10.33 Determining the severity of ARDS

Severity of hypoxaemia is calculated using a Pa/FiO_2 ratio. This is a number calculated by using the PaO_2 from an arterial blood gas measurement divided by the fraction of inspired oxygen (FiO_2, expressed as a fraction).

For example, a patient with a PaO_2 of 10 kPa (75 mmHg) on 50% oxygen, i.e. FiO_2 of 0.5, would have a Pa/FiO_2 ratio of 20 kPa (150 mmHg). This would be defined as moderately severe ARDS, if the other Berlin criteria were met (see Box 10.32). All measurements should be taken on a minimum of 5 cmH_2O of PEEP or CPAP.

- Mild: 40–26.6 kPa (300–200 mmHg)
- Moderate: 26.6–13.3 kPa (200–100 mmHg)
- Severe: ≤13.3 kPa (≤100 mmHg)

(CPAP = continuous positive airway pressure; PEEP = positive end-expiratory pressure)

10.34 Acute myocardial infarction: haemodynamic subsets

Cardiac output	Pulmonary oedema: No	Pulmonary oedema: Yes
Normal	Good prognosis and requires no treatment for heart failure	Due to moderate left ventricular dysfunction. Treat with vasodilators and diuretics
Low	Due to right ventricular dysfunction or concomitant hypovolaemia. Give fluid challenge and consider pulmonary artery catheter to guide therapy	Extensive myocardial infarction and poor prognosis. Consider intra-aortic balloon pump, vasodilators, diuretics and inotropes

Acute circulatory failure (cardiogenic shock)

Definition and aetiology

Cardiogenic shock is defined as hypoperfusion due to inadequate cardiac output or, more technically, a cardiac index of <2.2 L/min/m^2 (see Box 10.42). While cardiogenic shock is the final common pathway of many disease processes (e.g. sepsis, anaphylaxis, haemorrhage), the important primary causes of acute heart failure or cardiogenic shock (Fig. 10.16) are described here.

Myocardial infarction

In the majority of cases, cardiogenic shock following acute MI is due to left ventricular dysfunction. However, it may also be due to infarction of the right ventricle, or a variety of mechanical complications, including tamponade (due to infarction and rupture of the free wall), an acquired ventricular septal defect (due to infarction and rupture of the septum) and acute mitral regurgitation (due to infarction or rupture of the papillary muscles).

Severe myocardial systolic dysfunction causes a fall in cardiac output, BP and coronary perfusion pressure. Diastolic dysfunction causes a rise in left ventricular end-diastolic pressure, pulmonary congestion and oedema, leading to hypoxaemia that worsens myocardial ischaemia. This is further exacerbated by peripheral vasoconstriction. These factors combine to create the ‘downward spiral’ of cardiogenic shock (Fig. 10.17). Hypotension, oliguria, delirium and cold, clammy peripheries are the manifestations of a low cardiac output, whereas breathlessness, hypoxaemia, cyanosis and inspiratory crackles at the lung bases are typical features of pulmonary oedema. If necessary, a Swan–Ganz catheter can be used to measure the pulmonary artery pressures and cardiac output (p. 206). These findings can be used to categorise patients with acute MI into four haemodynamic subsets (Box 10.34) and titrate therapy accordingly.

In cardiogenic shock associated with acute MI, immediate percutaneous coronary intervention should be performed (p. 491). The viable myocardium surrounding a fresh infarct may contract poorly for a few days and then recover. This phenomenon is known as myocardial stunning and means that acute heart failure

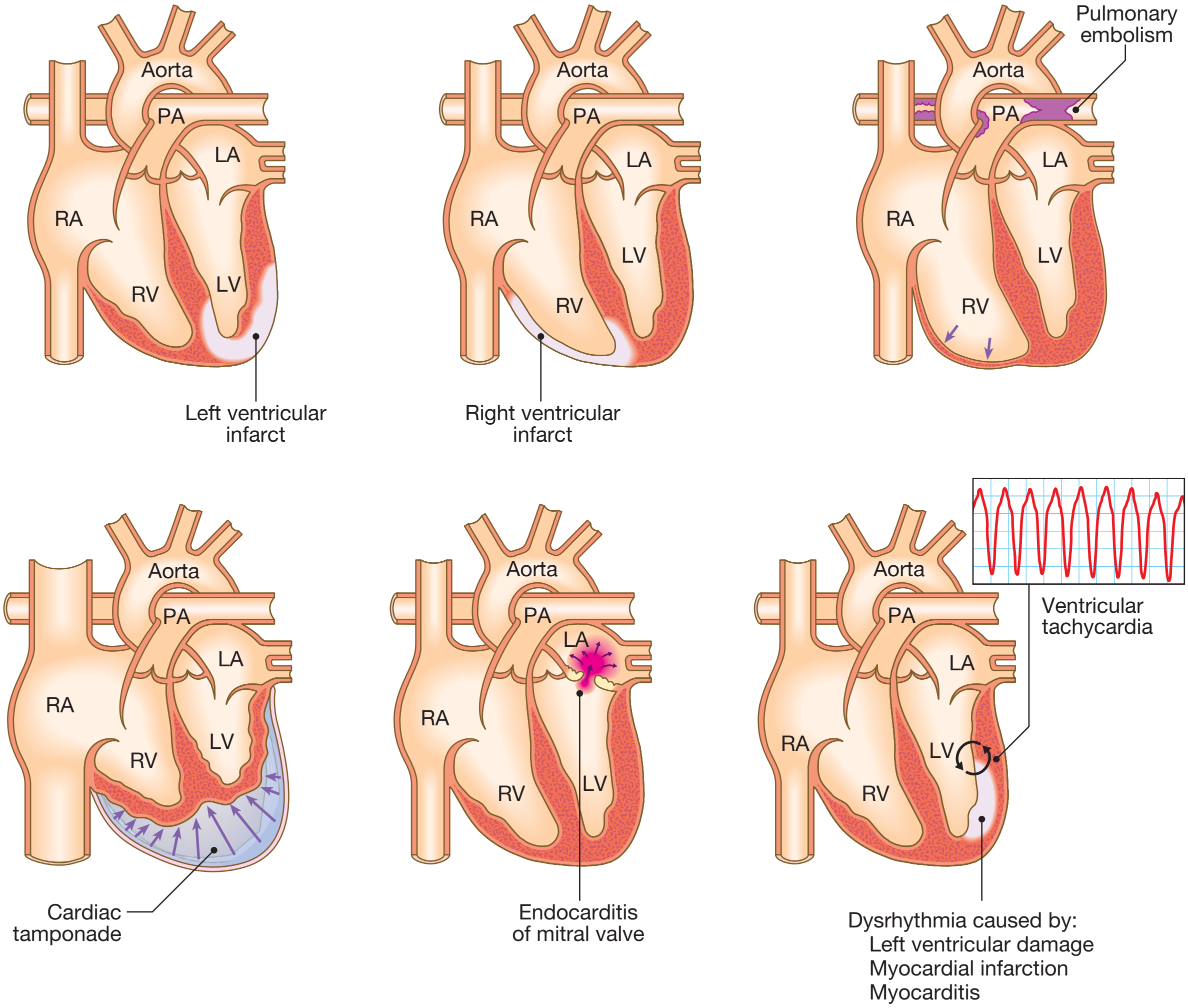

Fig. 10.16 Some common causes of cardiogenic shock.

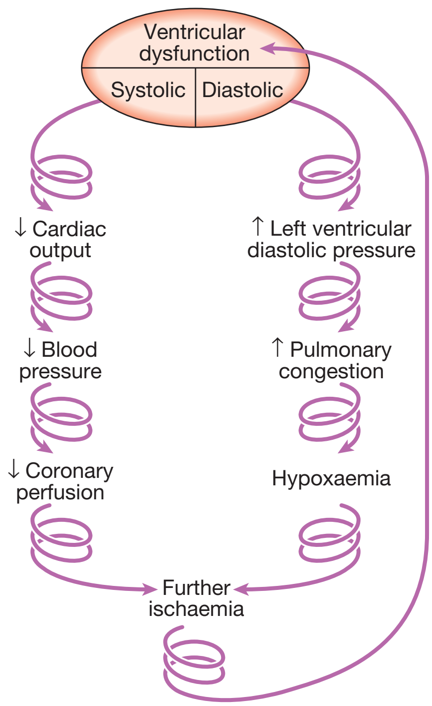

Fig. 10.17 The downward spiral of cardiogenic shock.

should be treated intensively because overall cardiac function may subsequently improve.

Acute massive pulmonary embolism

Massive PE may complicate leg or pelvic vein thrombosis and usually presents with sudden collapse. The clinical features and treatment are discussed on page 619. Bedside echocardiography may demonstrate a small, under-filled, vigorous left ventricle with a dilated right ventricle; it is sometimes possible to see thrombus in the right ventricular outflow tract or main pulmonary artery. In practice, it can be difficult to distinguish massive PE from a right ventricular infarct on transthoracic echocardiogram. CT pulmonary angiography usually provides a definitive diagnosis.

Acute valvular pathology, aortic dissection and cardiac tamponade

These conditions should be considered in an undifferentiated presentation of shock. The diagnosis and management of these conditions is discussed on pages 514, 506 and 544.

Post cardiac arrest

The initial management of cardiac arrest is discussed on page 456. Following the return of spontaneous circulation (ROSC), the majority of cardiac arrest survivors will need a period of time in intensive care to achieve physiological stability, identify

and manage the underlying cause of the arrest, and optimise neurological recovery.

Acute management

A MAP of >70 mmHg should be maintained to optimise cerebral perfusion. Shock is common following ROSC and is caused by a combination of the underlying condition leading to the arrest, myocardial stunning and a post-arrest vasodilated state. Support with inotropes, vasopressors and occasionally mechanical support from an intra-aortic balloon pump or venous–arterial ECMO (p. 207) may be required. Specific cardiac interventions and their indications are described in Chapter 16. Other physiological targets are listed in Box 10.35.

Prognosis

Predicting which patients will not recover from the brain injury sustained at the time of cardiac arrest is very difficult. Certain features suggest that the outcome will be poor: for example, the absence of pupillary and corneal reflexes, absence of a motor response and persistent myoclonic jerking.

Tools to assist prognostication following cardiac arrest are shown in Box 10.36. The clinician should, where feasible, delay prognostication until a period of 72 hours of targeted temperature management has been completed. The bilateral absence of the ‘N20’ spike on the somato-sensory evoked potential is the most specific test to predict irrecoverable brain injury. This test is performed by administering an electrical impulse over a peripheral nerve and recording the electrical impulses measured by the scalp electrodes overlying the part of the brain expected to receive the impulse. Where this is not available, prognostication based on all other available information, along with the perceived wishes relating to the level of disability the individual would be prepared to accept, should allow a decision regarding ongoing treatment to be made. Where there is doubt, more time should be given to allow assessment of neurological recovery.

i 10.35 Physiological targets following a return of spontaneous circulation (ROSC)

- *Temperature management.* Facilitate maintenance of temperature at 36°C and avoidance of pyrexia by the use of a cooling blanket. This should be continued for 72 hrs. Muscle relaxants may be required to prevent shivering
- *Blood pressure management.* Aim for a MAP of at least 70 mmHg and a systolic blood pressure of >120 mmHg
- *Glucose control.* Control the glucose to 6–10 mmol/L (108–180 mg/dL)
- *Normal CO_2* (4.5–6 kPa, 33–45 mmHg) *and oxygen saturation* (94–98%). Avoid both hypoxaemia and hyperoxia

i 10.36 Prognostication after cardiac arrest: predictors of poor neurological recovery

Coexisting problems

- Multi-organ failure
- Significant comorbidities

Clinical

- Persisting and generalised myoclonus
- Absence of pupillary or corneal reflexes
- Poor motor response (absent or extensor response)

Biochemical

- A neuron-specific enolase >33 µg/L

Imaging

- CT showing loss of grey–white differentiation
- Focal cause or consequence of cardiac arrest, e.g. subarachnoid haemorrhage

Electrophysiology

- EEG patterns may suggest brain injury, e.g. burst suppression
- Somato-sensory evoked potentials – bilateral absence of the N20 spike (recorded from scalp electrodes from cutaneous electrical impulse over the median nerve)

Other causes of multi-organ failure

As previously discussed, sepsis is the most common cause of multi-organ failure. However, multi-organ failure secondary to single organ dysfunction, such as cardiac failure, liver failure, renal failure or respiratory failure, is also common. The multisystem insult in these disease processes goes beyond the direct biochemical damage and tissue hypoxia caused by the primary organ dysfunction. It probably reflects cellular signalling pathways and the release of other systemic toxins by the failing organ, referred to as organ ‘crosstalk’.

Multi-organ failure can also be caused by a physiological insult that damages a wide variety of cells in different organs, including toxins from extrinsic sources such as envenomation and intrinsic sources such as myoglobin in rhabdomyolysis (p. 195). Multi-organ failure can also be caused by profound physical injury to cells from processes such as nuclear radiation, heat exposure or blast trauma.

Critical care medicine

Decisions around intensive care admission

Being a patient in intensive care is seldom a pleasant experience. The interventions are usually painful and the loss of liberties that are normally taken for granted can be devastating. While much of the unpleasant sensory and emotional experience can be modified with high-quality care and analgesia, there is a strong case that it can only be morally ‘right’ to admit a patient to intensive care if the end justifies the means. There must be a realistic hope that the patient will regain a quality of life that would be worth the pain and suffering that he or she will experience in intensive care. Few patients are able to comprehend fully what it means to be critically ill, so the physician should guide the process of determining who should be admitted to intensive care.

Selecting the appropriate level of intervention for an individual patient can be very difficult. The decision-making process should involve an assessment of the likelihood of reversibility of the disease, the magnitude of the interventions required, the underlying level of frailty, and the personal beliefs and wishes of the patient (commonly expressed through their next of kin).

As technology and science have improved, conditions that were previously regarded as terminal can now be supported and life can be considerably prolonged (Box 10.37). There have been several prominent examples of individuals who have received intensive care, but where an onlooker might have considered treatment to be futile owing to frailty, comorbidity or profound neurological injury. Such cases will, in part, shape the views and expectations of society, and it is unlikely that making decisions in this area will become any easier. Some suggested techniques to aid decision-making are listed in Box 10.38.

10.37 Critical illness in the context of congenital conditions

- **Longer survival**: there are many congenital conditions that would, in the past, have been fatal in childhood, but now patients survive into adulthood. Decision-making can be difficult when the adolescent has impaired decision-making capacity.
- **Parental views**: in such circumstances, the views of the parent or legal guardian become paramount.
- **Goals of care**: often a detailed explanation of what is, and is not, achievable in intensive care allows the direction of care to be switched to palliative when life expectancy is poor and quality of life is severely impaired.
- **Decision-making**: such conversations may require input from experts in the patient's congenital condition(s), and advanced decision-making regarding ICU admission should be encouraged whenever patients and families feel able to discuss such issues.

10.38 Techniques to improve admission decision-making

- *Always act in the best interests of the patient*: external influences are commonly present but these should be of only secondary importance
- *Maximise patient capacity*: wherever possible, the patient should be involved in discussions of escalation and resuscitation status
- *Communicate openly and honestly with the next of kin*: when communicating potential outcomes, it is best to use natural frequencies rather than percentages. For example, 'If we had 100 patients with the same illness as your mother, only 10 would survive' is easier for most people to understand than 'there is a 90% chance of death'
- *Reach mutual agreement with the next of kin*: it is rare for there to be discord between clinicians and family, and in most cases the most appropriate course of action is clear
- *Seek additional opinions*: other clinicians involved in the care of the patient will provide useful input. The premise should be to err on the side of escalation where the most appropriate course of action is unclear. Where there is an unresolvable difference in opinion, a mediation process or court ruling may be required to make the final decision. Thankfully, this is a very infrequent occurrence
- *Plan ahead*: advance planning in chronic, progressive disease can make the decision easier. Some health facilities use an escalation form, which specifies the interventions that should be offered or are acceptable to the patient. This can be useful as the binary decision of for/not for resuscitation fails to account for the array of interventions that can be performed before cardiac arrest occurs

Stabilisation and institution of organ support

In order to stabilise a critically unwell patient, the primary problem should be corrected as quickly as possible: for example, source control in sepsis and control of the bleeding point in haemorrhage. Immediate resuscitation and prioritisation of the safety of the patient are clearly important, but there is only a limited role for 'optimising' the patient if such measures may significantly delay a definitive treatment, such as laparotomy for a perforated viscus. In some cases, the definitive treatment is not readily apparent or treatments take time to have their full effect. In these cases, adequate organ support to stabilise the patient while the treatment is given becomes the main goal of care.

Respiratory support

Non-invasive respiratory support

Non-invasive respiratory support provides a bridge between simple oxygen delivery devices and invasive ventilation. It can be used in patients who are in respiratory distress but do not have an indication for invasive ventilation, or in those who are not suitable for intubation and ventilation for chronic health reasons. Patients must be cooperative, able to protect their airway, and have the strength to breathe spontaneously and cough effectively. Clinicians should avoid using non-invasive respiratory support to prolong the dying process in irreversible conditions such as end-stage lung disease. Likewise, a failure to respond to treatment or further deterioration should trigger a decision regarding intubation, as delayed invasive ventilation in this context is associated with worse outcome.

High-flow nasal cannulae

High-flow nasal cannulae (HFNCs) are devices that provide very high gas flows of fully humidified oxygen and air. They offer distinct advantages over non-invasive ventilation (NIV) in selected patients, mainly those with type I respiratory failure (particularly pneumonia) who have not reached an indication for invasive ventilation. They allow patient comfort and increased expectoration while providing some degree of positive end-expiratory pressure (PEEP) and a high oxygen concentration that can be titrated to the SO_2.

Continuous positive pressure ventilation

Continuous positive pressure ventilation therapy involves the application of a continuous positive airway pressure (CPAP) throughout the patient's breathing cycle, typically 5–10 cmH_2O. It helps to recruit collapsed alveoli and can enhance clearance of alveolar fluid. It is particularly effective at treating pulmonary atelectasis (which may be post-operative) and pulmonary oedema. It uses a simpler device than NIV but otherwise offers no direct benefit over it.

Non-invasive ventilation or bi-level ventilation

NIV provides ventilatory support via a tight-fitting nasal or facial mask. It can be delivered by using a simple bi-level ventilation (BiPAP) turbine ventilator, or an intensive care ventilator. These machines can deliver pressure at a higher level (approximately 15–25 cmH_2O) for inspiration and a lower pressure (usually 4–10 cmH_2O) to allow expiration. Ventilation can be spontaneous (triggered by a patient's breaths) or timed (occurring at a set frequency). Systems that synchronise with a patient's efforts are better tolerated and tend to be more effective in respiratory failure. Timed breaths are used for patients with central apnoea. NIV is the first-line therapy in patients with type II respiratory failure secondary to an acute exacerbation of COPD because it reduces the work of breathing and offloads the diaphragm, allowing it to recover strength. It is also useful in pulmonary oedema, obesity hypoventilation syndromes and some neuromuscular disorders. It should be initiated early, especially when severe respiratory acidosis secondary to hypercapnia is present. NIV can also be used to support selected patients with hypercapnia secondary to pneumonia, or during weaning from invasive ventilation, but its effectiveness in these contexts is less certain; early intubation or re-intubation is probably more beneficial.

Intubation and intermittent positive pressure ventilation

Taking control of the respiratory system in a critically ill patient is one of the most significant and risky periods in a patient's journey. Critical incidents are common because the patient is often deteriorating rapidly and is exhausted. The potential for cardiovascular collapse is further exacerbated by the negatively inotropic and vasodilating drugs used to induce anaesthesia, and the period of apnoea invoked to facilitate intubation (Box 10.39).

The main aims of intermittent positive pressure ventilation (IPPV) are to avoid critical hypoxaemia and hypercapnia while minimising damage to the alveoli and encouraging the patient to breathe spontaneously once it is safe to do so. The determination of what constitutes *critical* will depend on the status of each patient. For example, a patient with raised ICP will have a strong indication for normocapnia (because hypercapnia increases ICP). Unfortunately, achieving the minute volumes required to maintain normocapnia can, in itself, be harmful to the lungs (p. 204).

10.39 Optimising safety during intubation

- Intervene early in the disease process (once it has become clear that the disease trajectory is downward)
- Use a stable anaesthetic technique: low doses of sedative agents and rapidly acting paralytic agents
- Remember that intubation should be performed by the most experienced operator available
- Use techniques to optimise oxygenation and ventilation in the period around intubation, e.g. keeping non-invasive ventilation in situ for pre-oxygenation, leaving high-flow nasal cannulae on for the intubation process, and using a video-laryngoscope in an anticipated difficult intubation

Ventilator modes

Following intubation, most patients have a period of paralysis from the muscle relaxation. Mandatory ventilation is, therefore, required for a variable period, depending on the severity of the lung injury, the underlying disease process and the general condition of the patient. Mandatory ventilation means that the ventilator will deliver set parameters (either a set tidal volume or a set inspiratory pressure), regardless of patient effort. A physician can choose to support additional patient effort in between mandatory breaths with pressure support. This requires sufficient patient effort to 'trigger' the ventilator to deliver a synchronised breath, in time with the patient's own ventilation. Other parameters that should be considered when using mechanical ventilation are shown in Figure 10.18.

As a patient's illness resolves, or if the lung injury necessitating intubation is not severe, periods of spontaneous breathing with pressure support are commenced. While spontaneous breathing is preferable to mandatory ventilation modes, the shearing forces of patient effort can exacerbate lung injury in patients with severely damaged lungs. It is, therefore, important that a patient is permitted to breathe in a planned and controlled way.

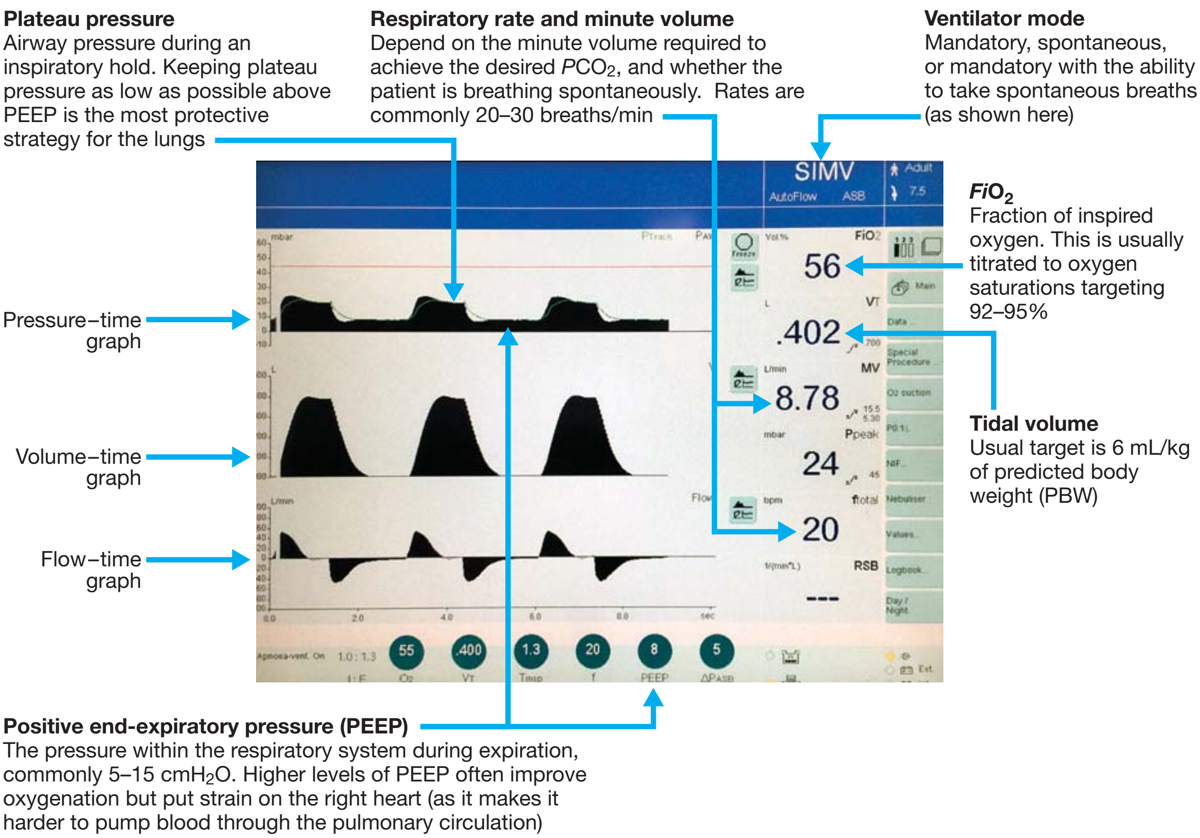

Fig. 10.18 Settings to be considered when commencing mechanical ventilation.

Ventilator-induced lung injury

Every positive-pressure breath causes cyclical inflation of alveoli followed by deflation. The resultant damage to alveoli occurs via several possible mechanisms:

- distending forces from the tidal volume, termed 'volutrauma'
- the pressure used to inflate the lung, referred to as 'barotrauma'
- alveoli collapsing at the end of expiration, called 'atelectotrauma'
- the release of inflammatory cytokines in response to cyclical distension, called 'biotrauma'.

The threshold of injurious ventilation is unique to each patient. Moderate ventilator pressures and volumes used to ventilate healthy lungs may not cause ventilator-induced lung injury (VILI), but the same settings may cause significant VILI if delivered to a patient with lungs that are already damaged from another disease process.

Strategies that may reduce the incidence and severity of VILI include:

- *Permissive hypercapnia*. In the majority of patients who are ventilated for respiratory failure, it is preferable to tolerate moderate degrees of hypercapnia rather than strive for normal blood gases at the expense of VILI. For example, in a patient with isolated respiratory failure, a physician may choose to tolerate a $PaCO_2$ of up to 10 kPa (75 mmHg), provided the H^+ is <63 nmol/L (pH >7.2).
- *'Open lung' ventilation*. Maintaining a positive pressure within the airways at the end of expiration prevents atelectotrauma. Use of low tidal volumes, higher levels of PEEP (Fig. 10.18) and recruitment manœuvres (occasional short periods of sustained high airway pressures to open up alveoli that have collapsed) can reduce the incidence of VILI.
- *Paralysis*. When respiratory failure is severe, patient effort may worsen VILI. An infusion of muscle relaxant can be used to moderate dyssynchrony with the ventilator.

Advanced respiratory support

Airway pressure release ventilation

Airway pressure release ventilation (APRV) is a mode of ventilation that lengthens the inspiratory time to the extreme, with a very short period of time for expiration. It relies on spontaneous movement of the diaphragm from patient effort to facilitate the mixing of gas within the respiratory system during the long period in full inspiration, followed by a very short period of low pressure to allow passive expiration. It has not, however, been demonstrated to be superior to conventional modes of ventilation, but may have a role in moderate to severe ARDS.

Prone positioning

In ARDS, the posterior parts of the lung lose airspaces due to atelectasis and inflammatory exudate. By placing patients on their front, the pattern of fluid distribution within the lung changes, and ventilation–perfusion matching is improved. This is used to enhance oxygenation in moderate to severe ARDS, and may have some disease-modifying effects as the dependent areas of the lung are changed periodically. Although there are risks associated with nursing a patient in the prone position, it is becoming a widespread therapy. Patients are usually placed in the prone position for 12–24 hours and then rotated back to the supine position for a similar period. This cycle continues until there is evidence of resolving lung injury.

Extracorporeal respiratory support

Sometimes, despite optimal invasive ventilation, it is not possible to maintain adequate oxygenation or prevent a profound respiratory acidosis. When a patient has a reversible cause of respiratory failure (or is a potential lung transplant recipient) and facilities are available, extracorporeal respiratory support should be considered.

Venous–venous extracorporeal membrane oxygenation

In venous–venous extracorporeal membrane oxygenation (VV ECMO), large-bore central venous cannulae are inserted into the superior vena cava (SVC) and/or the inferior vena cava (IVC) via the femoral or jugular veins, and advanced under ultrasound or fluoroscopic guidance (Fig. 10.19). Venous blood is then pumped through a membrane oxygenator. This device has thousands of tiny silicone tubes with air/oxygen gas on the other side of the tubes (the membrane). This facilitates the passage of oxygen into the blood and diffusion of carbon dioxide across the membrane, where it is removed by a constant flow of gas (sweep gas). The oxygenated blood is then returned to the right atrium, from where it flows through the lungs as it would in the physiological state. This means that even if the lungs are contributing no oxygenation or carbon dioxide removal, a patient can remain well oxygenated and normocapnic.

Extracorporeal carbon dioxide removal

In some patients it is possible to maintain oxygenation but there is refractory hypercapnia. There are devices available that can remove carbon dioxide using a much lower blood flow rate than VV ECMO. Consequently, smaller venous cannulae, similar to those used in renal dialysis, can be sufficient to have a 'CO_2 dialysis' effect. This can be useful in patients in whom normocapnia is essential (such as those with a raised ICP), or those with refractory hypercapnia and adequate oxygenation. In addition, extracorporeal carbon dioxide removal can be used to reduce the required minute volume, which is a beneficial strategy for protecting the lungs against VILI or facilitating early extubation.

Cardiovascular support

Initial resuscitation

A brief assessment can usually yield enough information to determine whether a patient is at significant risk of an imminent cardiac arrest. If the patient is obtunded and there is no palpable radial or brachial pulse, then treatment should proceed as described on page 457.

In anaphylactic shock, or undifferentiated shock in a peri-arrest situation, a single dose of intramuscular adrenaline (epinephrine) 0.5 mg (0.5 mL of 1 : 1000) can be life-saving. If expertise is available, a small dose of intravenous adrenaline can delay cardiac arrest long enough to identify the cause of shock and institute other supportive measures; a suggested dose would be 50 μg (0.5 mL of 1 : 10 000). If haemorrhage is considered a possibility, a 'major haemorrhage' alert should be activated, facilitating rapid access to large volumes of blood and blood products. A classification of shock is shown in Box 10.40.

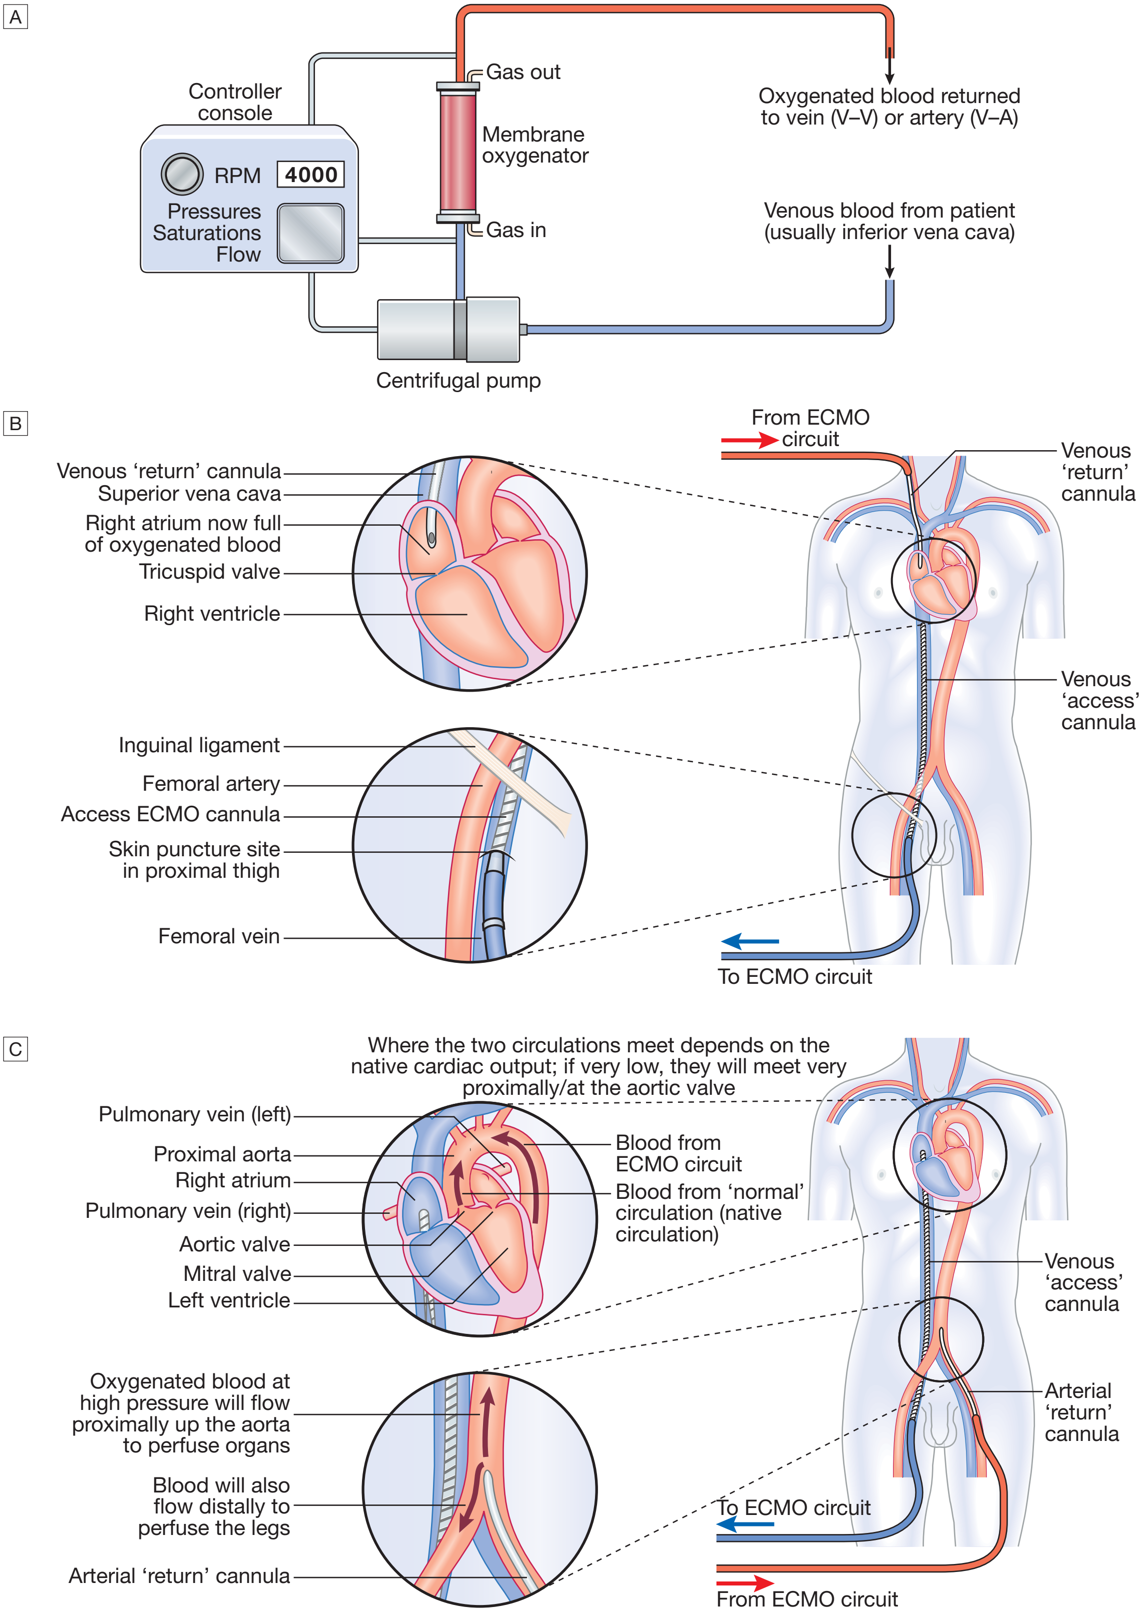

Fig. 10.19 Principles of extracorporeal membrane oxygenation (ECMO). A Basic ECMO circuit: venous–arterial (VA) and venous–venous (VV). B Example of a VV ECMO circuit. C Example of a VA ECMO circuit.

10.40 Categories of shock

Category	Description
Hypovolaemic	Can be haemorrhagic or non-haemorrhagic in conditions such as hyperglycaemic hyperosmolar state (p. 738) and burns
Cardiogenic	See page 199
Obstructive	Obstruction to blood flow around the circulation, e.g. major pulmonary embolism, cardiac tamponade, tension pneumothorax
Septic	See page 196
Anaphylactic	Inappropriate vasodilatation triggered by an allergen (e.g. bee sting), often associated with endothelial disruption and capillary leak (p. 75)
Neurogenic	Caused by major brain or spinal injury, which disrupts brainstem and neurogenic vasomotor control. High cervical cord trauma may result in disruption of the sympathetic outflow tracts, leading to inappropriate bradycardia and hypotension. Guillain–Barré syndrome (p. 1140) can involve the autonomic nervous system, resulting in periods of severe hypo- or hypertension
Others	e.g. Drug-related such as calcium channel blocker overdose; Addisonian crisis

Venous access for the administration of drugs and fluids is vital but often difficult in critically unwell patients. Wide-bore cannulae are required for rapid fluid administration. In extremis, the external jugular vein can be cannulated; it is often prominent in low cardiac output states and readily visible on the lateral aspect of the neck. Occluding the vein distally with finger pressure makes it easier to cannulate, but care must be taken to remain high in the neck to avoid causing a pneumothorax. Intra-osseous or central venous access can be established if there are no visible peripheral veins. Ultrasound can provide assistance for rapid and safe venous cannulation. Rapid infusion devices are widely available and should be used for the delivery of warmed, air-free fluid and blood products.

Fluid and vasopressor use

Resuscitation of the shocked patient should include a 10 mL/kg fluid challenge. Using colloid or crystalloid is acceptable; starch solutions are associated with additional renal dysfunction and should be avoided. The fluid challenge can be repeated if shock persists, to a maximum total of 30 mL/kg of fluid. However, commencing vasopressor therapy early in resuscitation is better than delaying until a large volume of fluid has been given. Amongst other beneficial effects, vasopressors induce venoconstriction, reducing the capacitance of the circulation and effectively mobilising more fluid into the circulation.

If a patient remains shocked after 30 mL/kg of fluid has been administered, a re-evaluation of the likely cause is required, looking particularly for concealed haemorrhage or an obstructive pathology. A bedside echocardiogram is especially useful at this stage to evaluate cardiac output and exclude tamponade. Noradrenaline (norepinephrine) should be commenced as the first-line vasoactive agent in most cases, unless there is a strong indication to use a pure inotropic or chronotropic agent: for example, in cardiogenic shock or shock associated with bradycardia. If there is evidence of low cardiac output, adrenaline (epinephrine) or dobutamine should be commenced. Both agents are equally effective, but dobutamine causes more vasodilatation and additional noradrenaline may be required to maintain an adequate MAP. Vasopressin is added if hypotension persists despite high doses of noradrenaline and cardiac output is thought to be adequate.

In extreme situations it is acceptable to start infusions of inotropes through a well-sited, large-bore peripheral cannula, although central venous access and an arterial line (for monitoring) should be inserted as soon as possible. The actions of commonly used vasoactive drugs are summarised in Box 10.41.

10.41 Actions of commonly used vasoactive agents

	Action		
Drug	Vasoconstrictor	Inotrope	Chronotrope
Adrenaline (epinephrine)	++	+++	++
Noradrenaline (norepinephrine)	++++	+	+
Dobutamine	–	++++	+++
Vasopressin	+++++	No action	– (reflex bradycardia)

Advanced haemodynamic monitoring

There are many different devices available to estimate cardiac output. Such devices employ a variety of mechanisms, including the Doppler effect of moving blood, changes in electrical impedance of the thorax, or the dilution of either an indicator substance or heat (thermodilution). The information is processed within the equipment, and often integrated with additional data, such as the arterial pressure waveform, to give an estimate of cardiac output and stroke volume.

When the aetiology of shock is straightforward and the patient is responding as predicted to treatment, the value of devices that estimate cardiac output is limited. Portable echocardiography has the advantage of giving qualitative information – for example, demonstrating aortic stenosis or a regional wall motion abnormality – as well as quantitative information on stroke volume, but it requires technical expertise.

Pulmonary artery (PA) catheters, sometimes referred to as Swan–Ganz catheters (Fig. 10.20), are invasive but provide useful information on pulmonary pressures, cardiac output, mixed venous oxygen saturations (see Box 10.30) and, by extrapolation, whether the cause of the shock is vasodilatation or pump failure. They can be helpful in complex cases, such as shock after cardiac surgery, or in patients with suspected pulmonary hypertension (Box 10.42). However, PA catheters are associated with some rare but serious complications, including lung infarction, PA rupture and thrombosis of the catheter itself. Such complications occur infrequently in centres that use PA catheters regularly; it should be stressed that a lack of familiarity within the wider clinical team is a relative contraindication to their use.

Mechanical cardiovascular support

When shock is so severe that it is not possible to maintain sufficient organ perfusion with fluids and inotropic support, it is

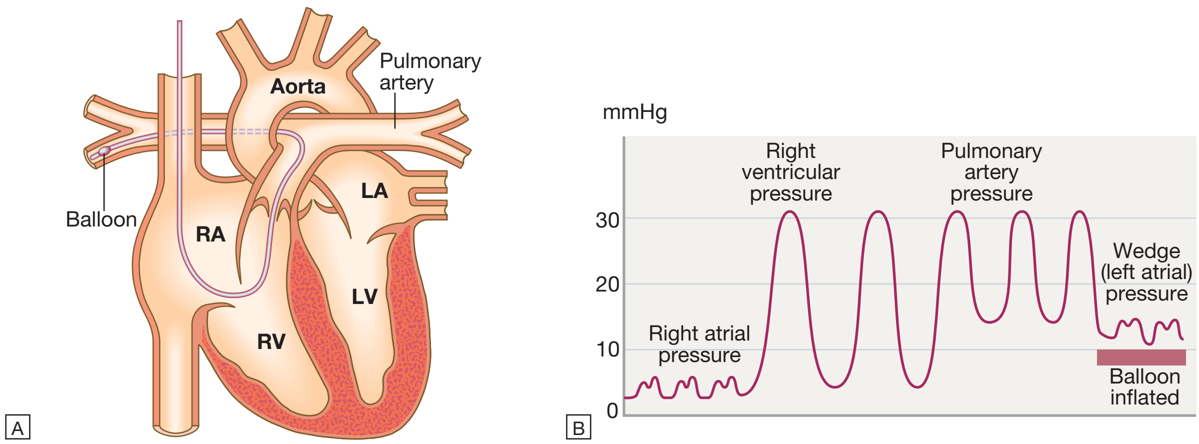

Fig. 10.20 A pulmonary artery (Swan–Ganz) catheter. A There is a small balloon at the tip of the catheter and pressure can be measured through the central lumen. The catheter is inserted via an internal jugular, subclavian or femoral vein and advanced through the right heart until the tip lies in the pulmonary artery. When the balloon is deflated, the pulmonary artery pressure can be recorded. B Advancing the catheter with the balloon inflated will 'wedge' the catheter in the pulmonary artery. Blood cannot then flow past the balloon, so the tip of the catheter will now record the pressure transmitted from the pulmonary veins and left atrium (known as the pulmonary artery capillary wedge pressure), which provides an indirect measure of the left atrial pressure. (LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle)

10

10.42 Interpreting haemodynamic data

Variable	Units	Reference range	Interpretation
Cardiac output (CO)	litres/minute (L/min)	4–8 L/min	Low cardiac output suggests pump failure
Cardiac index (CI) Cardiac output referenced to the size of the patient	litres/minute/metre^2 (L/min/m^2)	2.5–4 L/min/m^2	More useful than raw cardiac output alone, especially in smaller patients
Central venous pressure (CVP)	mmHg	0–6 mmHg	Reflects right atrial pressure – a non-specific measurement of right ventricular (RV) function and volume status Low levels suggest good RV function or hypovolaemia
Pulmonary artery systolic pressure (PA systolic)	mmHg	15–30 mmHg	Difficult to interpret in isolation Low levels suggest vasodilatation, hypovolaemia or right heart failure High levels are seen in many pathologies, e.g. left heart failure, primary pulmonary arterial hypertension (PAH), fluid overload
Pulmonary artery diastolic pressure (PA diastolic)	mmHg	5–15 mmHg	As with PA systolic pressure, difficult to interpret in isolation
Pulmonary artery capillary wedge pressure (PACWP)	mmHg	2–10 mmHg (should be within a few mmHg of PA diastolic)	Reasonable indication of left atrial pressure – raised in left heart failure and fluid overload Measurement is associated with injury to PA so should only be taken occasionally
Transpulmonary gradient (PA diastolic – PACWP)	mmHg	1–5 mmHg	A high gradient suggests the pathology is in the pulmonary arteries, e.g. primary PAH

sometimes necessary to use an internal device to augment or replace the inadequate native cardiac output.

Intra-aortic balloon pump

An intra-aortic balloon counter-pulsation device is a long tube that is usually inserted into the femoral artery and fed proximally into the thoracic aorta. The basic principle is that a helium-filled balloon is able to inflate and deflate rapidly in time with the cardiac cycle. It is inflated in diastole, thus augmenting forward flow of blood to the abdominal organs and improving diastolic pressure proximal to the balloon, thereby optimising coronary perfusion. While the principle is appealing, and an intra-aortic balloon pump (IABP) is often effective in achieving predetermined physiological goals, this does not translate into improved survival in cardiogenic shock. There are risks associated with thrombosis formation on the balloon, mesenteric ischaemia and femoral artery pseudo-aneurysm following removal of the device.

Venous–arterial extracorporeal membrane oxygenation

Venous–arterial extracorporeal membrane oxygenation (VA ECMO) can be life-saving in profound cardiogenic shock and has even been used effectively in refractory cardiac arrest. The circuit and principles are very similar to those described in 'VV ECMO' above (see p. 204 and Fig. 10.19) with one important difference: oxygenated blood is returned to the arterial system (rather than into the right atrium). This means that the pump needs to generate sufficient pressure to allow blood to flow

through the systemic circulation. The sites of venous and arterial access can be either central (via a thoracotomy or sternotomy) or peripheral via cannulae in the IVC/SVC and the femoral/subclavian artery. If the return cannula is peripherally sited (e.g. in the femoral artery), blood will flow back up the aorta from distal to proximal and perfuse the organs.

The outcome depends on the avoidance of complications (primarily, bleeding at the cannula site, intracranial haematoma, air embolism, infection and thrombosis) and improvement of the underlying condition. Most causes of profound cardiogenic shock are unlikely to resolve, and the potential availability of a longer-term solution, such as cardiac transplantation or insertion of a ventricular assist device, is a prerequisite for commencing VA ECMO in most centres.

Renal support

Renal replacement therapy (RRT) is explained in detail on page 420. The key points relating to RRT in an intensive care context are:

- Haemodynamic instability is common. Continuous therapies are widely believed to cause less haemodynamic instability than intermittent dialysis. However, many units use intermittent dialysis without significant problems.
- Haemodialysis and haemofiltration are equally good. Although there are theoretical benefits to removing inflammatory cytokines with haemofiltration, this does not translate into improved survival.
- Anticoagulation is usually achieved using citrate or heparin. Citrate has a better profile for anticoagulating the extracorporeal circuit without inducing an increased bleeding risk, but may accumulate in patients with profound multi-organ failure and should be avoided in very unstable individuals.
- Most patients who survive intensive care will regain adequate renal function to live without long-term renal support.
- A thorough investigation for reversible causes of renal dysfunction should always be undertaken in conjunction with instigation of renal support (see Fig. 15.18, p. 411).
- Shock appears to reverse more rapidly when renal support is instituted. Commencing renal support soon after a patient develops renal 'injury' (when serum creatinine is more than two times higher than baseline) is probably beneficial in the context of septic shock.

Neurological support

A diverse range of neurological conditions require management in intensive care. These include the various causes of coma, spinal cord injury, peripheral neuromuscular disease and prolonged seizures.

The goals of care in such cases are to:

- Protect the airway, if necessary by endotracheal intubation.
- Provide respiratory support to correct hypoxaemia and hypercapnia.
- Treat circulatory problems, e.g. neurogenic pulmonary oedema in subarachnoid haemorrhage, autonomic disturbances in Guillain–Barré syndrome, and spinal shock following high spinal cord injuries.
- Manage acute brain injury with control of ICP.
- Manage status epilepticus using antiepileptic agents such as levetiracetam, phenytoin and benzodiazepines. In refractory cases an infusion of sodium thiopental or ketamine may be required.

The aim of management in acute brain injury is to optimise cerebral oxygen delivery by maintaining normal arterial oxygen content and a cerebral perfusion pressure (CPP) of >60 mmHg. Secondary insults to the brain, such as hypoxaemia, hyper-/hypoglycaemia and prolonged seizures, must be avoided. ICP rises in acute brain injury as a result of haematoma, contusions, oedema or ischaemic swelling. Raised ICP causes damage to the brain in two ways: direct damage to the brainstem and motor tracts as a result of downward pressure and herniation through the tentorium cerebelli and foramen magnum, and indirect damage by reducing CPP. Cerebral blood flow is dependent on an adequate CPP. The CPP is determined by the formula:

$$CPP = MAP - ICP$$

ICP can be measured by pressure transducers that are inserted directly into the brain tissue. The normal upper limit for ICP is 15 mmHg and an upper acceptable limit of 20 mmHg is usually adopted in intensive care. Sustained pressures of >30 mmHg are associated with a poor prognosis. Various strategies are used to control ICP: maintaining normocapnia, preventing any impedance to venous drainage from the head, giving osmotic agents such as mannitol and hypertonic saline, and using hypothermia and decompressive craniectomy. No single technique has been shown to improve outcome in severe intracranial hypertension.

CPP should be maintained above 60 mmHg by ensuring adequate fluid replacement and, if necessary, by treating hypotension with a vasopressor such as noradrenaline (norepinephrine). Complex neurological monitoring must be combined with frequent clinical assessment of GCS, pupillary response to light, and focal neurological signs.

Daily clinical management in intensive care

Clinical review

In intensive care, detailed clinical examination should be performed daily to identify changes to a patient's condition and review the latest diagnostic information. Further focused clinical reviews are usually incorporated into twice-daily ward rounds. Each ward round offers an ideal opportunity to monitor and document compliance with relevant care bundles. A care bundle is a group of interventions that, when implemented concurrently, have provided evidence of clinical benefit. The mnemonic 'FAST HUG' provides a useful checklist of interventions that reduce intensive care complications: *f*eeding, *a*nalgesia, *s*edation, *t*hromboprophylaxis, *h*ead of bed elevation (to reduce the incidence of passive aspiration), *u*lcer prophylaxis and *g*lucose control.

Other key aspects of the daily review are outlined on page 174. The overarching aim of the review is to identify the issues that are impeding recovery from critical illness, and make alterations to address them. In addition, specific and realistic goals for each relevant organ system should be defined, facilitating the autonomous titration of therapy by the bedside critical care nurse. An example of daily goals may be: 'Titrate the noradrenaline (norepinephrine) to achieve a MAP of 65 mmHg, aim for a negative fluid balance, titrate FiO_2 to achieve oxygen saturations

10.43 Properties of sedative and analgesic agents used in ICU

Drug	Mode of action	Advantages	Disadvantages
Propofol	Intravenous anaesthetic	Rapid onset and offset	Large cumulative doses can cause multi-organ failure, especially in children – the 'propofol infusion syndrome'
Alfentanil	Potent opiate analgesic	Rapid onset and offset	High doses may be required Agitation may persist
Morphine	Opioid	Analgesia	Active metabolites and accumulation cause slow offset
Midazolam	Benzodiazepine sedative	Can be used in children	Active metabolites and accumulation cause slow offset
Remifentanil	Very potent opiate	Analgesia and tube tolerance	Respiratory depression – extreme caution in non-intubated patients
Dexmedetomidine	α_2-adrenergic agonist	Excellent tube tolerance Less delirium Can be used in awake patients	Cost and availability

10

of 92–95% and titrate sedation to a RASS score of 0 to –1' (Box 10.44).

Sedation and analgesia

Most patients require sedation and analgesia to ensure comfort, relieve anxiety and tolerate mechanical ventilation. Some conditions, such as critically high ICP or critical hypoxaemia, require deep sedation to reduce tissue oxygen requirements and protect the brain from the peaks in ICP associated with coughing or gagging. For the majority of patients, however, optimal sedation is an awake and lucid patient who is comfortable and able to tolerate an endotracheal tube (termed 'tube tolerance').

Over-sedation is associated with longer ICU stays, a higher prevalence of delirium, prolonged requirement for mechanical ventilation, and an increased incidence of ICU-acquired infection. Box 10.43 compares the various agents used for sedation in intensive care. The key principles are that the patient should primarily receive analgesia, rather than anaesthesia, and caution should be used with drugs that accumulate in hepatic and renal dysfunction. Often a combination of drugs is used to achieve the optimal balance of sedation and analgesia.

Sedation is monitored via clinical sedation scales that record responses to voice and physical stimulation. The Richmond Agitation–Sedation Scale (RASS) is the best-recognised tool (see Box 10.44 for details). Regular use of a scoring system to adjust sedation is associated with a shorter ICU stay. Many ICUs also have a daily 'sedation break', when all sedation is stopped in appropriate cases for a short period. This is commonly combined with a trial of spontaneous breathing aiming to shorten the duration of mechanical ventilation.

10.44 Richmond Agitation–Sedation Scale (RASS)

Score	Term	Description
+4	Combative	Overtly combative, violent or immediate danger to staff
+3	Very agitated	Pulls on/removes tubes or catheters, or aggressive to staff
+2	Agitated	Frequent non-purposeful movement or patient–ventilator dyssynchrony
+1	Restless	Anxious or apprehensive but no aggressive or vigorous movements
0	Alert and calm	
–1	Drowsy	Not fully alert but sustained awakening (>10 secs) with eye opening/contact to voice
–2	Light sedation	Brief awakening (<10 secs) with eye contact to voice
–3	Moderate sedation	Movement but no eye contact to voice
–4	Deep sedation	Movement to physical stimulation but no response to voice
–5	Unrousable	No response to voice or physical stimulation

Delirium in intensive care

Delirium is discussed on page 183. It is extremely common in critically ill patients and often becomes apparent as sedation is reduced. Hypoactive delirium is far more common than hyperactive delirium, but is easily missed unless routine screening is undertaken. A widely used bedside assessment is the CAM-ICU score. The patient is requested to squeeze the examiner's hand in response to instruction and questions, aiming to ascertain whether disordered thought or sensory inattention is present.

Delirium of any type is associated with poorer outcome. Management is focused on non-pharmacological interventions such as early mobilisation, reinstatement of day–night routine, noise reduction, cessation of drugs known to precipitate delirium, and treatment of potential underlying causes such as thiamin replacement in patients at risk of Wernicke's encephalopathy. Patients with agitated delirium that is refractory to verbal de-escalation should initially be managed with small doses of intramuscular antipsychotics, changed to the enteral route once control is established. Atypical antipsychotics such as olanzapine and quetiapine are more efficacious than traditional drugs such as haloperidol. Pharmacological interventions are not useful as prophylaxis or in hypoactive delirium. Additional information on diagnosis and management of delirium can be found on page 184.

Weaning from respiratory support

As the condition that necessitated ventilation resolves, respiratory support is gradually reduced: the process of 'weaning' from ventilation. Some approaches to weaning are described below.

Spontaneous breathing trials

A spontaneous breathing trial involves the removal of all respiratory support followed by close observation of how long the patient is able to breathe unassisted. The technique is particularly effective when linked to a reduction in sedation. PEEP and pressure support are reduced to low levels, or patients are disconnected from the ventilator and breathe oxygen or humidified air through the endotracheal tube. Signs of failure include rapid shallow breathing, hypoxaemia, rising $PaCO_2$, sweating and agitation. Patients who pass a spontaneous breathing trial are assessed for suitability of extubation (endotracheal tube removal).

Progressive reduction in pressure support ventilation

Progressive reduction in pressure support ventilation (PSV) is applied to each breath over a period of hours or days, according to patient response. Some ICU ventilators have software that allows the facility to wean the support provided automatically.

A useful tool to guide the weaning process is the rapid shallow breathing index (RSBI). This composite score of a patient's spontaneous respiratory rate and tidal volume (respiratory rate divided by tidal volume in litres) gives a numerical indication of how difficult the patient is finding breathing at that particular level of support. A RSBI value of >100 suggests that a patient is working at a level that would be unsustainable for longer periods.

Extubation

It is not possible to predict whether a patient is ready to be extubated accurately; the timing relies heavily on clinical judgement. There are, however, some simple rules that can aid decision-making. Patients must have stable ABGs with resolution of hypoxaemia and hypercapnia despite minimal ventilator pressure support and a low FiO_2. Conscious level must be adequate to protect the airway, comply with physiotherapy, and cough. Furthermore, an assessment must be made as to whether the patient can sustain the required minute volume without ventilator support. This depends on the condition of patients' lungs, their strength and other factors affecting the $PaCO_2$, such as temperature and metabolic rate. The need for re-intubation following extubation is associated with poorer outcome, but patients who are not given the opportunity to breathe without a ventilator will also be at increased risk of ventilator-associated complications such as pneumonia and myopathy.

Tracheostomy

A tracheostomy is a percutaneous tube passed into the trachea (usually between the first and second, or second and third tracheal rings) to facilitate longer-term ventilation. The advantages and disadvantages of tracheostomy insertion are listed in Box 10.45. When ventilation weaning has been unsuccessful, a tracheostomy provides a bridge between intubation and extubation; the patient can have increasing periods free of ventilator support but easily have support reinstated. A tracheostomy can be inserted percutaneously, using a bronchoscope in the trachea for guidance, or surgically under direct vision. Occasionally, a patient will have a tracheostomy in situ following a laryngectomy. Such patients are important to identify, as emergency management in the event of a tracheostomy problem (blockage or displacement) must be through the tracheostomy site; access will not be possible via the upper airway.

10.45 Advantages and disadvantages of tracheostomy

Advantages

- Patient comfort
- Improved oral hygiene
- Access for tracheal toilet
- Ability to speak with cuff deflated and a speaking valve attached
- Reduced equipment 'dead space' (the volume of tubing)
- Earlier weaning and ICU discharge
- Reduced sedation requirement
- Reduced vocal cord damage

Disadvantages

- Immediate complications: hypoxaemia, haemorrhage
- Tracheostomy site infection
- Tracheal damage; late stenosis

Nutrition

It is crucial that critically ill patients receive adequate calories, protein and essential vitamins and minerals. Calculation of exact requirements is complex and requires the expertise of a dietitian. It is, however, useful to make a rough estimation of requirements (p. 705). Under-feeding leads to muscle wasting and delayed recovery, while over-feeding can lead to biliary stasis, jaundice and steatosis. Enteral feeding is preferred where possible because it avoids the infective complications of total parenteral nutrition (TPN) and helps to maintain gut integrity. However, TPN is recommended for patients who are likely to have a sustained period without effective enteral feeding, or who are already malnourished. Caution must be taken to avoid the consequences of refeeding syndrome (p. 706).

Other essential components of intensive care

Survival after critical illness depends, to a large extent, on the prevention of medical complications during recovery from the primary insult.

Thromboprophylaxis

DVT, venous catheter-related thrombosis and PE are common in critically ill patients. Low-molecular-weight heparin (LMWH) should be administered to all patients, unless there is a contraindication. Often patients at highest risk of thrombosis, such as those with hepatic dysfunction or those who have suffered major trauma, have a relative contraindication to heparin. Such cases mandate daily evaluation of the risk–benefit ratio, and LMWH should be administered as soon as it is deemed safe to do so. Mechanical thromboprophylaxis, such as intermittent calf compression devices, are useful adjuvants in high-risk patients.

Glucose control

Hyperglycaemia is harmful in critical illness and may occur in people with pre-existing diabetes or undiagnosed diabetes, following administration of high-dose glucocorticoids, or as

a consequence of 'stress hyperglycaemia'. Hyperglycaemia is commonly managed by infusion of intravenous insulin titrated against a 'sliding scale'. Intensive management of hyperglycaemia with insulin can result in hypoglycaemia, which may also be harmful in critical illness. Therefore, a compromise is to titrate insulin to a blood glucose level of 6–10 mmol/L (108–180 mg/dL).

Blood transfusion

Many critically ill patients become anaemic due to reduced red cell production and red cell loss through bleeding and blood sampling. However, red cell transfusion carries inherent risks of immunosuppression, fluid overload, organ dysfunction from microemboli, and transfusion reactions. In stable patients, a haemoglobin level of 70 g/L (7 g/dL) is a safe compromise between optimisation of oxygen delivery and the risks of transfusion. This transfusion threshold should be adjusted upwards for situations where oxygen delivery is critical, such as in patients with active myocardial ischaemia.

Peptic ulcer prophylaxis

Stress ulceration during critical illness is a serious complication. Proton pump inhibitors or histamine-2 receptor antagonists are effective at reducing the incidence of ulceration. There is, however, a suggestion that the use of these agents, particularly in conjunction with antibiotics, may increase the incidence of nosocomial infection, especially with *Clostridium difficile* (p. 264). It is therefore common practice to stop ulcer prophylaxis once consistent absorption of enteral feed is established.

Complications and outcomes of critical illness

The majority of patients will survive their episode of critical illness. While some will return to full, active lives, there are many who have ongoing physical, emotional and psychological problems.

Adverse neurological outcomes

Brain injury

Head injury, hypoxic–ischaemic injury and infective, inflammatory and vascular pathologies can all irreversibly injure the brain. If treatment is unsuccessful, patients will either die or be left with a degree of disability. In the latter situation, the provision of ongoing organ support will depend on the severity of the injury, the prognosis, and the wishes of the patient (usually expressed via relatives). Brain death is a state in which cortical and brainstem function is irreversibly lost. Diagnostic criteria for brain death vary between countries (Box 10.46); if satisfied, these criteria allow physicians to withdraw active treatment and discuss the potential for organ donation. Diagnosing brain death is complex and should be done only by physicians with appropriate expertise, as clinical differentiation from reduced consciousness can be challenging (Box 10.47). Where there is doubt – for example, in patients with coexisting spinal injury or localised brainstem pathology – additional investigations should be performed.

The 'locked-in' syndrome, in which the patient is paralysed except for eye movements, requires preserved hemispheric function (and thus consciousness), but a lesion in the ventral pons (usually caused by infarction) results in complete paralysis. The term 'vegetative state' implies some retention of brainstem function and minimal cortical function, with loss of awareness of the environment. In contrast, 'minimally conscious state' implies that there is some degree of awareness and intact brainstem function. Confident distinction between these states is important and requires careful assessment, often over a period of time. Brain death is, by definition, irreversible but other states may offer hope for improvement.

i 10.46 UK criteria for the diagnosis of brain death

Preconditions for considering a diagnosis of brain death

- The patient is deeply comatose:
  a. There must be no suspicion that coma is due to depressant drugs, such as narcotics, hypnotics, tranquillisers
  b. Hypothermia has been excluded – rectal temperature must exceed 35°C
  c. There is no profound abnormality of serum electrolytes, acid–base balance or blood glucose concentrations, and any metabolic or endocrine cause of coma has been excluded
- The patient is maintained on a ventilator because spontaneous respiration has been inadequate or has ceased. Drugs, including neuromuscular blocking agents, must have been excluded as a cause of the respiratory failure
- The diagnosis of the disorder leading to brain death has been firmly established. There must be no doubt that the patient is suffering from irremediable structural brain damage

Tests for confirming brain death

- All brainstem reflexes are absent:
  a. The pupils are fixed and unreactive to light
  b. The corneal reflexes are absent
  c. The vestibulo-ocular reflexes are absent – there is no eye movement following the injection of 20 mL of ice-cold water into each external auditory meatus in turn
  d. There are no motor responses to adequate stimulation within the cranial nerve distribution
  e. There is no gag reflex and no reflex response to a suction catheter in the trachea
- No respiratory movement occurs when the patient is disconnected from the ventilator for long enough to allow the carbon dioxide tension to rise above the threshold for stimulating respiration ($PaCO_2$ must reach 6.7 kPa/50 mmHg)

The diagnosis of brain death should be made by two doctors of a specified status and experience. The tests are usually repeated after a short interval to allow blood gases to normalise before brain death is finally confirmed

ICU-acquired weakness

Weakness is common among survivors of critical illness. It is usually symmetrical, proximal and most marked in the lower limbs. Critical illness polyneuropathy and myopathy can occur simultaneously and, within the constraints of an altered sensorium, it can be impossible to distinguish the two conditions clinically. Risk factors for both processes include the severity of multi-organ failure, poor glycaemic control and the use of muscle relaxants and glucocorticoids.

Critical illness polyneuropathy

This is due to peripheral nerve axonal loss and characteristically presents as proximal muscle weakness with preserved sensation.

10.47 Classification of brain death and reduced conscious states

Diagnosis	Features	Investigation	Prognosis
Brain death	See Box 10.46	Often not required if cranial imaging shows compatible cause and patient meets clinical criteria In diagnostic doubt: four-vessel angiogram (fluoroscopic or CT) of cerebral vessels or isotope scan of brain to demonstrate absence of cerebral blood flow	Time of confirmed brain death is recorded as time of death Potential to donate organs – donation after brain death (DBD) donor
Vegetative state (VS) 'Persistent VS' >1 month 'Permanent VS' >1 year	No reaction to verbal stimuli Some reaction to noxious stimuli Sleep–wake cycles (periods of eye opening) Maintained respiratory drive Intact brainstem reflexes Occasional automatic movements (yawning, swallowing)	Cranial imaging for primary cause Maintained cortical blood flow	Poor. May be better with traumatic aetiology
Minimally conscious state	Some reaction to verbal stimuli Some reaction to noxious stimuli Spontaneous movements Intact brainstem reflexes	EEG demonstrates reactivity	Variable. Recovery of function more likely than in VS
Locked-in syndrome	Cortex is intact but bilateral motor tracts are damaged Can be partial or complete, i.e. some response to verbal stimuli (e.g. vertical eye movements to communicate) Variable brainstem reflexes No limb movement to noxious stimuli	Imaging for primary cause – commonly MRI or CT will show brainstem or pontine infarction	Variable and depends on cause – progress can continue over months to years

It may also manifest as failure to wean from the ventilator secondary to respiratory muscle weakness. Electrophysiological studies of the affected nerves can be helpful, especially to rule out other potential causes such as Guillain–Barré syndrome. Conduction studies typically show reduced amplitude of transmitted voltage action potential with preserved velocity (compare with findings in Guillain–Barré syndrome; pp. 1076 and 1140). There are no specific treatments aside from resolution of the underlying cause and rehabilitation. Weakness may persist long into the convalescence stage of illness. In some cases, the clinical picture may be more in keeping with individual nerve involvement. This may be due to local pressure effects or part of a generalised picture. Great care must be taken to avoid pressure on high-risk areas such as the neck of the fibula where the common peroneal nerve navigates a superficial course. Nerve palsies such as foot drop can be permanent.

Critical illness myopathy

Although loss of muscle bulk is related to immobility and the catabolic state of critical illness, it is likely that microvascular and intracellular pathophysiological processes are also involved in critical illness myopathy. These processes result in loss of actin myofibrils and muscle weakness. Typically, the CK is normal or only mildly elevated. Like critical illness polyneuropathy, critical illness myopathy is usually a clinical diagnosis. Nerve conduction studies and electromyography may be suggestive of critical illness myopathy, and helpful in ruling out other pathology, but a muscle biopsy is required to confirm the diagnosis (p. 1076). It characteristically shows selective loss of the thick myofibrils and muscle necrosis. Management is conservative and the prognosis is good in ICU survivors.

Other long-term problems

The experience of critical illness and the necessary invasive management can leave patients with profound psychological sequelae akin to the post-traumatic stress syndrome seen in many survivors of conflict. Specialist help is required in managing these issues. Sometimes recovering patients benefit from returning to the ICU to see the environment in a different way and gain a better understanding of the processes and procedures that haunt them.

Long-term physical consequences are also common. Many diseases are not completely cured but follow a relapsing–remitting course; patients who have been critically ill with sepsis are far more likely than others in the general population to suffer from it again. Organ damage often persists and iatrogenic complications are common (e.g. damage to the vocal cords or tracheal stenosis from mucosal pressure caused by the cuff of the endotracheal tube). Intensive care follow-up clinics provide an excellent forum for addressing such issues, and for coordinating care involving a variety of medical specialties.

The older patient

Critically ill older patients present additional challenges following intensive care discharge (Box 10.48). As the ability to make a full recovery depends on frailty rather than chronological age, it can be helpful to use a validated frailty scoring system (p. 1306) to inform admission decision-making.

Rehabilitation medicine has much to offer survivors of critical illness, and an early referral is beneficial when it is clear that a patient is likely to survive with significant morbidity.

10.48 The critically ill older patient

- **ICU demography**: increasing numbers of critically ill older patients are admitted to the ICU; more than 50% of patients in many general ICUs are over 65 years old.
- **Outcome**: affected to some extent by age, as reflected in APACHE II (see Box 10.50), but age should not be used as the sole criterion for withholding or withdrawing ICU support.
- **Cardiopulmonary resuscitation (CPR)**: successful hospital discharge following in-hospital CPR is rare in patients over 70 years old in the presence of significant chronic disease.
- **Functional independence**: tends to be lost during an ICU stay and prolonged rehabilitation may subsequently be necessary.
- **Specific problems**:
  Skin fragility and ulceration
  Poor muscle strength: difficulty weaning from ventilator and mobilising
  Delirium: compounded by sedatives and analgesics
  High prevalence of underlying nutritional deficiency.

Withdrawal of active treatment and death in intensive care

Futility

The idea of futility is not new: Hippocrates stated that physicians should 'refuse to treat those who are overmastered by their disease, realising that in such cases medicine is powerless'. In intensive care, where the concept of futility is often used as a criterion to limit or withdraw life-sustaining treatment, it is helpful to have a working definition on which families and physicians can agree. It is, therefore, reasonable to define futility in such circumstances as the point at which recovery to a quality of life that the patient would find acceptable has passed. The primary insult may be neurological (irreversible brain injury not meeting criteria for brain death), or multi-organ failure that is refractory to treatment.

Death

Whilst most patients prefer to die at home, many spend their final days in hospital. Chapter 34 details the medical, legal and ethical priorities that should guide patient management once the decision to withdraw active treatment has been made (p. 1354). The decision to shift the focus of care to palliation should not change its intensity; it is the over-arching objective that changes. Only interventions that will improve the quality of a patient's remaining life should be offered. In the ICU, it is often appropriate to continue infusions of sedatives and analgesics, as reducing or stopping them may cause unnecessary pain and agitation. Measures that were instituted to prolong life should be withdrawn (usually including cessation of inotropes and extubation) to allow the patient to die peacefully with their family and friends present.

Organ donation

Donation after brain death

The diagnosis of brain death is discussed on page 211. Once brain death has been confirmed, consideration should be given to organ donation, termed 'donation after brain death' (DBD). Time of death is recorded as the time when the first series of brain death tests are undertaken, although the deceased patient continues to be ventilated. The practice of organ donation varies throughout the world but the principles remain the same.

Organ donation specialists are contacted and they begin the process of establishing the suitability of any organs for transplantation and matching potential recipients. Many patients will have expressed their wishes through an organ donor registration scheme but agreement of family and next of kin is a moral (and sometimes legal) prerequisite. Once the organ retrieval theatre team have been assembled and all preliminary tests have been completed, the deceased patient is transferred to the operating theatre and the organs are sequentially removed.

Donation after cardiac death

If a patient does not meet brain death criteria but withdrawal of treatment has been agreed, donation of organs with residual function may be appropriate. This is termed 'donation after cardiac death' (DCD). If the patient dies within a short period following the commencement of 'warm ischaemic time' (the time to asystole following the onset of physiological derangement after the withdrawal of active treatment), then DCD can proceed. The deceased patient is transferred to an operating theatre and the agreed organs (often lungs, liver, kidney and pancreas) are retrieved. As heart valves and corneas can be retrieved later (within a longer time frame), tissue retrieval may occur in the mortuary.

Postmortem examination or autopsy

There are several indications to request a postmortem examination. A coroner (or legal equivalent) may initiate the process if a death is unexpected or violent, or has occurred under suspicious circumstances. The treating physician(s) may request one if they are unable to establish a cause of death or there is agreement that it may yield information of interest to the family or clinical team. The postmortem diagnosis is frequently at odds with the antemortem diagnosis and it is a very useful learning exercise to review the results with all those involved in the patient's care.

Discharge from intensive care

Discharge is appropriate when the original indication for admission has resolved and the patient has sufficient physiological reserve to continue to recover without the facilities of intensive care. Many ICUs and HDUs function as combined units, allowing 'step-down' of patients to HDU care without changing the clinical team involved. Discharge from ICU is stressful for patients and families, and clear communication with the clinical team accepting responsibility is vital. Nursing ratios change from 1 : 1 (one nurse per patient) or 1 : 2 to much lower staffing levels. Discharges from ICU or HDU to standard wards should take place within normal working hours to ensure adequate medical and nursing support and detailed handover. Discharge outside normal working hours is associated with higher ICU re-admission rates and increased mortality. The receiving team should be provided with a written summary, including the information listed in Box 10.49. The ICU team should remain available for advice; many ICU teams provide an outreach service to supply advice and facilitate continuity of care.

Critical care scoring systems

Admission and discharge criteria vary between ICUs, so it is important to define the characteristics of the patients admitted in

10.49 How to write an ICU discharge summary: information to be included

- Summary of diagnosis and progress in intensive care
- Current medications and changes to regular medications with justifications
- Antibiotic regime and suggested review dates
- Results of positive microbiological tests
- Positions of invasive devices and insertion dates
- Escalation plan in the event of deterioration
- Pending investigations and specialty consultations
- If the physiology remains abnormal due to chronic disease, rapid response triggers should be adjusted accordingly

order to assess the effects of the care provided on the outcomes achieved. Two systems are widely used to measure severity of illness (see Box 10.50 for further details):

- *APACHE II*: Acute Physiology Assessment and Chronic Health Evaluation
- *SOFA score*: Sequential Organ Failure Assessment tool.

When combined with the admission diagnosis, scoring systems have been shown to correlate well with the risk of death in hospital. Such outcome predictions are useful at a population level but lack the specificity to be of use in decision-making for individual patients. This is in contrast to well-validated, disease-specific tools, such as the CURB-65 tool for pneumonia, which can be helpful in guiding individual management (see Fig. 17.32, p. 583).

Predicted mortality figures by diagnosis have been calculated from large databases generated from a range of ICUs. These allow a particular unit to evaluate its performance compared to the reference ICUs by calculating standardised mortality ratios (SMRs) for each diagnostic group. A value of unity indicates the same performance as the reference ICUs, while a value below 1 indicates a better than predicted outcome. If a unit has a high SMR in a certain diagnostic category, it should prompt investigation into the management of patients with that diagnosis, in order to identify aspects of care that could be improved.

10.50 Comparison of APACHE II and SOFA scores

APACHE II score

- An assessment of admission characteristics (e.g. age and pre-existing organ dysfunction) and the maximum/minimum values of 12 routine physiological measurements during the first 24 hours of admission (e.g. temperature, blood pressure, GCS) that reflect the physiological impact of the illness
- Composite score out of 71
- Higher scores are given to patients with more serious underlying diagnoses, medical history or physiological instability; higher mortality correlates with higher scores

SOFA score

- A score of 1–4 is allocated to six organ systems (respiratory, cardiovascular, liver, renal, coagulation and neurological) to represent the degree of organ dysfunction, e.g. platelet count $>150\times10^9$/L scores 1 point, $<25\times10^9$/L scores 4 points
- Composite score out of 24
- Higher scores are associated with increased mortality

i Fever

Documentation of fever

- 'Feeling hot' or sweaty does not necessarily signify fever – diagnosed only when a body temperature of over 38.0°C is recorded
- Axillary and aural measurement is less accurate than oral or rectal
- Outpatients may be trained to keep a temperature chart

Rigors

- Shivering (followed by excessive sweating) occurs with a rapid rise in body temperature from any cause

Night sweats

- Associated with particular infections (e.g. TB, infective endocarditis); sweating from any cause is worse at night

Excessive sweating

- Alcohol, anxiety, thyrotoxicosis, diabetes mellitus, acromegaly, lymphoma and excessive environmental heat all cause sweating without temperature elevation

Recurrent fever

- There are various causes, e.g. *Borrelia recurrentis*, bacterial abscess

Accompanying features

- Severe headache and photophobia, although characteristic of meningitis, may accompany other infections.
- Delirium during fever is more common in young children or the elderly
- Myalgia may occur with viral infections, such as influenza, and with sepsis including meningococcal sepsis
- Shock may accompany severe infections and sepsis (p. 196)

i History-taking in suspected infectious disease*

Presenting complaint

- Diverse manifestations of infectious disease make accurate assessment of features and duration critical; e.g. fever and cough lasting 2 days imply an acute respiratory tract infection but suggest TB if they last 2 months

Review of systems

- Must be comprehensive

Past medical history

- Define the 'host' and likelihood of infection(s)
- Include surgical and dental procedures involving prosthetic materials
- Document previous infections

Medication history

- Include non-prescription drugs, use of antimicrobials and immunosuppressants
- Identify medicines that interact with antimicrobials or that may cause fever

Allergy history

- Esp. to antimicrobials, noting allergic manifestation (e.g. rash versus anaphylaxis)

Family and contact history

- Note infections and their duration
- Sensitively explore exposure to key infections, e.g. TB and HIV

Travel history

- Include countries visited and where previously resident (relevant to exposure and likely vaccination history, e.g. likelihood of BCG vaccination in childhood)

Occupation

- e.g. Anthrax in leather tannery workers

Recreational pursuits

- e.g. Leptospirosis in canoeists and windsurfers

Animal exposures

- Include pets, e.g. dogs/hydatid disease

Dietary history

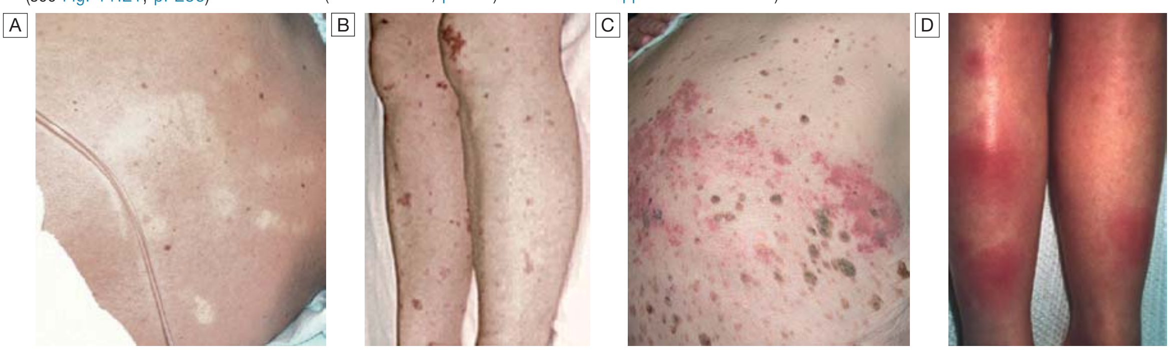
- Consider under-cooked meats, shellfish, unpasteurised dairy products or well water
- Establish who else was exposed, e.g. to food-borne pathogens

History of intravenous drug injection or receipt of blood products

- Risks for blood-borne viruses, e.g. HIV-1, HBV and HCV

Sexual history

- Explore in a confidential manner (Ch. 13); remember that the most common mode of HIV-1 transmission is heterosexual (Ch. 12)



Vaccination history and use of prophylactic medicines

- Consider occupation- or age-related vaccines
- In a traveller or infection-predisposed patient, establish adherence to prophylaxis

*Always consider non-infectious aetiologies in the differential diagnosis. (HBV/HCV = hepatitis B/C virus; HIV-1 = human immunodeficiency virus-1; TB = tuberculosis)

1 Skin lesions in infectious diseases

- Diffuse erythema, e.g. A
- Migrating erythema, e.g. enlarging rash of erythema migrans in Lyme disease (see Fig. 11.21, p. 256)
- Purpuric or petechial rashes, e.g. B
- Macular or papular rashes, e.g. primary infection with HIV (see Box 12.8, p. 312)
- Vesicular or blistering rash, e.g. C
- Erythema multiforme (see Fig. 29.53 and Box 29.32, pp. 1264 and 1265)
- Nodules or plaques, e.g. Kaposi's sarcoma (p. 315)
- Erythema nodosum (D and Box 29.33, p. 1265)

A Streptococcal toxic shock syndrome. B Meningococcal sepsis. C Shingles. D Erythema nodosum.

The principles of infection and its investigation and therapy are described in Chapter 6. This chapter and the following ones on human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) and sexually transmitted infection (STI) describe the approach to patients with potential infectious disease, the individual infections and the resulting syndromes.

Presenting problems in infectious diseases

Infectious diseases present with myriad clinical manifestations. Many of these are described in other chapters or below.

Fever

'Fever' implies an elevated core body temperature of more than 38.0°C (p. 138). Fever is a response to cytokines and acute phase proteins (pp. 65 and 70), and occurs in infections and in non-infectious conditions.

Clinical assessment

The differential diagnosis is very broad so clinical features are used to guide the most appropriate investigations. The systematic approach described on page 216 should be followed. Box 11.1 describes the assessment of elderly patients.

Investigations

If the clinical features do not suggest a specific infection, then initial investigations should include:

- a full blood count (FBC) with differential, including eosinophil count
- urea and electrolytes, liver function tests (LFTs), blood glucose and muscle enzymes
- inflammatory markers, erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP)
- a test for antibodies to HIV-1 (p. 310)
- autoantibodies, including antinuclear antibodies (ANA)
- chest X-ray and electrocardiogram (ECG)
- urinalysis and urine culture
- blood culture (p. 106)
- throat swab for culture or polymerase chain reaction (PCR)

11.1 Fever in old age

- **Temperature measurement**: fever may be missed because oral temperatures are unreliable. Rectal measurement may be needed but core temperature is increasingly measured using eardrum reflectance.
- **Delirium**: common with fever, especially in those with underlying cerebrovascular disease or dementia.
- **Prominent causes of pyrexia of unknown origin**: include tuberculosis and intra-abdominal abscesses, complicated urinary tract infection and infective endocarditis. Non-infective causes include polymyalgia rheumatica/temporal arteritis and tumours. A smaller fraction of cases remain undiagnosed than in young people.
- **Pitfalls in the elderly**: conditions such as stroke or thromboembolic disease can cause fever but every effort must be made to exclude concomitant infection.
- **Common infectious diseases in the very frail** (e.g. nursing home residents): pneumonia, urinary tract infection, soft tissue infection and gastroenteritis.

- other specimens, as indicated by history and examination, e.g. wound swab; sputum culture; stool culture, microscopy for ova and parasites, and *Clostridium difficile* toxin assay
- specific tests and their priority, indicated by geographical location: malaria films on 3 consecutive days or a malaria rapid diagnostic test (antigen detection, p. 276), a test for non-structural protein 1 (NS1) in dengue (antigen detection) and blood cultures for *Salmonella* Typhi, as well as abdominal ultrasound, would be standard initial tests in many regions in Africa, Asia, Oceania, and Central and South America.

Subsequent investigations in patients with HIV-related (p. 313), immune-deficient (p. 223), nosocomial or travel-related (p. 230) pyrexia and in individuals with associated symptoms or signs of involvement of the respiratory, gastrointestinal or neurological systems are described elsewhere.

Management

Fever and its associated systemic symptoms can be treated with paracetamol, and by tepid sponging to cool the skin. Replacement of salt and water is important in patients with drenching sweats. Further management is focused on the underlying cause.

Fever with localising symptoms or signs

In most patients, the site of infection is apparent after clinical evaluation (p. 216), and the likelihood of infection is reinforced by investigation results (e.g. neutrophilia with raised ESR and CRP in bacterial infections). Not all apparently localising symptoms are reliable, however; headache, breathlessness and diarrhoea can occur in sepsis or malaria without localised infection in the central nervous system (CNS), respiratory tract or gastrointestinal tract, and abdominal pain may be a feature of basal pneumonia. Careful interpretation of the clinical features is vital (e.g. severe headache associated with photophobia, rash and neck stiffness suggests meningitis, whereas moderate headache with cough and rhinorrhoea is consistent with a viral upper respiratory tract infection).

Common infections that present with fever are shown in Figure 11.1. Further investigation and management are specific to the cause, but may include empirical antimicrobial therapy (p. 116) pending confirmation of the microbiological diagnosis.

Pyrexia of unknown origin

Pyrexia of unknown origin (PUO) was classically defined as a temperature above 38.0°C on multiple occasions for more than 3 weeks, without diagnosis, despite initial investigation in hospital for 1 week. The definition has been relaxed to allow for investigation over 3 days of inpatient care, three outpatient visits or 1 week of intensive ambulatory investigation. Subsets of PUO are described as HIV-1 related, immune-deficient or nosocomial. Up to one-third of cases of PUO remain undiagnosed.

Clinical assessment

Major causes of PUO are outlined in Box 11.2. Rare causes, such as periodic fever syndromes (p. 81), should be considered in those with a family history. Children and younger adults are more likely to have infectious causes – in particular, viral infections. Older adults are more likely to have certain infectious and non-infectious causes (see Box 11.1). Detailed history and examination should be repeated at regular intervals to detect emerging features (e.g. rashes, signs of infective endocarditis

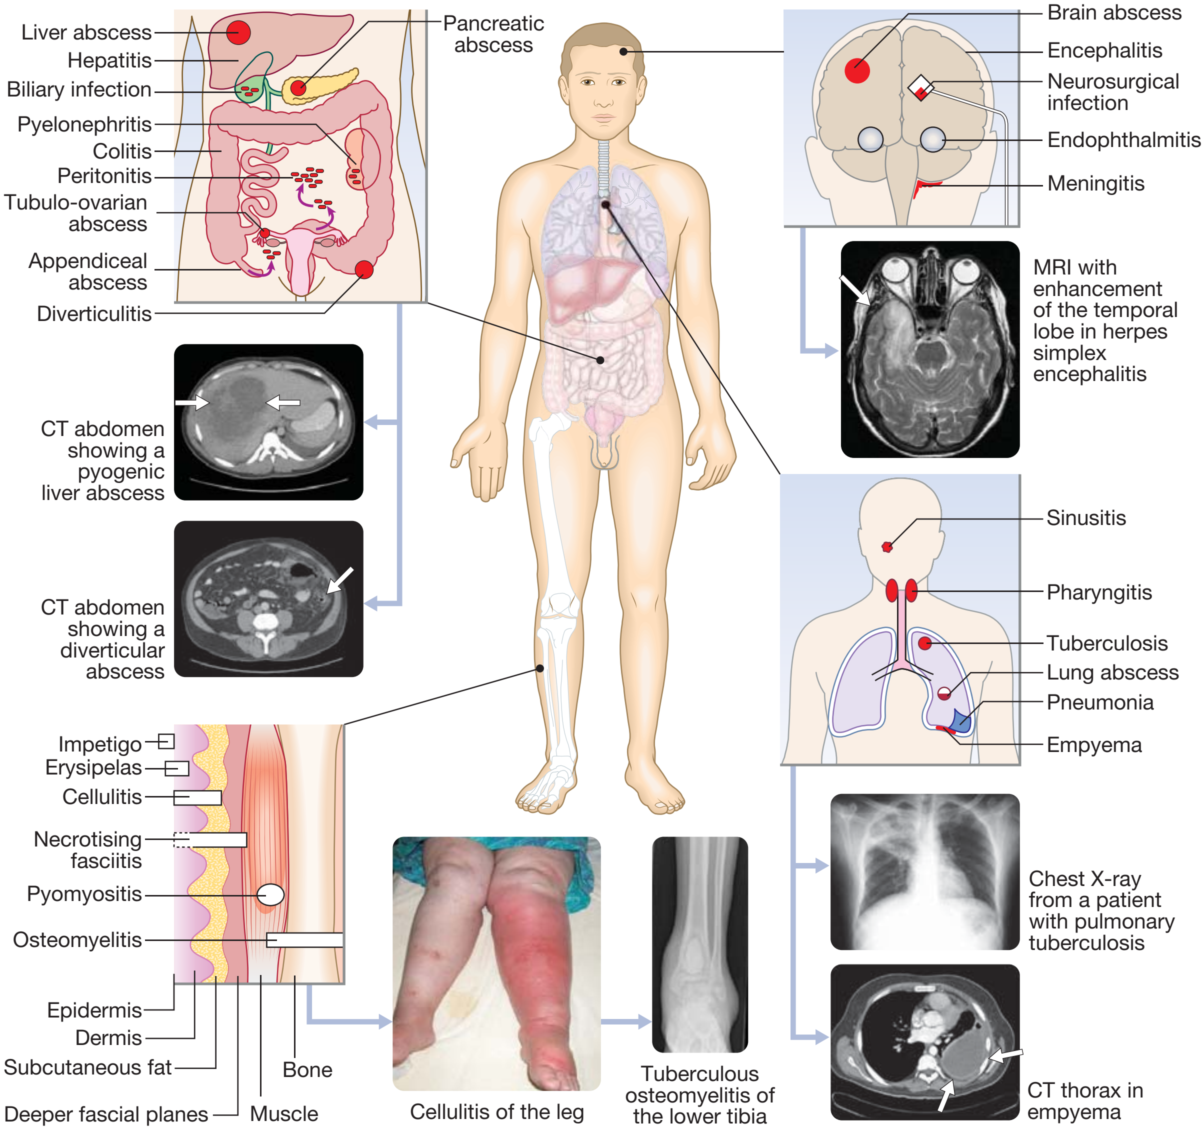


Fig. 11.1 Common infectious syndromes presenting with fever and localised features. Major causes are grouped by approximate anatomical location and include central nervous system infection; respiratory tract infections; abdominal, pelvic or urinary tract infections; and skin and soft tissue infections (SSTIs) or osteomyelitis. For each site of infection, particular syndromes and their common causes are described elsewhere in the book. The causative organisms vary, depending on host factors, which include whether the patient has lived in or visited a tropical country or particular geographical location, has acquired the infection in a health-care environment or is immunocompromised. *Insets (cellulitis of the leg) Courtesy of Dr Ravi Gowda, Royal Hallamshire Hospital, Sheffield; (pulmonary tuberculosis) Courtesy of Dr Ann Chapman, Royal Hallamshire Hospital, Sheffield; (empyema, pyogenic liver abscess, diverticular abscess, tuberculous osteomyelitis) Courtesy of Dr Robert Peck, Royal Hallamshire Hospital, Sheffield.*

(p. 527) or features of vasculitis). In men, the prostate should be considered as a potential source of infection.

Clinicians should be alert to the possibility of factitious fever, in which high temperature recordings are engineered by the patient (Box 11.3).

Investigations

If initial investigation of fever is negative, further microbiological and non-microbiological investigations should be considered (Boxes 11.4 and 11.5). As with initial investigation of fever described above, the selection and prioritisation of tests will be influenced by the geographical location of potential exposure to pathogens (Box 11.4). These will usually include:

- induced sputum or other specimens for mycobacterial stains and culture
- serological tests, including an HIV test, and ferritin estimation
- imaging of the abdomen by ultrasonography or computed tomography (CT)
- echocardiography.

Lesions identified on imaging should usually be biopsied in order to seek evidence of relevant pathogens by culture, histopathology or nucleic acid detection. Particularly in patients who have received prior antimicrobials, 16S rRNA analysis (Box 6.2, p. 101) may aid diagnosis if a microorganism is not cultured. The chance of a successful diagnosis is greatest if procedures for obtaining

11.2 Aetiology of pyrexia of unknown origin (PUO)

Infections (~30%)

Specific locations
- Abscesses: hepatobiliary, diverticular, urinary tract (including prostate), pulmonary, CNS
- Infections of oral cavity (including dental), head and neck (including sinuses)
- Bone and joint infections
- Infective endocarditis*

Specific organisms
- TB (particularly extrapulmonary)*
- HIV-1 infection
- Other viral infections: cytomegalovirus (CMV), Epstein–Barr virus (EBV)
- Fungal infections (e.g. *Aspergillus* spp., *Candida* spp. or dimorphic fungi)
- Infections with fastidious organisms (e.g. *Bartonella* spp., *Tropheryma whipplei*)

Specific patient groups
- Recently spent time in a region with geographically restricted infection:
  Malaria*, dengue, rickettsial infections, *Brucella* spp., amoebic liver abscess, enteric fevers (Africa, Asia, Oceania, Central and South America), *Leishmania* spp. (southern Europe, India, Africa and Latin America), *Burkholderia pseudomallei* (South-east Asia), Middle East respiratory syndrome coronavirus (MERS-CoV; Arabian Peninsula)
- Residence in or travel to a region with endemic infection:
  TB* (Africa, Asia, Central and South America), extensively drug-resistant TB (XDR-TB; South Africa), *Brucella* spp. (Africa, Asia, Central and South America), HIV-1 (Africa, Asia), *Trypanosoma cruzi* (Central and South America)
- Nosocomial infections:
  Pneumonia*, infections related to prosthetic materials and surgical procedures, urinary tract infections, central venous catheter infections
- HIV-positive individuals:
  Acute retroviral syndrome
  AIDS-defining infections (disseminated *Mycobacterium avium* complex (DMAC), *Pneumocystis jirovecii* pneumonia, CMV and others)

Malignancy (~20%)

Haematological malignancy
- Lymphoma*, leukaemia and myeloma

Solid tumours
- Renal, liver, colon, stomach, pancreas

Connective tissue disorders (~15%)

Older adults
- Temporal arteritis/polymyalgia rheumatica*

Younger adults
- Still's disease (juvenile rheumatoid arthritis)*
- Systemic lupus erythematosus (SLE)
- Vasculitic disorders, including polyarteritis nodosa, rheumatoid disease with vasculitis and granulomatosis with polyangiitis (formerly known as Wegener's granulomatosis)
- Polymyositis
- Behçet's disease
- Rheumatic fever (in regions where still endemic, e.g. Asia, Oceania and parts of Africa)

Miscellaneous (~20%)

Cardiovascular
- Atrial myxoma, aortitis, aortic dissection

Respiratory
- Sarcoidosis, pulmonary embolism and other thromboembolic disease, extrinsic allergic alveolitis

Gastrointestinal
- Inflammatory bowel disease, granulomatous hepatitis, alcoholic liver disease, pancreatitis

Endocrine/metabolic
- Thyrotoxicosis, thyroiditis, hypothalamic lesions, phaeochromocytoma, adrenal insufficiency, hypertriglyceridaemia

Haematological
- Haemolytic anaemia, paroxysmal nocturnal haemoglobinuria, thrombotic thrombocytopenic purpura, myeloproliferative disorders, Castleman's disease, graft-versus-host disease (after allogeneic haematopoietic stem cell transplantation)

Inherited
- Familial Mediterranean fever and periodic fever syndromes

Drug reactions*
- e.g. Antibiotic fever, drug hypersensitivity reactions etc.

Factitious fever

Idiopathic (~15%)

*Most common causes within each group.

11.3 Clues to the diagnosis of factitious fever

- A patient who looks well
- Bizarre temperature chart with absence of diurnal variation and/or temperature-related changes in pulse rate
- Temperature >41°C
- Absence of sweating during defervescence
- Normal erythrocyte sedimentation rate and C-reactive protein despite high fever
- Evidence of self-injection or self-harm
- Normal temperature during supervised (observed) measurement
- Infection with multiple commensal organisms (e.g. enteric or mouth flora)

and transporting the correct samples in the appropriate media are carefully planned between the clinical team, the radiologist or surgeon performing the procedure, and the local microbiologist and histopathologist. Positron emission tomography (PET) scans may aid diagnosis of vasculitis or help selection of biopsy sites. Liver biopsy may be justified – for example, to identify idiopathic granulomatous hepatitis – if there are biochemical or radiological abnormalities. Bone marrow biopsies have a diagnostic yield of up to 15%, most often revealing haematological malignancy, myelodysplasia or tuberculosis, and also identifying brucellosis, typhoid fever or visceral leishmaniasis. Bone marrow should be sent for culture, as well as microscopy. Laparoscopy is occasionally undertaken with biopsy of abnormal tissues. Splenic aspiration in specialist centres is the diagnostic test of choice for

11.4 Microbiological investigation of pyrexia of unknown origin[1]

Location-independent investigations

Microscopy
- Blood for atypical lymphocytes (EBV, CMV, HIV-1, hepatitis viruses or *Toxoplasma gondii*)
- Respiratory samples for mycobacteria and fungi
- Stool for ova, cysts and parasites
- Biopsy for light microscopy (bacteria, mycobacteria, fungi) and/or electron microscopy (viruses, protozoa (e.g. microsporidia) and other fastidious organisms (e.g. *Tropheryma whipplei*))
- Urine for white or red blood cells and mycobacteria (early morning urine ×3)

Culture
- Aspirates and biopsies (e.g. joint, deep abscess, debrided tissues)
- Blood, including prolonged culture and special media conditions
- Sputum for mycobacteria
- CSF
- Gastric aspirate for mycobacteria
- Stool
- Swabs
- Urine ± prostatic massage in older men

Antigen detection
- Blood, e.g. HIV p24 antigen, cryptococcal antigen, *Aspergillus* galactomannan ELISA and for *Aspergillus* and other causes of invasive, fungal infection (1,3)-β-D-glucan
- CSF for cryptococcal antigen
- Bronchoalveolar lavage fluid for *Aspergillus* galactomannan
- Nasopharyngeal aspirate/throat swab for respiratory viruses, e.g. IAV or RSV
- Urine, e.g. for *Legionella* antigen

Nucleic acid detection
- Blood for *Bartonella* spp. and viruses
- CSF for viruses and key bacteria (meningococcus, pneumococcus, *Listeria monocytogenes*)
- Nasopharyngeal aspirate/throat swab for respiratory viruses
- Sputum for *Mycobacterium tuberculosis* (MTB) and rifampicin (RIF) resistance with geneXpert MTB/RIF cartridge-based nucleic acid amplification test
- Bronchoalveolar lavage fluid, e.g. for respiratory viruses
- Tissue specimens, e.g. for *T. whipplei*
- Urine, e.g. for *Chlamydia trachomatis*, *Neisseria gonorrhoeae*
- Stool, e.g. for norovirus, rotavirus

Immunological tests
- Serology (antibody detection) for viruses, including HIV-1, and some bacteria
- Interferon-gamma release assay for diagnosis of exposure to tuberculosis (but note this will not distinguish latent from active disease and can only be used to trigger further investigations of active disease)

Geographically restricted tests[2]

Microscopy
- Blood for trypanosomiasis, malaria and *Borrelia* spp.
- Stool for geographically restricted ova, cysts and parasites
- Biopsy for light microscopy (dimorphic fungi, *Leishmania* spp. and other parasites)
- Urine for red blood cells and schistosome ova

Antigen detection
- Blood, e.g. dengue virus NS1 antigen, *Histoplasma* antigen (restricted availability) and malaria antigen (e.g. HRP-2 for *Plasmodium falciparum* or parasite-specific LDH for *P. falciparum* and *P. vivax*)

Nucleic acid detection
- Blood for causes of viral haemorrhagic fever
- CSF for geographically restricted viruses, e.g. Japanese encephalitis virus
- Nasopharyngeal aspirate/throat swab or bronchoalveolar lavage fluid for geographically restricted respiratory viruses, e.g. MERS-CoV

Immunological tests
- Serology (antibody detection) for viruses, dimorphic fungi and protozoa

[1]This list does not apply to every patient with a pyrexia of unknown origin. Appropriate tests should be selected in a stepwise manner, according to specific predisposing factors, epidemiological exposures and local availability, and should be discussed with a microbiologist. [2]Addition of these tests should be guided by the location of presentation or travel history.
(CMV = cytomegalovirus; CSF = cerebrospinal fluid; EBV = Epstein–Barr virus; ELISA = enzyme-linked immunosorbent assay; HIV-1 = human immunodeficiency virus-1; HRP-2 = histidine-rich protein 2; IAV = influenza A virus; LDH = lactate dehydrogenase; MERS-CoV = Middle East respiratory syndrome coronavirus; NS1 = non-structural 1; RSV = respiratory syncytial virus)

11.5 Additional investigations in PUO

- Serological tests for connective tissue disorders:
  - Autoantibody screen
  - Complement levels
  - Immunoglobulins
  - Cryoglobulins
- Ferritin
- Echocardiography
- Ultrasound of abdomen
- CT/MRI of thorax, abdomen and/or brain
- Imaging of the skeletal system:
  - Plain X-rays
  - CT/MRI spine
  - Isotope bone scan
- Labelled white cell scan
- Positron emission tomography (PET)/single-photon emission computed tomography (SPECT)
- Biopsy:
  - Bronchoscopy and lavage ± transbronchial biopsy
  - Lymph node aspirate or biopsy
  - Biopsy of radiological lesion
  - Biopsy of liver
  - Bone marrow aspirate and biopsy
  - Lumbar puncture
  - Laparoscopy and biopsy
  - Temporal artery biopsy

suspected visceral leishmaniasis. Temporal artery biopsy should be considered in patients over the age of 50 years, even in the absence of physical signs or a raised ESR. 'Blind' biopsy of other structures in the absence of localising signs or laboratory or radiology results is unhelpful.

Prognosis

No cause is found in approximately 10% of PUO cases, but as long as there is no significant weight loss or signs of another disease, the long-term mortality is low.

Fever in the injection drug-user

Intravenous injection of recreational drugs is widespread in many parts of the world (p. 1184). Infective organisms are introduced by non-sterile (often shared) injection equipment (Fig. 11.2). The risks increase with prolonged drug use and injection into large veins of the groin and neck necessitated by progressive thrombosis of superficial peripheral veins. The most common causes of fever are soft tissue or respiratory infections.

Clinical assessment

The history should address the following risk factors:

- *Site of injection.* Femoral vein injection is associated with vascular complications such as deep venous thrombosis (50% of which are septic) and accidental arterial injection with false aneurysm formation or a compartment syndrome due to swelling within the fascial sheath. Local complications include ilio-psoas abscess, and septic arthritis of the hip joint or sacroiliac joint. Injection of the jugular vein can be associated with cerebrovascular complications. Subcutaneous and intramuscular injection has been related to infection by clostridial species, the spores of which contaminate heroin. *Clostridium novyi*

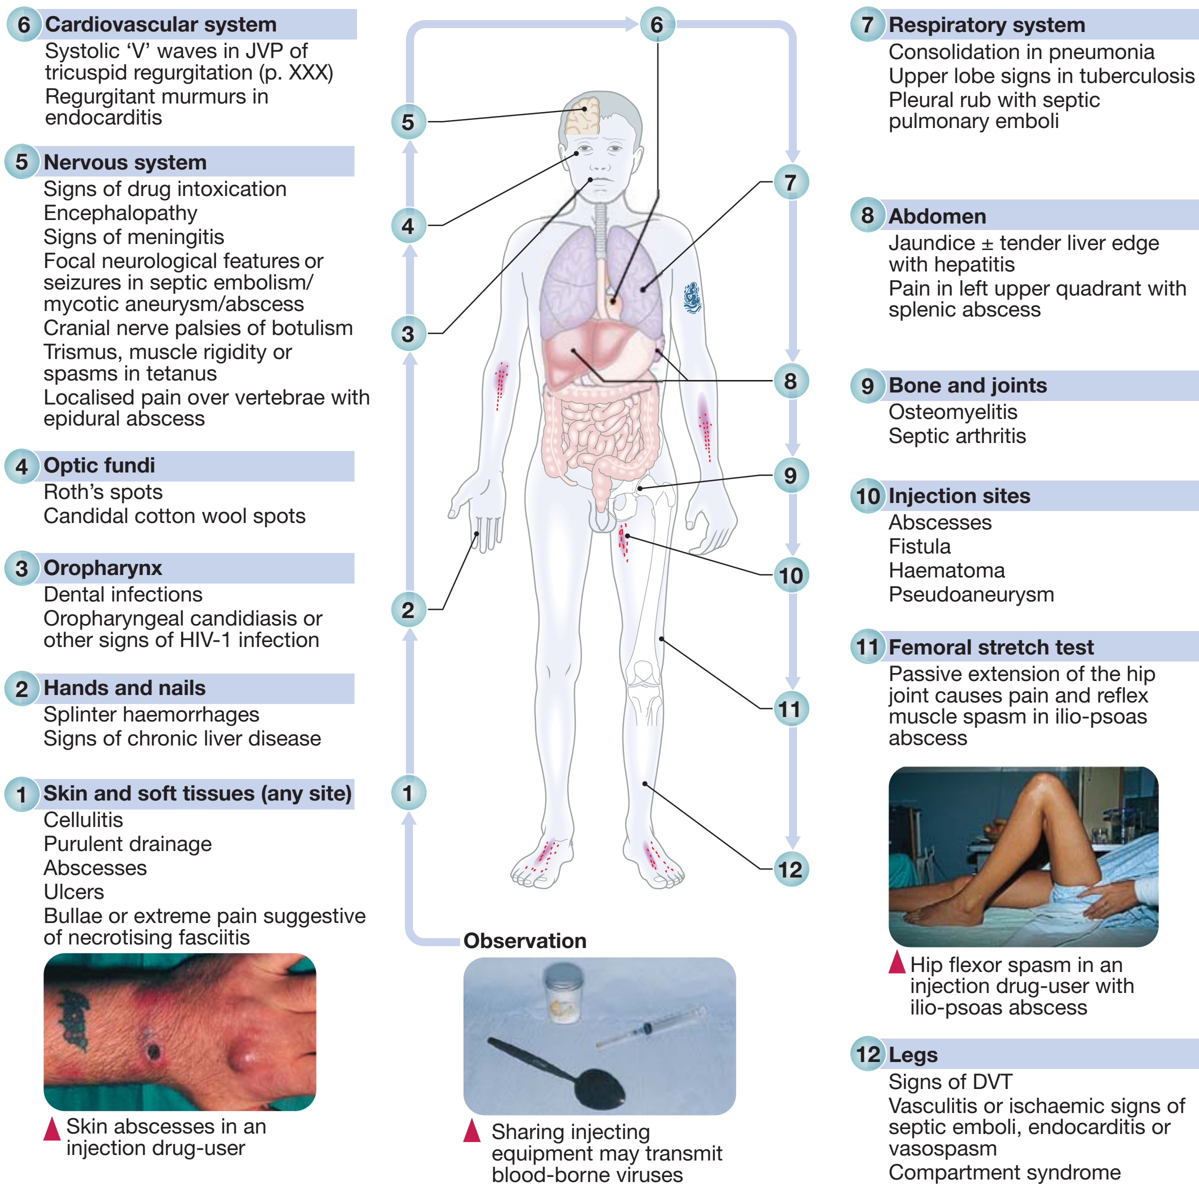

Fig. 11.2 Fever in the injection drug-user: key features of clinical examination. Full examination (p. 216) is required but features most common amongst injection drug-users are shown here. (DVT = deep venous thrombosis; JVP = jugular venous pulse)

causes a local lesion with significant toxin production, leading to shock and multi-organ failure. Tetanus, wound botulism, anthrax and gas gangrene also occur.
- *Technical details of injection.* Sharing of needles and other injecting paraphernalia (including spoons and filters) increases the risk of blood-borne virus infection (e.g. HIV-1, hepatitis B or C virus). Some users lubricate their needles by licking them prior to injection, thus introducing mouth organisms (e.g. anaerobic streptococci, *Fusobacterium* spp. and *Prevotella* spp.). Contamination of commercially available lemon juice, used to dissolve heroin before injection, has been associated with blood-stream infection with *Candida* spp.
- *Substances injected.* Injection of cocaine is associated with a variety of vascular complications. Certain formulations of heroin have been linked with particular infections, e.g. wound botulism with black tar heroin. Drugs are often mixed with other substances, e.g. talc.
- *Blood-borne virus status.* Results of previous HIV-1 and hepatitis virus tests or vaccinations for hepatitis viruses should be recorded.
- *Surreptitious use of antimicrobials.* Addicts may use antimicrobials to self-treat infections, masking initial blood culture results.

Key findings on clinical examination are shown in Figure 11.2. It can be difficult to distinguish the effects of infection from the effects of drugs or drug withdrawal (excitement, tachycardia, sweating, marked myalgia, delirium). Stupor and delirium may result from drug administration but may also indicate meningitis or encephalitis. Non-infected venous thromboembolism is also common in this group.

Investigations

The initial investigations are as for any fever (see above), including a chest X-ray and blood cultures. Since blood sampling may be difficult, contamination is often a problem. Echocardiography to detect infective endocarditis should be performed in all injection drug-users with bacteraemia due to *Staphylococcus aureus* or other organisms associated with endocarditis (Fig. 11.3A); thromboembolic phenomena; or a new or previously undocumented murmur. Endovascular infection should also be suspected if lung abscesses or pneumatoceles are detected radiologically. Infected thrombus at injection sites, such as the groin, is common, and may lead to abscess formation. Additional imaging should be focused on sites of injection or of localising symptoms and signs (Fig. 11.3B). Any pathological fluid collections should be sampled.

Urinary toxicology tests may suggest a non-infectious cause of the presenting complaint. While being investigated, all injection drug-users should be offered testing for infection with hepatitis B and C virus and HIV-1.

Injection drug-users may have more than one infection. Skin and soft tissue infections are most often due to *Staph. aureus* or streptococci, and sometimes to *Clostridium* spp. or anaerobes. Pulmonary infections are most often due to the common pathogens causing community-acquired pneumonia, tuberculosis or septic emboli (Fig. 11.3C). Endocarditis with septic emboli commonly involves *Staph. aureus* and viridans streptococci, but *Pseudomonas aeruginosa* and *Candida* spp. are also encountered.

Management

Empirical therapy of fever in the injection drug-user includes an antistaphylococcal penicillin (e.g. flucloxacillin) or, if meticillin-resistant *Staph. aureus* (MRSA) is prevalent in the community, a

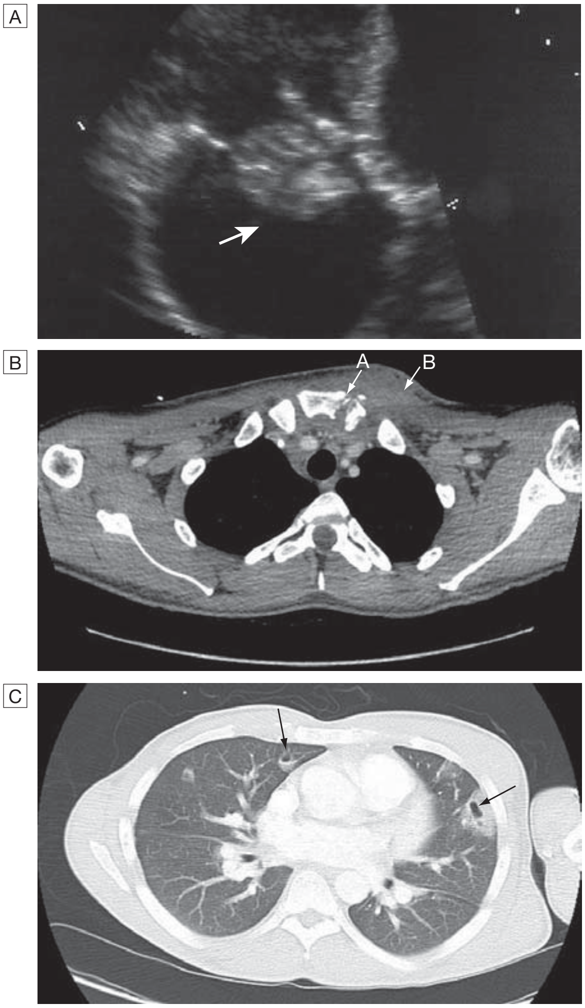

Fig. 11.3 Causes of fever in injection drug-users. **A** Endocarditis: large vegetation on the tricuspid valve (arrow). **B** Septic arthritis of the left sternoclavicular joint (arrow A) (note the erosion of the bony surfaces at the sternoclavicular joint) with overlying soft tissue collection (arrow B). **C** Tricuspid valve endocarditis caused by *Staphylococcus aureus*. Thoracic CT scan shows multiple embolic lesions with cavitation (arrows). The patient presented with haemoptysis. *C, Courtesy of Dr Julia Greig, Royal Hallamshire Hospital, Sheffield.*

glycopeptide (e.g. vancomycin) or lipopeptide (e.g.daptomycin). Once microbiological results are available, therapy can be narrowed to focus on the microorganism identified. In injection drug-users, meticillin-sensitive *Staph. aureus* is customarily treated with high-dose intravenous flucloxacillin, with shorter durations for uncomplicated right-sided endocarditis. Right-sided endocarditis caused by MRSA is usually treated with 4 weeks of vancomycin plus gentamicin for the first week. Specialist advice should be sought.

For localised infections of the skin and soft tissues, oral therapy with agents active against staphylococci, streptococci and anaerobes is appropriate (e.g. flucloxacillin plus co-amoxiclav or clindamycin). Non-adherence to prescribed antimicrobial regimens leads to a high rate of complications.

Fever in the immunocompromised host

Immunocompromised hosts include those with congenital immunodeficiency (p. 77), HIV infection (Ch. 12) and iatrogenic

immunosuppression induced by chemotherapy (p. 1330), transplantation (p. 88) or immunosuppressant medicines, including high-dose glucocorticoids. Metabolic abnormalities, such as under-nutrition or hyperglycaemia, may also contribute. Multiple elements of the immune system are potentially compromised. A patient may have impaired neutrophil function from chemotherapy, impaired T-cell and/or B-cell responses due to underlying malignancy, T-cell and phagocytosis defects due to glucocorticoids, mucositis from chemotherapy and an impaired skin barrier due to insertion of a central venous catheter.

Fever may result from infectious or non-infectious causes, including drugs, vasculitis, neoplasm, lymphoproliferative disease, graft-versus-host disease (in recipients of haematopoietic stem cell transplants (HSCT); p. 936), organising pneumonitis or Sweet's syndrome (reddish nodules or plaques with fever and leucocytosis, in association with haematological malignancy).

Clinical assessment

The following should be addressed in the history:

- Identification of the immunosuppressant factors and nature of the immune defect.
- Any past infections and their treatment. Infections may recur and antimicrobial resistance may have been acquired in response to prior therapy.
- Exposure to infections, including opportunistic infections that would not cause disease in an immunocompetent host.
- Prophylactic medicines and vaccinations administered.

Examination should include inspection of the normal physical barriers provided by skin and mucosal surfaces and, in particular, central venous catheters, the mouth, sinuses, ears and perianal area (digital rectal examination should be avoided). Disseminated infections can manifest as cutaneous lesions. The areas around fingernails and toenails should also be inspected closely.

Investigations

Initial screening tests are as described above (p. 218). Immunocompromised hosts often have decreased inflammatory responses leading to attenuation of physical signs, such as neck stiffness with meningitis, radiological features and laboratory findings, such as leucocytosis. Chest CT scan should be considered in addition to chest X-ray when respiratory symptoms occur. Abdominal imaging may also be warranted, particularly if there is right lower quadrant pain, which may indicate typhlitis (inflammation of the caecum) in neutropenic patients. Blood cultures from a central venous catheter, urine cultures, and stool cultures if diarrhoea is present are also recommended.

Nasopharyngeal aspirates are sometimes diagnostic, as immunocompromised hosts may shed respiratory viruses for prolonged periods. Skin lesions should be biopsied if nodules are present, and investigation should include fungal stains. Useful molecular techniques include PCR for cytomegalovirus (CMV) and *Aspergillus* spp. DNA, and antigen assays (e.g. cryptococcal antigen (CrAg) for *Cryptococcus neoformans*, galactomannan for *Aspergillus* spp. in blood, and (1,3)-β-D-glucan for *Aspergillus* spp. and other causes of invasive fungal infection (though this will not identify mucoraceous moulds) or *Legionella pneumophila* type 1 in urine). Antibody detection is rarely useful in immunocompromised patients. Patients with respiratory signs or symptoms should be considered for bronchoalveolar lavage to detect *Pneumocystis jirovecii*, other fungi, bacteria and viruses.

Neutropenic fever

Neutropenic fever is defined as a neutrophil count of less than 0.5×10^9/L (p. 925) and a single axillary temperature above 38.5°C or three recordings above 38.0°C over a 12-hour period, although the infection risk increases progressively as the neutrophil count drops below 1.0×10^9/L. Patients with neutropenia are particularly prone to bacterial and fungal infection. Gram-positive organisms are the most common pathogens, particularly in association with in-dwelling catheters.

Empirical broad-spectrum antimicrobial therapy is commenced as soon as neutropenic fever occurs and cultures have been obtained. The most common regimens for neutropenic sepsis are broad-spectrum penicillins, such as piperacillin–tazobactam IV. The routine addition of aminoglycosides to these agents is not supported by trial data. If fever has not resolved after 3–5 days, empirical antifungal therapy (e.g. caspofungin) is added (p. 125). An alternative antifungal strategy is to use azole prophylaxis in high-risk patients and markers of early fungal infection, such as galactomannan and/or fungal PCR, to guide initiation of antifungal treatment (a 'pre-emptive approach').

Post-transplantation fever

Fever in transplant recipients may be due to infection, episodes of graft rejection in solid organ transplant recipients, or graft-versus-host disease following HSCT (p. 936).

Infections in solid organ transplant recipients are grouped according to the time of onset (Box 11.6). Those in the first month are mostly related to the underlying condition or surgical complications. Those occurring 1–6 months after transplantation are characteristic of impaired T-cell function. Risk factors for CMV infection have been identified; patients commonly receive either prophylaxis or intensive monitoring involving regular testing for CMV DNA by PCR and early initiation of anti-CMV therapy using intravenous ganciclovir or oral valganciclovir if tests become positive.

Following HSCT, infections in the first 4 weeks are more common in patients receiving a myeloablative-conditioning

i 11.6 Infections in transplant recipients

Time post transplantation	Infections
Solid organ transplant recipients	
0–1 month	Bacterial or fungal infections related to the underlying condition or surgical complications
1–6 months	CMV, other opportunistic infections (e.g. *Pneumocystis jirovecii* pneumonia)
>6 months	Bacterial pneumonia, other bacterial community-acquired infections, shingles, cryptococcal infection, PTLD
Myeloablative haematopoietic stem cell transplant recipients	
Pre-engraftment (typically 0–4 weeks)	Bacterial and fungal infections, respiratory viruses or HSV reactivation
Post-engraftment:	
Early (<100 days)	CMV, *Pneumocystis jirovecii* pneumonia, moulds or other opportunistic infections
Late (>100 days)	Community-acquired bacterial infections, shingles, CMV, PTLD

(CMV = cytomegalovirus; HSV = herpes simplex virus; PTLD = post-transplant lymphoproliferative disorder)

regimen (Box 11.6). Later infections are more common if an allogeneic procedure is performed.

Post-transplant lymphoproliferative disorder (PTLD) is an Epstein–Barr virus (EBV)-associated lymphoma that can complicate transplantation, particularly when primary EBV infection occurs after transplantation.

Positive blood culture

Blood-stream infection (BSI) is a frequent presentation of infection. This can be community-acquired or hospital-acquired ('nosocomial'). The most common causes are shown in Box 11.7. In immunocompromised hosts, a wider range of microorganisms may be isolated, e.g. fungi in neutropenic hosts.

Primary BSI describes the situation in which there is no known extravascular source of infection (e.g. pneumonia or urinary tract infection), and is more common in *Staph. aureus* BSI. In community-acquired *Staph. aureus* bacteraemia, 20–30% of cases are associated with infectious endocarditis and up to 10% are due to osteomyelitis. Peripheral and central venous catheters are an important source of nosocomial BSI.

BSI has an associated mortality of 15–40%, depending on the setting, host and microbial factors.

Clinical assessment

The history should determine the setting in which BSI has occurred. Host factors predisposing to infection include skin disease, diabetes mellitus, injection drug use, the presence of a central venous, urinary or haemodialysis catheter, and surgical procedures, especially those involving the implantation of prosthetic materials (in particular, endovascular prostheses).

Physical examination should focus on signs of endocarditis (p. 527), evidence of bone or joint infection (tenderness or restriction of movement), and abdominal or flank tenderness. Central venous catheters should be examined for erythema or purulence at the exit site. Particularly in cases with *Candida* spp. infection or suspected infectious endocarditis, fundoscopy after pupil dilatation should be performed.

Investigations

Positive blood cultures may be caused by contaminants. When isolated from only one bottle, or from all bottles from one venesection, coagulase-negative staphylococci often represent contamination. Repeated isolation of this organism, however, should raise suspicion of infective endocarditis or, in a patient with any form of prosthetic material, prosthesis infection. Viridans streptococci occasionally cause transient non-significant bacteraemia or blood culture contamination but, in view of their association with infective endocarditis, significant infection must always be excluded. *Bacillus* spp. ('aerobic spore bearers') and *Clostridium* spp. often represent incidental transient bacteraemia or contamination, but certain species (e.g. *C. septicum*) are more likely to be genuine pathogens.

Further investigations are influenced by the causative organism and setting. Initial screening tests are similar to those for fever (p. 218) and should include chest X-ray, urine culture and, in many cases, ultrasound or other imaging of the abdomen. Imaging should also include any areas of bone or joint pain and any prosthetic material, e.g. a prosthetic joint or an aortic graft.

Echocardiography should be considered for those patients with BSI who have valvular heart disease or clinical features of endocarditis (p. 527), those whose cultures reveal an organism that is a common cause of endocarditis (e.g. *Staph. aureus*, viridans streptococci or enterococci), those in whom multiple blood cultures are positive for the same organism, and those with a rapid positive result on culture. The sensitivities of transthoracic echocardiography (TTE) and transoesophageal echocardiography (TOE) for the detection of vegetations are 50–90% and over 95%, respectively. Therefore, if TTE is negative, TOE should be performed.

Certain rare causes of BSI have specific associations that warrant further investigation. Endocarditis caused by *Streptococcus gallolyticus* subsp. *gallolyticus* (formerly *Strep. bovis* biotype I) and BSI with *C. septicum* are both associated with colonic carcinoma and their isolation is an indication for colonoscopy.

Management

BSI requires antimicrobial therapy and attention to the source of infection, including surgical drainage if appropriate. Two weeks of therapy may be sufficient for *Staph. aureus* BSI from central and peripheral venous catheter infections when the source is identified and removed, for uncomplicated skin and soft tissue infections, and for uncomplicated right-sided infective endocarditis. Other *Staph. aureus* BSIs are usually treated for 4–6 weeks.

i 11.7 Common causes of blood-stream infection

Community-acquired	
• *Escherichia coli*	• *Streptococcus pneumoniae*
• *Staphylococcus aureus*, including MRSA	• Other streptococci
Nosocomial	
• *Staph. aureus*, including MRSA	• Enterococci, including VRE
• Coagulase-negative staphylococci	• Gram-negative bacteria
	• *Candida* spp.

(MRSA = meticillin-resistant *Staphylococcus aureus*; VRE = vancomycin-resistant enterococci)

Central venous catheter infections

Infections of central venous catheters typically involve the catheter lumen and are associated with fever, positive blood cultures and, in some cases, signs of purulence or exudate at the site of insertion. Infection is more common in temporary catheters inserted into the groin or jugular vein than in those in the subclavian vein. Tunnelled catheters, e.g. Hickman catheters, may also develop tunnel site infections.

Staphylococci account for 70–90% of catheter infections, with coagulase-negative staphylococci more common than *Staph. aureus*. Other causes include enterococci and Gram-negative bacilli. Unusual Gram-negative organisms, such as *Citrobacter freundii* and *Pseudomonas fluorescens*, raise the possibility of non-sterile infusion equipment or infusate. *Candida* spp. are a common cause of line infections, particularly in association with total parenteral nutrition. Non-tuberculous mycobacteria may cause tunnel infections.

Investigations and management

In bacteraemic patients with fever and no other obvious source of infection, a catheter infection is likely. Local evidence of erythema, purulence or thrombophlebitis supports the diagnosis. However, microbiological confirmation is essential (p. 106). Catheter-related infection is suggested by higher colony counts

or shorter time to positivity in blood cultures obtained through the catheter than in peripheral blood cultures. If the line is removed, a semi-quantitative culture of the tip may confirm the presence of 15 or more colony-forming units, but this is retrospective and does not detect luminal infection.

For coagulase-negative staphylococcal line infections, the options are to remove the line and provide 5–7 days' therapy or, particularly in the case of tunnelled catheters, to treat empirically with a glycopeptide antibiotic, e.g. vancomycin, with or without the use of antibiotic-containing lock therapy to the catheter for approximately 14 days. For *Staph. aureus* infection, the chance of curing an infection with the catheter in situ is low and the risks from infection are high. Therefore, unless the risks of catheter removal outweigh the benefits, treatment involves catheter removal, followed by 14 days of antimicrobial therapy; the same applies to infections with *Pseudomonas aeruginosa*, *Candida* spp., atypical mycobacteria or *Bacillus* spp. Infections complicated by endocarditis, thrombophlebitis, metastatic infection or tunnel infection also require catheter removal.

Infection prevention is a key component of the management of vascular catheters. Measures include strict attention to hand hygiene, optimal siting, full aseptic technique on insertion and subsequent interventions, skin antisepsis with chlorhexidine and isopropyl alcohol, daily assessment of catheter sites (e.g. with visual infusion phlebitis (VIP) score; see Box 11.37, p. 251), and daily consideration of the continuing requirement for catheterisation. The use of catheters impregnated with antimicrobials, such as chlorhexidine or silver, is advocated in some settings.

Sepsis

Sepsis is discussed on page 196 and there are many causes (Box 11.8). The results of blood cultures and pre-existing host factors guide initial investigations. Patients who are immunocompromised may have a broader range of causal pathogens that may be harder to culture, including mycobacteria and fungi. In many regions, malaria and dengue must also be excluded.

Severe skin and soft tissue infections

Skin and soft tissue infections (SSTIs) are an important cause of sepsis. Cases can be classified as in Box 11.9, according to the clinical features and microbiological findings. In some cases, severe systemic features may be out of keeping with mild local features.

Necrotising fasciitis

In necrotising fasciitis, cutaneous erythema and oedema progress to bullae or areas of necrosis. Unlike in cellulitis, pain may be disproportionately intense in relation to the visible cutaneous features or may spread beyond the zone of erythema. The infection spreads quickly along the fascial plane. Type 1 necrotising fasciitis is a mixed infection with Gram-negative bacteria and anaerobes, often seen post-operatively in diabetic or immunocompromised hosts. Subcutaneous gas may be present. Type 2 necrotising fasciitis is caused by group A or other streptococci. Approximately 60% of cases are associated with streptococcal toxic shock syndrome (p. 253). Type 3 infection

11.8 Causes of sepsis

Infection	Setting
Bacterial	
Staphylococcus aureus, coagulase-negative staphylococci	Bacteraemia may be associated with endocarditis, intravascular cannula infection, or skin or bone foci
Streptococcus pneumoniae	Invasive pneumococcal disease, usually with pneumonia or meningitis; asplenia
Other streptococci	Invasive streptococcal disease, especially necrotising fasciitis Viridans streptococci in neutropenic host with severe mucositis
Staphylococcal or streptococcal toxic shock syndrome	Toxin-mediated, blood cultures negative; clues include erythrodermic rash and epidemiological setting
Enterococci	Most often with abdominal focus
Neisseria meningitidis	Sepsis in children or young adults with petechial rash and/or meningitis
Escherichia coli, other Gram-negative bacteria	Urinary or biliary tract infection, or other abdominal infections
Pseudomonas aeruginosa, multidrug-resistant Gram-negative bacteraemia	Nosocomial infection
Salmonella Typhi or Paratyphi	In countries with a high incidence of enteric fever
Yersinia pestis	In plague
Burkholderia pseudomallei	Endemic in areas of Thailand; more likely to involve patients with diabetes mellitus or immunocompromised
Capnocytophaga canimorsus	Associated with dog bites and asplenic individuals
Clostridium difficile	Severe colitis, particularly in the elderly
Polymicrobial infection with Gram-negatives and anaerobes	Bowel perforation, bowel ischaemia
Mycobacterium tuberculosis, *M. avium* complex (MAC)	HIV-positive or immunocompromised with miliary tuberculosis or disseminated MAC
Fungal	
Candida spp.	Line infection or post-operative complication, nosocomial or immunocompromised host
Histoplasma capsulatum, other dimorphic fungi	Immunocompromised host
Parasitic	
Falciparum malaria	Malaria with high-level parasitaemia and multi-organ failure or as a complication of bacterial superinfection
Babesia microti	Asplenic individual
Strongyloides stercoralis hyperinfection syndrome	Gram-negative infection complicating *Strongyloides* infection in immunocompromised host

i 11.9 Severe necrotising soft tissue infections

- Necrotising fasciitis (primarily confined to subcutaneous fascia and fat)
- Clostridial anaerobic cellulitis (confined to skin and subcutaneous tissue)
- Non-clostridial anaerobic cellulitis
- Progressive bacterial synergistic gangrene (*Staphylococcus aureus* + micro-aerophilic streptococcus) ('Meleney's gangrene', primarily confined to skin)
- Pyomyositis (discrete abscesses within individual muscle groups)
- Clostridial myonecrosis (gas gangrene)
- Anaerobic streptococcal myonecrosis (non-clostridial infection mimicking gas gangrene)
- Group A streptococcal necrotising myositis

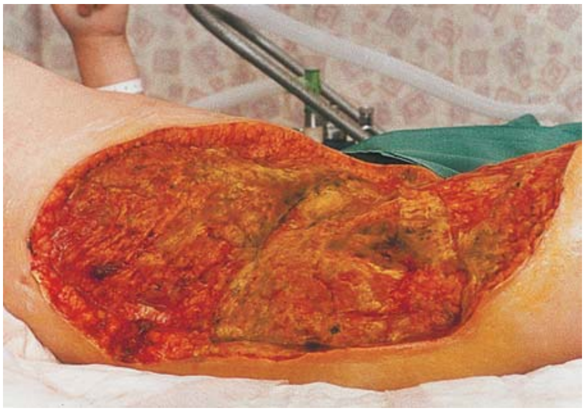

Fig. 11.4 Excision following necrotising fasciitis in an injection drug-user.

involves organisms such as *Aeromonas hydrophila* and *Vibrio vulnificus*, which is found in tropical to subtropical regions and is associated with marine exposure. Type 4 is caused by fungi such as mucoraceous moulds and may also vary geographically in incidence with recent reports of increased cases in India and other regions.

Necrotising fasciitis is a medical emergency, requiring immediate surgical débridement with inspection of the involved muscle groups, in addition to antimicrobial therapy (Fig. 11.4). Empirical treatment is with broad-spectrum agents (e.g. piperacillin–tazobactam plus clindamycin; meropenem with clindamycin). Ceftazidime or ciprofloxacin with doxycycline may be used where marine exposure is a factor, and antifungals for suspected fungal necrotising fasciitis, but it is important to combine these with effective coverage against streptococcal infection. MRSA-associated necrotising fasciitis has emerged in some regions and in these places appropriate therapy for MRSA, such as a glycopeptide or linezolid, should be added to the empirical regimen until microbiological results allow narrowing of the antimicrobial spectrum. Hyperbaric oxygen therapy may be considered for polymicrobial infection. Group A streptococcal infection is treated with benzylpenicillin plus clindamycin, and often immunoglobulin, though to date clinical trials have not provided clear evidence of the benefit of immunoglobulin.

Gas gangrene

Although *Clostridium* spp. may colonise or contaminate wounds, no action is required unless there is evidence of spreading infection. Infection may be limited to tissue that is already damaged (anaerobic cellulitis) or may involve healthy muscle (gas gangrene).

In anaerobic cellulitis, usually due to *C. perfringens* or other clostridia infecting devitalised tissue following a wound, gas forms locally and extends along tissue planes but bacteraemia does not occur. Prompt surgical débridement of devitalised tissue and therapy with penicillin or clindamycin is usually effective.

Gas gangrene (clostridial myonecrosis) is defined as acute invasion of healthy living muscle undamaged by previous trauma, and is most commonly caused by *C. perfringens*. In at least 70% of cases, it follows deep penetrating injury sufficient to create an anaerobic (ischaemic) environment and allow clostridial introduction and proliferation. Severe pain at the site of the injury progresses rapidly over 18–24 hours. Skin colour changes from pallor to bronze/purple discoloration and the skin is tense, swollen, oedematous and exquisitely tender. Gas in tissues may be obvious, with crepitus on clinical examination, or visible on X-ray, CT or ultrasound. Signs of systemic toxicity develop rapidly, with high leucocytosis, multi-organ dysfunction, raised creatine kinase and evidence of disseminated intravascular coagulation and haemolysis. Antibiotic therapy with high-dose intravenous penicillin and clindamycin is recommended, coupled with aggressive surgical débridement of the affected tissues. Alternative agents include cephalosporins and metronidazole. Hyperbaric oxygen has a putative but controversial role.

Other SSTIs

'Synergistic gangrene' is a polymicrobial infection with anaerobes and other bacteria (*Staph. aureus* or Gram-negatives). When this affects the genital/perineal area, it is known as 'Fournier's gangrene'. Severe gangrenous cellulitis in immunocompromised hosts may involve Gram-negative bacteria or fungi. *Entamoeba histolytica* can cause soft tissue necrosis following abdominal surgery in areas of the world where infection is common. Contact with sea water or shellfish consumption in tropical to subtropical regions worldwide, such as the Gulf of Mexico, can lead to infection with *Vibrio vulnificus*. This infection causes soft tissue necrosis and bullae, and may lead to necrotising fasciitis. Patients with chronic liver disease are particularly susceptible to this infection and can develop sepsis.

Acute diarrhoea and vomiting

Acute diarrhoea (p. 783), sometimes with vomiting, is the predominant symptom in infective gastroenteritis (Box 11.10). Acute diarrhoea may also be a symptom of other infectious and non-infectious diseases (Box 11.11). Stress, whether psychological or physical, can also produce loose stools.

The World Health Organisation (WHO) estimates that there are more than 1.7 billion cases of acute diarrhoea annually globally, with 760 000 deaths in children under 5. In developed countries, diarrhoea remains an important problem, with the elderly being most vulnerable (Box 11.12). The majority of episodes are due to infections spread by the faecal–oral route and transmitted either on fomites, on contaminated hands, or in food or water. Measures such as the provision of clean drinking water, appropriate disposal of human and animal sewage, and the application of simple principles of food hygiene can all limit gastroenteritis.

The clinical features of food-borne gastroenteritis vary. Some organisms (*Bacillus cereus*, *Staph. aureus* and *Vibrio cholerae*) elute exotoxins that cause vomiting and/or so-called 'secretory' diarrhoea (watery diarrhoea without blood or faecal leucocytes,

i 11.10 Causes of infectious gastroenteritis

Toxin in food: <6 hrs incubation

- *Bacillus cereus* (p. 262)
- *Staphylococcus aureus* (p. 262)

- Rotavirus (p. 249)
- Norovirus (p. 249)

Protozoal: long incubation

- Giardiasis (p. 287)
- Cryptosporidiosis (pp. 287 and 317)
- Microsporidiosis (p. 317)
- Amoebic dysentery (p. 286)*
- Cystoisosporiasis (p. 233)

*Associated with bloody diarrhoea.

i 11.11 Differential diagnosis of acute diarrhoea and vomiting

Infectious causes

- Gastroenteritis
- *Clostridium difficile* infection (p. 264)
- Acute diverticulitis (p. 833)
- Sepsis (p. 196)
- Pelvic inflammatory disease (p. 336)
- Meningococcaemia (p. 1119)
- Pneumonia (especially 'atypical disease', p. 582)
- Malaria (p. 273)

Non-infectious causes

Gastrointestinal

- Inflammatory bowel disease (p. 813)
- Bowel malignancy (p. 827)
- Overflow from constipation (p. 834)
- Enteral tube feeding

Metabolic

- Diabetic ketoacidosis (p. 735)
- Thyrotoxicosis (p. 635)
- Uraemia (p. 414)
- Neuro-endocrine tumours releasing (e.g.) VIP or 5-HT

Drugs and toxins

- NSAIDs
- Cytotoxic agents
- Antibiotics
- Proton pump inhibitors
- Dinoflagellates (p. 149)
- Plant toxins (p. 150)
- Heavy metals
- Ciguatera fish poisoning (p. 149)
- Scombrotoxic fish poisoning (p. 150)

(5-HT = 5-hydroxytryptamine, serotonin; NSAIDs = non-steroidal anti-inflammatory drugs; VIP = vasoactive intestinal peptide)

11.12 Infectious diarrhoea in old age

- **Incidence**: not increased but the impact is greater.
- **Mortality**: most deaths due to gastroenteritis in the developed world are in adults aged over 70. Most are presumed to be caused by dehydration leading to organ failure.
- ***Clostridium difficile* infection (CDI)**: more common, especially in hospital and nursing home settings, usually following antibiotic exposure.

reflecting small bowel dysfunction). In general, the time from ingestion to the onset of symptoms is short and, other than dehydration, little systemic upset occurs. Other organisms, such as *Shigella* spp., *Campylobacter* spp. and enterohaemorrhagic *Escherichia coli* (EHEC), may directly invade the mucosa of the small bowel or produce cytotoxins that cause mucosal ulceration, typically affecting the terminal small bowel and colon. The incubation period is longer and more systemic upset occurs, with prolonged bloody diarrhoea. *Salmonella* spp. are capable of invading enterocytes and of causing both a secretory response and invasive disease with systemic features. This is seen with *Salmonella* Typhi and *Salmonella* Paratyphi (enteric fever), but may occasionally be seen with other non-typhoidal *Salmonella* spp., particularly in the immunocompromised host and the elderly.

Clinical assessment

The history should address foods ingested (Box 11.13), duration and frequency of diarrhoea, presence of blood or steatorrhoea, abdominal pain and tenesmus, and whether other people have been affected. Fever and bloody diarrhoea suggest an invasive, colitic, dysenteric process. An incubation period of less than 18 hours suggests toxin-mediated food poisoning, and longer than 5 days suggests diarrhoea caused by protozoa or helminths. Person-to-person spread suggests certain infections, such as shigellosis or cholera.

Examination includes assessment of the degree of dehydration. Assessment for early signs of hypotension, such as thirst, headache, altered skin turgor, dry mucous membranes and postural hypotension, is important, particularly in tropical regions where dehydration progresses rapidly. Signs of more marked dehydration include supine hypotension and tachycardia, decreased urinary output, delirium and sunken eyes. The blood pressure, pulse rate, urine output and ongoing stool losses should be monitored closely.

i 11.13 Foods associated with infectious illness, including gastroenteritis

Raw seafood

- Norovirus
- *Vibrio* spp.
- Hepatitis A

Raw eggs

- *Salmonella* serovars

Undercooked meat or poultry

- *Salmonella* serovars
- *Campylobacter* spp.
- EHEC
- Hepatitis E (pork products)
- *Clostridium perfringens*

Unpasteurised milk or juice

- *Salmonella* serovars.
- *Campylobacter* spp.
- EHEC
- *Yersinia enterocolitica*

Unpasteurised soft cheeses

- *Salmonella* serovars
- *Campylobacter* spp.
- ETEC
- *Yersinia enterocolitica*
- *Listeria monocytogenes*

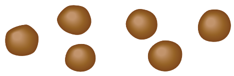
Home-made canned goods

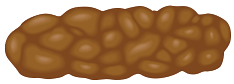
- *Clostridium botulinum*

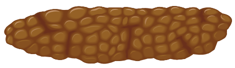
Raw hot dogs, pâté

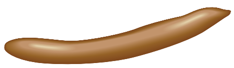
- *Listeria monocytogenes*

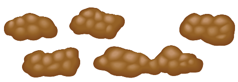
(EHEC = enterohaemorrhagic *Escherichia coli*; ETEC = enterotoxigenic *E. coli*)

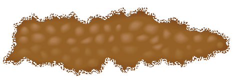












Type 1		Separate hard lumps, like nuts (hard to pass)
Type 2		Sausage-shaped but lumpy
Type 3		Like a sausage but with cracks on its surface
Type 4		Like a sausage or snake, smooth and soft
Type 5		Soft blobs with clear-cut edges (passed easily)
Type 6		Fluffy pieces with ragged edges, a mushy stool
Type 7		Watery, no solid pieces Entirely liquid

Fig. 11.5 Bristol stool chart. The stool is given a 'score' of 1–7 by reference to the verbal and visual description. This is recorded on a chart (usually known as a 'Bristol stool chart') or in a patient monitoring database. *Adapted from Lewis SJ, Heaton KW. Stool form scale as a useful guide to intestinal transit time. Scand J Gastroenterol 1997; 32:920–924.*

The severity of diarrhoea may be assessed by reference to the Bristol stool form scale (Bristol stool chart), which allows an objective assessment of stool consistency by providing a verbal and visual reference scale (Fig. 11.5). The Bristol stool form scale was developed in the 1990s to monitor patients with irritable bowel syndrome, but its main use (at least in UK hospitals) is to monitor hospital inpatients with loose stool to assist in decisions on stool sampling and infection prevention precautions, especially in relation to *C. difficile*.

Investigations

These include stool inspection for blood and microscopy for leucocytes, and also an examination for ova, cysts and parasites if the history indicates residence or travel to areas where these infections are prevalent. Stool culture should be performed and *C. difficile* toxin sought. FBC and serum electrolytes indicate the degree of inflammation and dehydration. Where cholera is prevalent, examination of a wet film with dark-field microscopy for darting motility may provide a diagnosis. In a malarious area, a blood film for malaria parasites should be obtained. Blood and urine cultures and a chest X-ray may identify alternative sites of infection, particularly if the clinical features suggest a syndrome other than gastroenteritis.

Management

All patients with acute, potentially infective diarrhoea should be appropriately isolated to minimise person-to-person spread of infection. If the history suggests a food-borne source, public health measures must be implemented to identify the source and to establish whether other linked cases exist (p. 114).

Fluid replacement

Replacement of fluid losses in diarrhoeal illness is crucial and may be life-saving.

Although normal daily fluid intake in an adult is only 1–2 L, there is considerable additional fluid movement in and out of the gut in secretions (see Fig. 21.7, p. 769). Altered gut resorption with diarrhoea can result in substantial fluid loss; for example, 10–20 L of fluid may be lost in 24 hours in cholera. The fluid lost in diarrhoea is isotonic, so both water and electrolytes need to be replaced. Absorption of electrolytes from the gut is an active process requiring energy. Infected mucosa is capable of very rapid fluid and electrolyte transport if carbohydrate is available as an energy source. Oral rehydration solutions (ORS) therefore contain sugars, as well as water and electrolytes (Box 11.14). ORS can be just as effective as intravenous replacement fluid, even in the management of cholera. In mild to moderate gastroenteritis, adults should be encouraged to drink fluids and, if possible, continue normal dietary food intake. If this is impossible – due to vomiting, for example – intravenous fluid administration will be required. In very sick patients or those with cardiac or renal disease, monitoring of urine output and central venous pressure may be necessary.

The volume of fluid replacement required should be estimated based on the following considerations:

- *Replacement of established deficit*. After 48 hours of moderate diarrhoea (6–10 stools per 24 hrs), the average adult will be 2–4 L depleted from diarrhoea alone. Associated vomiting will compound this. Adults with this symptomatology should therefore be given rapid replacement of 1–1.5 L, either orally (ORS) or by intravenous infusion (normal saline), within the first 2–4 hours of presentation. Longer symptomatology or more persistent/severe diarrhoea rapidly produces fluid losses comparable to diabetic ketoacidosis and is a metabolic emergency requiring active intervention.

11.14 Composition of oral rehydration solution and other replacement fluids*

Fluid	Na	K	Cl	Energy
WHO	90	20	80	54
Dioralyte	60	20	60	71
Pepsi	6.5	0.8	–	400
7UP	7.5	0.2	–	320
Apple juice	0.4	26	–	480
Orange juice	0.2	49	–	400
Breast milk	22	36	28	670

*Values given in mmol/L for electrolyte and kcal/L for energy components.
(WHO = World Health Organisation)

- *Replacement of ongoing losses*. The average adult's diarrhoeal stool accounts for a loss of 200 mL of isotonic fluid. Stool losses should be carefully charted and an estimate of ongoing replacement fluid calculated. Commercially available rehydration sachets are conveniently produced to provide 200 mL of ORS; one sachet per diarrhoea stool is an appropriate estimate of supplementary replacement requirements.
- *Replacement of normal daily requirement*. The average adult has a daily requirement of 1–1.5 L of fluid in addition to the calculations above. This will be increased substantially in fever or a hot environment.

Antimicrobial agents

In non-specific gastroenteritis, routine use of antimicrobials does not improve outcome and may lead to antimicrobial resistance or side-effects. They are usually used where there is systemic involvement, a host with immunocompromise or significant comorbidity.

Evidence suggests that, in EHEC infections, the use of antibiotics may make the complication of haemolytic uraemic syndrome (HUS; p. 408) more likely due to increased toxin release. Antibiotics should therefore not be used in this condition.

Conversely, antibiotics are indicated in *Shigella dysenteriae* infection and in invasive salmonellosis – in particular, typhoid fever. Antibiotics may also be advantageous in cholera epidemics, reducing infectivity and controlling the spread of infection.

Antidiarrhoeal, antimotility and antisecretory agents

These agents are not usually recommended in acute infective diarrhoea. Loperamide, diphenoxylate and opiates are potentially dangerous in dysentery in childhood, causing intussusception. Antisecretory agents, such as bismuth and chlorpromazine, may make the stools appear more bulky but do not reduce stool fluid losses and may cause significant sedation. Adsorbents, such as kaolin or charcoal, have little effect.

Non-infectious causes of food poisoning

While acute food poisoning and gastroenteritis are most frequently caused by infections, non-infectious causes must also be considered in the differential diagnosis. These are discussed on page 149.

Antimicrobial-associated diarrhoea

Antimicrobial-associated diarrhoea (AAD) is a common complication of antimicrobial therapy, especially with broad-spectrum agents. It is most common in the elderly but can occur at all ages. Although the specific mechanism is unknown in most cases of AAD, *C. difficile* (p. 264) is implicated in 20–25% of cases and is the most common cause among patients with evidence of colitis. *C. perfringens* is a rarer cause that usually remains undiagnosed, and *Klebsiella oxytoca* may also cause antibiotic-associated haemorrhagic colitis.

Infections acquired in the tropics

Recent decades have seen unprecedented increases in long-distance business and holiday travel, as well as extensive migration. Although certain diseases retain their relatively fixed geographical distribution, being dependent on specific vectors or weather conditions, many travel with their human hosts and some may then be transmitted to other people. This means that the pattern of infectious diseases seen in each country changes constantly, and travel history and information on countries previously lived in, particularly during childhood, are crucial.

11.15 How to assess health needs in travellers before departure*

- Destination
- Personal details, including previous travel experience
- Dates of trip
- Itinerary and purpose of trip
- Personal medical history, including pregnancy, medication and allergies (e.g. to eggs, vaccines, antibiotics)
- Past vaccinations:
  - Childhood schedule followed? Diphtheria, tetanus, pertussis, polio, *Neisseria meningitidis* types B/C, *Haemophilus influenzae* B (HiB)
  - Travel-related? Typhoid, yellow fever, hepatitis A, hepatitis B, meningococcal ACW135Y, rabies, Japanese B encephalitis, tick-borne encephalitis
- Malaria prophylaxis: questions influencing the choice of antimalarial drugs are destination, past experience with antimalarials, history of epilepsy or psychiatric illness

*Further information is available at fitfortravel.nhs.uk.

In general, the diversity of infectious diseases is greater in tropical than in temperate countries, and people in temperate countries have immunity to a narrower range of infections, reflecting less exposure in childhood and less ongoing boosting of immunity later in life, so that the most common travel-associated infections are those that are acquired by residents of temperate countries during visits to the tropics. In addition, those who have lived in tropical areas may lose immunity when they move to temperate countries and become susceptible when visiting their homeland.

Most travel-associated infections can be prevented. Pre-travel advice is tailored to the destination and the traveller (Box 11.15). It includes avoidance of insect bites (using at least 20% diethyltoluamide (DEET)), sun protection (sunscreen with a sun protection factor (SPF) of at least 15), food and water hygiene ('Boil it, cook it, peel it or forget it!'), how to respond to travellers' diarrhoea (seek medical advice if bloody or if it lasts more than 48 hrs) and, if relevant, safe sex (condom use).

Fever acquired in the tropics

Presentation with unexplained fever is common in travellers who are visiting or have recently travelled to tropical areas. Fever may also occur in those living in tropical regions if they have not developed immunity to the endemic pathogen or if this immunity is compromised by factors such as pregnancy. Frequent final diagnoses in such patients are malaria, typhoid fever, viral hepatitis and dengue fever. Travellers to affected areas may have viral haemorrhagic fevers (VHFs) such as Ebola, Lassa, Crimean–Congo and Marburg (see Box 11.36, p. 245), avian influenza (H5N1) or Middle East respiratory syndrome (MERS), which require special isolation precautions.

Clinical assessment

The approach to unexplained fever is as described above and key questions relating to infections acquired in tropical regions are listed in Box 11.16. Medicines purchased in some countries may have reduced efficacy, e.g. for malaria prophylaxis. Consult reliable up-to-date sources about resistance to antimalarial drugs

in the country visited. Vaccinations against yellow fever and hepatitis A and B are sufficiently effective to virtually exclude these infections. Oral and injectable typhoid vaccinations are 70–90% effective.

The differential diagnosis is guided by the clinical scenario, presence of specific exposures (Box 11.17) and incubation period (Box 11.18). *Falciparum* malaria tends to present between 7 and 28 days after exposure in an endemic area. VHF, dengue and rickettsial infection can usually be excluded if more than 21 days have passed between leaving the area and onset of illness.

11.16 How to obtain a history from travellers to the tropics with fever

Questions	Factors to ascertain
Countries visited and dates of travel	Relate travel to known outbreaks of infection or antimicrobial resistance
Determine the environment visited	Travel to rural environments, forests, rivers or lakes
Clarify where the person slept	Sleeping in huts, use of bed nets, sleeping on the ground
Establish what he/she was doing	Exposure to people with medical illness, animals, soil, lakes and rivers
History of insect bites	Type of insect responsible, circumstances (location, time of day etc.), preventive measures
Dietary history	Ingestion of uncooked foods, salads and vegetables, meats (especially if under-cooked), shellfish, molluscs, unpasteurised dairy products, unbottled water and sites at which food prepared
Sexual history	History of sexual intercourse with commercial sex workers, local population or travellers from other countries
Malaria prophylaxis	Type of prophylaxis
Vaccination history	Receipt of pre-travel vaccines and appropriateness to area visited
History of any treatments received while abroad	Receipt of medicines, local remedies, blood transfusions or surgical procedures

11.17 Specific exposures and causes of fever in the tropics

Exposure	Infection or disease
Mosquito bite	Malaria, dengue fever, Chikungunya, filariasis, tularaemia
Tsetse fly bite	African trypanosomiasis
Tick bite	Rickettsial infections including typhus, Lyme disease, tularaemia, Crimean–Congo haemorrhagic fever, Kyasanur forest disease, babesiosis, tick-borne encephalitis
Louse bite	Typhus
Flea bite	Plague
Sandfly bite	Leishmaniasis, arbovirus infection
Reduviid bug	Chagas' disease
Animal contact	Q fever, brucellosis, anthrax, plague, tularaemia, viral haemorrhagic fevers, rabies
Fresh-water swimming	Schistosomiasis, leptospirosis, *Naegleria fowleri*
Exposure to soil	Inhalation: dimorphic fungi Inhalation or inoculation: *Burkholderia pseudomallei* Inoculation (most often when barefoot): hookworms, *Strongyloides stercoralis*
Raw or under-cooked fruit and vegetables	Enteric bacterial infections, hepatitis A or E virus, *Fasciola hepatica*, *Toxocara* spp., *Echinococcus granulosus* (hydatid disease), *Entamoeba histolytica*
Under-cooked pork	*Taenia solium* (cysticercosis)
Crustaceans or molluscs	Paragonimiasis, gnathostomiasis, *Angiostrongylus cantonensis* infection, hepatitis A virus, cholera
Unpasteurised dairy products	Brucellosis, salmonellosis, abdominal tuberculosis, listeriosis
Untreated water	Enteric bacterial infections, giardiasis, *Cryptosporidium* spp. (chronic in immunocompromised), hepatitis A or E virus

11

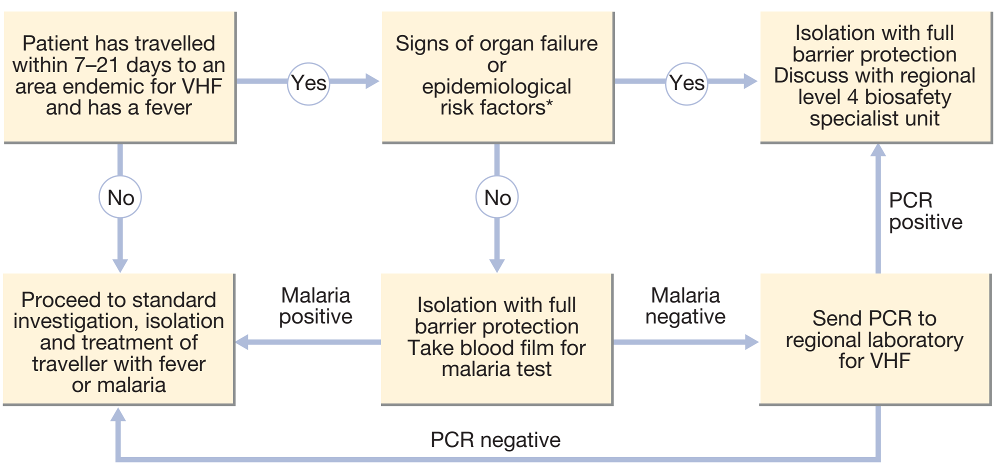


Fig. 11.6 Approach to the patient with suspected viral haemorrhagic fever (VHF). See page 245. *Epidemiological risk factors: staying with a febrile individual, caring for a sick individual, or contact with body fluids from a suspected human or animal case of VHF. (PCR = polymerase chain reaction)

11.18 Incubation times and illnesses in travellers

<2 weeks

Non-specific fever
- Malaria
- Chikungunya
- Dengue
- Scrub typhus
- Spotted group rickettsiae
- Acute HIV
- Acute hepatitis C virus
- *Campylobacter*
- Salmonellosis
- Shigellosis
- East African trypanosomiasis
- Leptospirosis
- Relapsing fever
- Influenza
- Yellow fever

Fever and coagulopathy (usually thrombocytopenia)
- Malaria
- VHF
- Meningococcaemia
- Enteroviruses
- Leptospirosis and other bacterial pathogens associated with coagulopathy

Fever and central nervous system involvement
- Malaria
- Typhoid fever
- Rickettsial typhus (epidemic caused by *Rickettsia prowazekii*)
- Meningococcal meningitis
- Arboviral encephalitis
- East African trypanosomiasis
- Other causes of encephalitis or meningitis
- Angiostrongyliasis
- Rabies

Fever and pulmonary involvement
- Influenza
- Pneumonia, including *Legionella* pneumonia
- Acute histoplasmosis
- Acute coccidioidomycosis
- Q fever
- SARS

Fever and rash
- Viral exanthems (rubella, measles, varicella, mumps, HHV-6, enteroviruses
- Chikungunya
- Dengue
- Spotted or typhus group rickettsiosis
- Typhoid fever
- Parvovirus B19
- HIV-1

2–6 weeks
- Malaria
- Tuberculosis
- Hepatitis A, B, C and E viruses
- Visceral leishmaniasis
- Acute schistosomiasis
- Amoebic liver abscess
- Leptospirosis
- African trypanosomiasis
- VHF
- Q fever
- Acute American trypanosomiasis
- Viral causes of mononucleosis syndromes

>6 weeks
- Non-*falciparum* malaria
- Tuberculosis
- Hepatitis B and E viruses
- HIV-1
- Visceral leishmaniasis
- Filariasis
- Onchocerciasis
- Schistosomiasis
- Amoebic liver abscess
- Chronic mycoses
- African trypanosomiasis
- Rabies
- Typhoid fever

(HHV-6 = human herpesvirus-6; SARS = severe acute respiratory syndrome; VHF = viral haemorrhagic fever)
Adapted from Traveller's Health Yellow Book, CDC Health Information for International Travel 2008.

Clinical examination is summarised on page 216. Particular attention should be paid to the skin, throat, eyes, nail beds, lymph nodes, abdomen and heart. Patients may be unaware of tick bites or eschars (p. 270). Body temperature should be measured at least twice daily.

11.19 Investigation of tropically acquired acute fever without localising signs

Features on full blood count	Further investigations
Neutrophil leucocytosis	
Bacterial sepsis	Blood culture
Leptospirosis	Culture of blood and urine, serology
Borreliosis (tick- or louse-borne relapsing fever)	Blood film
Amoebic liver abscess	Ultrasound
Normal white cell count and differential	
Malaria (may have low platelets or anaemia)	Blood film, antigen test
Typhoid fever	Blood and stool culture
Typhus	Serology
Lymphocytosis	
Viral fevers, including VHF	Serology, PCR
Infectious mononucleosis	Monospot test, serology
Malaria	Blood film, antigen test
Rickettsial fevers	Serology
Atypical lymphocytes	
Dengue and other VHF	Serology, antigen, PCR
Infectious mononucleosis-like syndromes	Serology, PCR
HIV (acute retroviral syndrome)	Serology, antigen
Hepatitis viruses	Serology, antigen, PCR
Parasitic, malaria, trypanosomiasis	Blood film, antigen test, PCR

(PCR = polymerase chain reaction; VHF = viral haemorrhagic fever)

Investigations and management

Initial investigations should start with blood films for malaria parasites, FBC, urinalysis and chest X-ray if indicated. Box 11.19 lists diagnoses and investigations to consider in unexplained acute fever.

Management is directed at the underlying cause. In patients with suspected VHF (p. 245), strict infection control measures with isolation and barrier nursing are implemented to prevent contact with the patient's body fluids. The risk of VHF should be determined using epidemiological risk factors and clinical signs (Fig. 11.6), and further management undertaken as described on page 246.

Diarrhoea acquired in the tropics

Gastrointestinal illness is the most common infection amongst visitors to the tropics, with *Salmonella* spp., *Campylobacter* spp. and *Cryptosporidium* spp. infections prevalent worldwide (Box 11.20). *Shigella* spp. and *Entamoeba histolytica* (amoebiasis) are usually encountered in visitors to or residents of the Indian subcontinent or sub-Saharan and southern Africa.

The approach to patients with acute diarrhoea is described on page 227. The benefits of treating travellers' diarrhoea with antimicrobials are marginal, with slight reductions in stool

11.20 Most common causes of travellers' diarrhoea

- Enterotoxigenic *E. coli* (ETEC)
- *Shigella* spp.
- *Campylobacter jejuni*
- *Salmonella* serovars
- *Plesiomonas shigelloides*
- Non-cholera *Vibrio* spp.
- *Aeromonas* spp.

frequency and likelihood of cure at 72 hours offset by increased side-effects. The differential diagnosis of diarrhoea persisting for more than 14 days is wide (see Box 21.18, p. 784). Parasitic and bacterial causes, tropical malabsorption, inflammatory bowel disease and neoplasia should all be considered. Box 11.21 lists causes encountered particularly in visitors to or residents of the tropics. The workup should include tests for parasitic causes of chronic diarrhoea, such as examination of stool and duodenal aspirates for ova and parasites, and serological investigation.

Tropical sprue is a malabsorption syndrome (p. 807) with no defined aetiology. It was typically associated with a long period of residence in the tropics or with overland travel but is now rarely seen. *Giardia lamblia* infection may progress to a malabsorption syndrome that mimics tropical sprue. If no cause is found, empirical treatment for *Giardia lamblia* infection with metronidazole is often helpful.

HIV-1 has now emerged as a major cause of chronic diarrhoea. This may be due to HIV enteropathy or infection with agents such as *Cryptosporidium* spp., *Cystoisospora belli* (syn. *Isospora belli*) or microsporidia (p. 316). However, many other causes of chronic AIDS-associated diarrhoea seen in the developed world are less common in tropical settings, e.g. CMV or disseminated *Mycobacterium avium* complex infections.

i 11.21 Causes of chronic diarrhoea acquired in the tropics

- *Giardia lamblia*
- Strongyloidiasis
- Enteropathic *Escherichia coli*
- HIV enteropathy
- Intestinal flukes
- Tropical sprue
- Chronic intestinal schistosomiasis
- Chronic calcific pancreatitis
- Hypolactasia (primary and secondary)

Eosinophilia acquired in the tropics

Eosinophilia occurs in a variety of haematological, allergic and inflammatory conditions discussed on page 927. It may also arise in HIV-1 and human T-cell lymphotropic virus (HTLV)-1 infection. However, eosinophils are important in the immune response to parasitic infections, in particular those involving parasites with a tissue migration phase. In the context of travel to or residence in the tropics, a patient with an eosinophil count of more than 0.4×10^9/L should be investigated for both non-parasitic (see Box 23.9, p. 926) and parasitic causes (Box 11.22).

The response to parasite infections is often different when travellers to and residents of endemic areas are compared. Travellers often have recent and light infections associated with eosinophilia. Residents have often been infected for a long time, have evidence of chronic pathology and no longer have eosinophilia.

Clinical assessment

A history of travel to known endemic areas for schistosomiasis, onchocerciasis and the filariases will indicate possible causes. Assessment should establish how long patients have spent in endemic areas and the history should address all the elements in Box 11.16.

Physical signs or symptoms that suggest a parasitic cause for eosinophilia include transient rashes (schistosomiasis or strongyloidiasis), fever (Katayama syndrome; p. 295), pruritus (onchocerciasis) or migrating subcutaneous swellings (loiasis, gnathostomiasis) (see Box 11.22). Paragonimiasis can give rise to haemoptysis, and the migratory phase of intestinal nematodes or lymphatic filariasis may cause cough, wheezing and transient pulmonary infiltrates. Schistosomiasis, strongyloidiasis and gnathostomiasis induce transient respiratory symptoms with infiltrates in the acute stages and, when eggs reach the pulmonary vasculature in chronic schistosomiasis infection, can

11

i 11.22 Parasite infections that cause eosinophilia

Infestation	Pathogen	Clinical syndrome with eosinophilia
Strongyloidiasis	*Strongyloides stercoralis*	Larva currens
Soil-transmitted helminthiases		
Hookworm	*Necator americanus*	Anaemia
	Ancylostoma duodenale	Anaemia
Ascariasis	*Ascaris lumbricoides*	Löffler's syndrome
Toxocariasis	*Toxocara canis*	Visceral larva migrans
Schistosomiasis	*Schistosoma haematobium*	Katayama fever
	S. mansoni, *S. japonicum*	Chronic infection
Filariases		
Loiasis	*Loa loa*	Skin nodules
Wuchereria bancrofti	*W. bancrofti*	Lymphangitis, lymphadenopathy, orchitis, intermittent bouts of cellulitis, lymphoedema and elephantiasis
Brugia malayi	*B. malayi*	Brugian elephantiasis similar but typically less severe than that caused by *W. bancrofti*
Mansonella perstans	*M. perstans*	Asymptomatic infection, occasionally subconjunctival nodules
Onchocerciasis	*Onchocerca volvulus*	Visual disturbance, dermatitis
Other nematode infections	*Trichinella spiralis*	Myositis
	Gnathostoma spinigerum	Pruritus, migratory nodules, eosinophilic meningitis
Cestode infections	*Taenia saginata*, *T. solium*	Usually asymptomatic; eosinophilia associated with migratory phase
	Echinococcus granulosus	Lesions in liver or other organ; eosinophilia associated with leakage from cyst
Liver flukes	*Fasciola hepatica*	Hepatic symptoms; eosinophilia associated with migratory phase
	Clonorchis sinensis	As for fascioliasis
	Opisthorchis felineus	As for fascioliasis
Lung fluke	*Paragonimus westermani*	Lung lesions

11.23 Initial investigation of eosinophilia

Investigation	Pathogens sought
Stool microscopy	Ova, cysts and parasites
Terminal urine	Ova of *Schistosoma haematobium*
Duodenal aspirate	Filariform larvae of *Strongyloides*, liver fluke ova
Day bloods	Microfilariae *Brugia malayi*, *Loa loa*
Night bloods	Microfilariae *Wuchereria bancrofti*
Skin snips	*Onchocerca volvulus*
Slit-lamp examination	*Onchocerca volvulus*
Serology	Schistosomiasis, filariasis, strongyloidiasis, hydatid, trichinosis, gnathostomiasis etc.

result in shortness of breath with features of right heart failure due to pulmonary hypertension. Fever and hepatosplenomegaly are seen in schistosomiasis, *Fasciola hepatica* infection and toxocariasis (visceral larva migrans). Intestinal worms, such as *Ascaris lumbricoides* and *Strongyloides stercoralis*, can cause abdominal symptoms, including intestinal obstruction and diarrhoea. In the case of heavy infestation with *Ascaris*, this may be due to fat malabsorption and there may be associated nutritional deficits. *Schistosoma haematobium* can cause haematuria or haematospermia. *Toxocara* spp. can give rise to choroidal lesions with visual field defects. *Angiostrongylus cantonensis* and gnathostomiasis induce eosinophilic meningitis, and the hyperinfection syndrome caused by *S. stercoralis* in immunocompromised hosts induces meningitis due to Gram-negative bacteria. Myositis is a feature of trichinosis (trichinellosis) and cysticercosis, while periorbital oedema is found in trichinosis.

Investigations

The diagnosis of a parasitic infestation requires direct visualisation of adult worms, larvae or ova. Serum antibody detection may not distinguish between active and past infection and is often unhelpful in those born in endemic areas. Radiological investigations may provide circumstantial evidence of parasite infestation. Box 11.23 describes initial investigations for eosinophilia.

Management

A specific diagnosis guides therapy. In the absence of a specific diagnosis, many clinicians will give an empirical course of praziquantel if the individual has potentially been exposed to schistosomiasis, or with albendazole/ivermectin if strongyloidiasis or intestinal nematodes are likely causes.

Skin conditions acquired in the tropics

Community-based studies in the tropics consistently show that skin infections (bacterial and fungal), scabies and eczema are the most common skin problems (Box 11.24). Scabies and eczema are discussed on pages 1241 and 1244. Cutaneous leishmaniasis and onchocerciasis have defined geographical distributions (pp. 284 and 292). In travellers, secondarily infected insect bites, pyoderma, cutaneous larva migrans and non-specific dermatitis are common.

During the investigation of skin lesions, enquiry should be made about habitation, activities undertaken and regions visited (see Box 11.16). Examples of skin lesions in tropical disease are shown in Figure 11.7.

11.24 Rash in tropical travellers/residents

Maculopapular rash
- Dengue
- HIV-1
- Typhoid
- *Spirillum minus*
- Rickettsial infections
- Measles

Petechial or purpuric rash
- Viral haemorrhagic fevers
- Yellow fever
- Meningococcal sepsis
- Leptospirosis
- Rickettsial spotted fevers
- Malaria

Vesicular rash
- Monkeypox
- Insect bites
- Rickettsial pox

Urticarial rash
- Katayama fever (schistosomiasis)
- *Toxocara* spp.
- *Strongyloides stercoralis*
- Fascioliasis

Ulcers
- Leishmaniasis
- *Mycobacterium ulcerans* (Buruli ulcer)
- Dracunculosis
- Anthrax
- Rickettsial eschar
- Tropical ulcer (*Fusobacterium ulcerans* and *Treponema vincentii*)
- Ecthyma (staphylococci, streptococci)

Papules
- Scabies
- Insect bites
- Prickly heat
- Ringworm
- Onchocerciasis

Nodules or plaques
- Leprosy
- Chromoblastomycosis
- Dimorphic fungi
- Trypanosomiasis
- Onchocerciasis
- Myiasis (larvae of tumbu fly or botfly)
- Tungiasis (*Tunga penetrans*)

Migratory linear rash
- Cutaneous larva migrans (CLM; dog hookworms)
- *Strongyloides stercoralis* (larva currens, more rapid than CLM)

Migratory papules/nodules
- *Loa loa*
- Gnathostomiasis
- Schistosomiasis

Thickened skin
- Mycetoma (actinomycetoma/eumycetoma)
- Elephantiasis (filariasis)

Skin biopsies are helpful in diagnosing aetiology. Culture of biopsy material may be needed to diagnose bacterial, fungal, parasitic and mycobacterial infections.

Infections in adolescence

Particular issues of relevance in adolescent patients are shown in Box 11.25.

Infections in pregnancy

Box 11.26 shows some of the infections encountered in pregnancy.

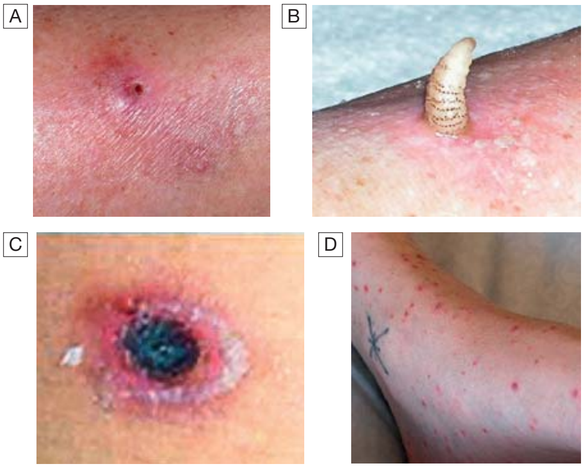

Fig. 11.7 Examples of skin lesions in patients with fever in the tropics. **A** Subcutaneous nodule due to botfly infection. **B** Emerging larva after treatment with petroleum jelly. **C** Eschar of scrub typhus. **D** Rat bite fever. *A, B and D, Courtesy of Dr Ravi Gowda, Royal Hallamshire Hospital, Sheffield. 11.25 Key issues in infectious diseases in adolescence

- **Common infectious syndromes**: infectious mononucleosis, bacterial pharyngitis, whooping cough, pneumonia, staphylococcal skin/soft tissue infections, urinary tract infections, acute gastroenteritis.
- **Life-threatening infections**: meningococcal infection (sepsis and/or meningitis).
- **Sexually transmitted infections**: human papillomavirus (HPV), HIV-1, hepatitis B virus and chlamydia. These may reflect either voluntary sexual activity or sexual coercion/abuse.
- **Travel-related infections**: diarrhoea, malaria etc. are relatively common.
- **Infections in susceptible groups**: patients with cystic fibrosis, congenital immunodeficiency, acute leukaemia and other adolescent malignancies are vulnerable to specific groups of infections.
- **Infections requiring prolonged antimicrobial use**: adherence to chronic therapy is challenging, for both oral (antituberculous or antiretroviral) and systemic (osteomyelitis, septic arthritis or post-operative infections) treatments. Outpatient antimicrobial therapy is preferred to minimise hospitalisation.
- **Vaccination**: engagement with age-specific vaccine programmes should be ensured, e.g. HPV, childhood booster vaccines and meningococcal vaccine.
- **Risk reduction**: education relating to sexual health and alcohol and recreational drug usage is important.

11

11.26 Infections in pregnancy

Infection	Consequence	Prevention and management
Rubella	Congenital malformation	Childhood vaccination and vaccination of non-immune mothers post-delivery
Cytomegalovirus	Neonatal infection, congenital malformation	Limited prevention strategies
Zika virus	Congenital malformation	Avoidance of travel, delay in pregnancy if infected
Varicella zoster virus	Neonatal infection, congenital malformation, severe infection in mother	VZ immunoglobulin (see Box 11.31)
Herpes simplex virus (HSV)	Congenital or neonatal infection	Aciclovir and consideration of caesarean section for mothers who shed HSV from genital tract at time of delivery. Aciclovir for infected neonates
Hepatitis B virus	Chronic infection of neonate	Hepatitis B immunoglobulin and active vaccination of newborn
Hepatitis E virus	Fulminant hepatitis, pre-term delivery, fetal loss	Maintenance of standard food hygiene practices
HIV-1	Chronic infection of neonate	Antiretroviral drugs for mother and infant and consideration of caesarean section if HIV-1 viral load detectable. Avoidance of breastfeeding
Parvovirus B19	Congenital infection	Avoidance of individuals with acute infection if pregnant
Measles	More severe infection in mother and neonate, fetal loss	Childhood vaccination, human normal immunoglobulin in non-immune pregnant contacts and vaccination post-delivery
Dengue	Neonatal dengue if mother has infection <5 weeks prior to delivery	Vector (mosquito) control
Syphilis	Congenital malformation	Serological testing in pregnancy with prompt treatment of infected mothers
Neisseria gonorrhoeae and *Chlamydia trachomatis*	Neonatal conjunctivitis (ophthalmia neonatorum, p. 340)	Treatment of infection in mother and neonate
Listeriosis	Neonatal meningitis or bacteraemia, bacteraemia or pyrexia of unknown origin in mother	Avoidance of unpasteurised cheeses and other dietary sources
Brucellosis	Possibly increased incidence of fetal loss	Avoidance of unpasteurised dairy products
Group B streptococcal infection	Neonatal meningitis and sepsis. Sepsis in mother after delivery	Risk- or screening-based antimicrobial prophylaxis in labour (recommendations vary between countries)
Toxoplasmosis	Congenital malformation	Diagnosis and prompt treatment of cases, avoidance of under-cooked meat while pregnant
Malaria	Fetal loss, intrauterine growth retardation, severe malaria in mother	Avoidance of insect bites. Intermittent preventative treatment during pregnancy to decrease incidence in high-risk countries

Viral infections

Systemic viral infections with exanthem

Childhood exanthems are characterised by fever and widespread rash. Maternal antibody usually gives protection for the first 6–12 months of life. Comprehensive immunisation programmes have dramatically reduced the number of paediatric infections but incomplete uptake results in infections in later life.

Measles

The WHO has set the objective of eradicating measles globally using the live attenuated vaccine. However, vaccination of more than 95% of the population is required to prevent outbreaks. Natural illness produces life-long immunity.

Clinical features

Infection is by respiratory droplets with an incubation period of 6–19 days. A prodromal illness occurs, 1–3 days before the rash, with upper respiratory symptoms, conjunctivitis and the presence of the pathognomonic Koplik's spots: small white spots surrounded by erythema on the buccal mucosa (Fig. 11.8A). As natural antibody develops, the maculopapular rash appears, spreading from the face to the extremities (Fig. 11.8B). Generalised lymphadenopathy and diarrhoea are common. Complications are more common in older children and adults, and include otitis media, bacterial pneumonia, transient hepatitis, pancreatitis and clinical encephalitis (approximately 0.1% of cases). A rare late complication is subacute sclerosing panencephalitis (SSPE), which occurs up to 7 years after infection. Diagnosis is clinical (although this has become unreliable in areas where measles is no longer common) and by detection of antibody (serum immunoglobulin M (IgM), seroconversion or salivary IgM).

Measles is a serious disease in the malnourished, vitamin-deficient or immunocompromised, in whom the typical rash may be missing and persistent infection with a giant cell pneumonitis or encephalitis may occur. In tuberculosis infection, measles suppresses cell-mediated immunity and may exacerbate disease; for this reason, measles vaccination should be deferred until after commencing antituberculous treatment. Measles does not cause congenital malformation but may be more severe in pregnant women.

Mortality clusters at the extremes of age, averaging 1:1000 in developed countries and up to 1:4 in developing countries. Death usually results from a bacterial superinfection, occurring as a complication of measles: most often pneumonia, diarrhoeal disease or noma/cancrum oris, a gangrenous stomatitis. Death may also result from complications of measles encephalitis.

Management and prevention

Normal immunoglobulin attenuates the disease in the immunocompromised (regardless of vaccination status) and in non-immune pregnant women, but must be given within 6 days of exposure. Vaccination can be used in outbreaks and vitamin A may improve the outcome in uncomplicated disease. Antibiotic therapy is reserved for bacterial complications. All children aged 12–15 months should receive measles vaccination (as combined measles, mumps and rubella (MMR), a live attenuated vaccine), and a further MMR dose at age 4 years.

Rubella (German measles)

Rubella causes exanthem in the non-immunised.

Clinical features

Rubella is spread by respiratory droplet, with infectivity from up to 10 days before to 2 weeks after the onset of the rash. The incubation period is 15–20 days. In childhood, most cases are subclinical, although clinical features may include fever, maculopapular rash spreading from the face, and lymphadenopathy. Complications are rare but include thrombocytopenia and hepatitis. Encephalitis and haemorrhage are occasionally reported. In adults, arthritis involving hands or knees is relatively common, especially in women.

If transplacental infection takes place in the first trimester or later, persistence of the virus is likely and severe congenital disease may result (Box 11.27). Even if normal at birth, the infant has an increased incidence of other diseases developing later, e.g. diabetes mellitus.

Diagnosis

Laboratory confirmation of rubella is required if there has been contact with a pregnant woman. This is achieved either by detection of rubella IgM in serum or by IgG seroconversion. In the exposed pregnant woman, absence of rubella-specific IgG confirms the potential for congenital infection.

Prevention

All children should be immunised with MMR vaccine. Congenital rubella syndrome may be controlled by testing women of child-bearing age for rubella antibodies and offering vaccination if seronegative. Antenatal rubella screening was offered to pregnant mothers in the UK for many years for this reason. However, this

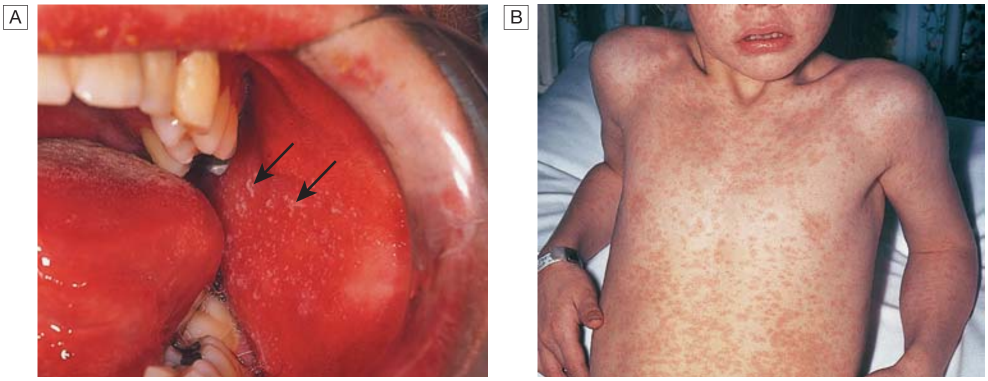

Fig. 11.8 Measles. A Koplik's spots (arrows) seen on buccal mucosa in the early stages of clinical measles. B Typical measles rash.

11.27 Rubella infection: risk of congenital malformation

Stage of gestation	Likelihood of malformations
1–2 months	65–85% chance of illness, multiple defects/ spontaneous abortion
3 months	30–35% chance of illness, usually a single congenital defect (most frequently deafness, cataract, glaucoma, mental retardation or congenital heart disease, especially pulmonary stenosis or patent ductus arteriosus)
4 months	10% risk of congenital defects, most commonly deafness
>20 weeks	Occasional deafness

practice ceased in 2016 because: rubella is so rare in the UK as to be considered eliminated; pre-pregnancy MMR vaccination is considered to be a more effective method of protecting pregnant women; and the screening test may give inaccurate results, causing unnecessary stress to pregnant women.

Parvovirus B19

Parvovirus B19 causes exanthem and other clinical syndromes. Some 50% of children and 60–90% of adults are seropositive. Most infections are spread by the respiratory route, although spread via contaminated blood is also possible. The virus has particular tropism for red cell precursors.

Clinical features

Many infections are subclinical. Clinical manifestations result after an incubation period of 14–21 days (Box 11.28). The classic exanthem (erythema infectiosum) is preceded by a prodromal fever and coryzal symptoms. A 'slapped cheek' rash is characteristic but the rash is very variable (Fig. 11.9). In adults, polyarthropathy is common. Infected individuals have a transient block in erythropoiesis for a few days, which is of no clinical consequence, except in individuals with increased red cell turnover due to haemoglobinopathy or haemolytic anaemia. These individuals develop an acute anaemia that may be severe (transient aplastic crisis; p. 968). Erythropoiesis usually recovers spontaneously after 10–14 days. Immunocompromised individuals, including those with congenital immunodeficiency or AIDS, can develop a more sustained block in erythropoiesis in response to the chronic viraemia that results from their inability to clear the infection. Infection during the first two trimesters of pregnancy can result in intrauterine infection and impact on fetal bone marrow; it causes 10–15% of non-immune (non-Rhesus-related) hydrops fetalis, a rare complication of pregnancy.

Diagnosis

IgM to parvovirus B19 suggests recent infection but may persist for months and false positives occur. Seroconversion to IgG positivity confirms infection but in isolation a positive IgG is of little diagnostic utility. Detection of parvovirus B19 DNA in blood is particularly useful in immunocompromised patients. Giant pronormoblasts or haemophagocytosis may be demonstrable in the bone marrow.

Management

Infection is usually self-limiting. Symptomatic relief for arthritic symptoms may be required. Severe anaemia requires transfusion.

11.28 Clinical features of parvovirus B19 infection

Affected age group	Clinical manifestations
Fifth disease (erythema infectiosum)	
Small children	Three clinical stages: a 'slapped cheek' appearance, followed by a maculopapular rash progressing to a reticulate eruption on the body and limbs, then a final stage of resolution. Often the child is quite well throughout
Gloves and socks syndrome	
Young adults	Fever and an acral purpuric eruption with a clear margin at the wrists and ankles. Mucosal involvement also occurs
Arthropathies	
Adults and occasionally children	Symmetrical small-joint polyarthropathy. In children it tends to involve the larger joints in an asymmetrical distribution
Impaired erythropoiesis	
Adults, those with haematological disease, the immunosuppressed	Mild anaemia; in an individual with an underlying haematological abnormality it can precipitate transient aplastic crisis, or in the immunocompromised a more sustained but often milder pure red cell aplasia
Hydrops fetalis	
Transplacental fetal infection	Asymptomatic or symptomatic maternal infection that can cause fetal anaemia with an aplastic crisis, leading to non-immune hydrops fetalis and spontaneous abortion

Fig. 11.9 Slapped cheek syndrome. The typical facial rash of parvovirus B19 infection.

Persistent viraemia in immunocompromised hosts may require immunoglobulin therapy to clear the virus.

Pregnant women should avoid contact with cases of parvovirus B19 infection; if they are exposed, serology should be performed to establish whether they are non-immune.

Passive prophylaxis with normal immunoglobulin has been suggested for non-immune pregnant women exposed to infection but there are limited data to support this recommendation. The pregnancy should be closely monitored by ultrasound scanning, so that hydrops fetalis can be treated by fetal transfusion.

Human herpesvirus 6 and 7

Human herpesvirus 6 (HHV-6) is a lymphotropic virus that causes a childhood viral exanthem (exanthem subitum), rare cases of an infectious mononucleosis-like syndrome and infection in the immunocompromised host. Infection is almost universal, with approximately 95% of children acquiring this virus by 2 years of age. Transmission is via saliva.

i 11.29 Herpesvirus infections

Virus	Infection
Herpes simplex virus (HSV)	
HSV-1 (p. 247)	Herpes labialis ('cold sores') Stomatitis, pharyngitis Corneal ulceration Finger infections ('whitlows') Eczema herpeticum Encephalitis
HSV-2 (p. 247)	Genital ulceration and neonatal infection (acquired during vaginal delivery) Acute meningitis or transverse myelitis; rarely, encephalitis
Varicella zoster virus (VZV)	Chickenpox (varicella) Shingles (herpes zoster)
Cytomegalovirus (CMV) (p. 242)	Congenital infection Infectious mononucleosis (heterophile antibody-negative) Hepatitis Disease in immunocompromised patients: retinitis, encephalitis, pneumonitis, hepatitis, enteritis Fever with abnormalities in haematological parameters
Epstein–Barr virus (EBV) (p. 241)	Infectious mononucleosis Burkitt's and other lymphomas Nasopharyngeal carcinoma Oral hairy leucoplakia (AIDS patients) Other lymphomas, post-transplant lymphoproliferative disorder (p. 225)
Human herpesvirus 6 and 7 (HHV-6, HHV-7)	Exanthem subitum Disease in immunocompromised patients
Human herpesvirus 8 (HHV-8) (p. 248)	Kaposi's sarcoma, primary effusion lymphoma, multicentric Castleman's disease

HHV-7 is very closely related to HHV-6 and is believed to be responsible for a proportion of cases of exanthem subitum. Like HHV-6, HHV-7 causes an almost universal infection in childhood, with subsequent latent infection and occasional infection in the immunocompromised host.

Clinical features

Exanthem subitum is also known as roseola infantum or sixth disease (Box 11.29). A high fever is followed by a maculopapular rash as the fever resolves. Fever and/or febrile convulsions may also occur without a rash. Rarely, older children or adults may develop an infectious mononucleosis-like illness, hepatitis or rash. In the immunocompromised, infection is rare but can cause fever, rash, hepatitis, pneumonitis, cytopenia or encephalitis.

Diagnosis and management

Exanthem subitum is usually a clinical diagnosis but can be confirmed by antibody and/or DNA detection. The disease is self-limiting. Treatment with ganciclovir or foscarnet is used in immunocompromised hosts infected with HHV-6.

Chickenpox (varicella)

Varicella zoster virus (VZV) is a dermotropic and neurotropic virus that produces primary infection, usually in childhood, which may reactivate in later life. VZV is spread by aerosol and direct contact. It is highly infectious to non-immune individuals. Disease in children is usually well tolerated. Manifestations are more severe in adults, pregnant women and the immunocompromised.

Clinical features

The incubation period is 11–20 days, after which a vesicular eruption begins (Fig. 11.10), often on mucosal surfaces first, followed by rapid dissemination in a centripetal distribution (most dense on trunk and sparse on limbs). New lesions occur every 2–4 days and each crop is associated with fever. The rash progresses from small pink macules to vesicles and pustules within 24 hours. Infectivity lasts from up to 4 days (but usually 48 hours) before the lesions appear until the last vesicles crust over. Due to intense itching, secondary bacterial infection from scratching is the most common complication of primary chickenpox. Self-limiting cerebellar ataxia and encephalitis are rare complications.

Adults, pregnant women and the immunocompromised are at increased risk of visceral involvement, which presents as pneumonitis, hepatitis or encephalitis. Pneumonitis can be fatal and is more likely to occur in smokers. Maternal infection in

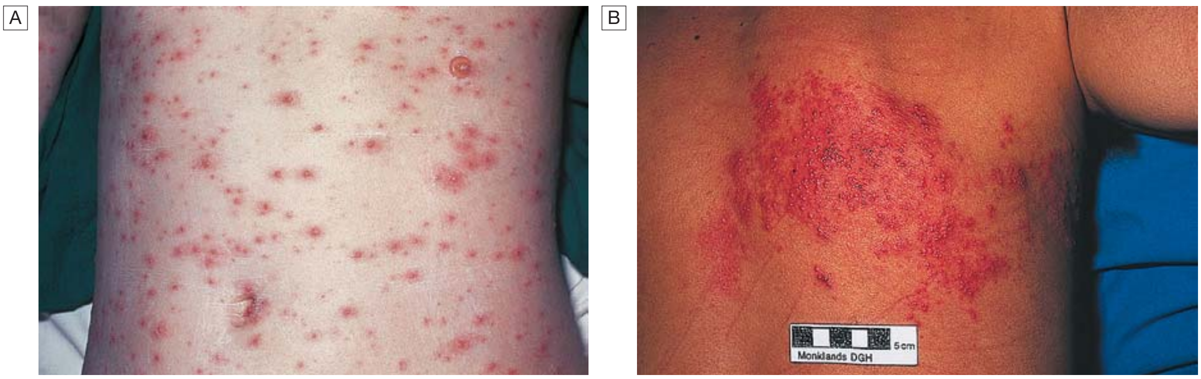

Fig. 11.10 Varicella zoster virus infection. A Chickenpox. B Shingles in a thoracic dermatome.

early pregnancy carries a 3% risk of neonatal damage with developmental abnormalities of eyes, CNS and limbs. Chickenpox within 5 days of delivery leads to severe neonatal varicella with visceral involvement and haemorrhage.

Diagnosis

Diagnosis is primarily clinical, by recognition of the rash. If necessary, this can be confirmed by detection of antigen (direct immunofluorescence) or DNA (PCR) of aspirated vesicular fluid. Serology is used to identify seronegative individuals at risk of infection.

Management and prevention

The benefits of antivirals for uncomplicated primary VZV infection in children are marginal, shortening the duration of rash by only 1 day, and treatment is not normally required. Antivirals are, however, used for uncomplicated chickenpox in adults when the patient presents within 24–48 hours of onset of vesicles, in all patients with complications, and in those who are immunocompromised, including pregnant women, regardless of duration of vesicles (Box 11.30). More severe disease, particularly in immunocompromised hosts, requires initial parenteral therapy. Immunocompromised patients may have prolonged viral shedding and may require prolonged treatment until all lesions crust over.

Human VZ immunoglobulin (VZIG) is used to attenuate infection in people who have had significant contact with VZV, are susceptible to infection (i.e. have no history of chickenpox or shingles and are seronegative for VZV IgG) and are at risk of severe disease (e.g. immunocompromised or pregnant) (Box 11.31). Ideally, VZIG should be given within 7 days of exposure, but it may attenuate disease even if given up to 10 days afterwards. Susceptible contacts who develop severe chickenpox after receiving VZIG should be treated with aciclovir.

A live, attenuated VZV vaccine is available and in routine use in the USA and other countries, but in the UK its use has been restricted to non-immune health-care workers and household contacts of immunocompromised individuals. Children receive one dose after 1 year of age and a second dose at 4–6 years of age; seronegative adults receive two doses at least 1 month apart. The vaccine may also be used prior to planned iatrogenic immunosuppression, e.g. before transplant and for the elderly aged over 70 to prevent shingles.

11.30 Therapy for herpes simplex and varicella zoster virus infection

Disease state	Treatment options
Primary genital HSV	Famciclovir 250 mg 3 times daily for 7–10 days Valaciclovir 1 g twice daily for 7–10 days Oral aciclovir 200 mg 5 times daily or 400 mg 3 times daily for 7–10 days
Severe and preventing oral intake	Aciclovir 5 mg/kg 3 times daily IV until patient can tolerate oral therapy
Recurrent genital HSV-1 or 2	Oral aciclovir 200 mg 5 times daily or 400 mg 3 times daily for 5 days Famciclovir 125 mg twice daily for 5 days Valaciclovir 500 mg twice daily for 3–5 days or 2 g twice daily for 1 day. Shorter durations increasingly favoured
Primary or recurrent oral HSV	Usually no treatment If required, usually short duration, e.g. valaciclovir 2 g twice daily for 1 day
Mucocutaneous HSV infection in immunocompromised host	Aciclovir 5 mg/kg 3 times daily IV for 7–10 days Oral aciclovir 400 mg 4 times daily for 7–10 days Famciclovir 500 mg 3 times daily for 7–10 days Valaciclovir 1 g twice daily for 7–10 days
Chickenpox in adult or child	Oral aciclovir 800 mg 5 times daily for 5 days Famciclovir 500 mg 3 times daily for 5 days Valaciclovir 1 g 3 times daily for 5 days
Immunocompromised host/pregnant woman	Aciclovir 5 mg/kg 3 times daily IV until patient is improving, then complete therapy with oral therapy until all lesions are crusting over
Shingles	Treatment and doses as for chickenpox but duration typically 7–10 days
Visceral involvement (non-CNS) in HSV	Aciclovir IV 5 mg/kg 3 times daily for 14 days
Visceral involvement (non-CNS) in VZV	Aciclovir IV 5 mg/kg 3 times daily for 7 days
Severe complications (encephalitis, disseminated infection)	Aciclovir IV 10 mg/kg 3 times daily (up to 20 mg/kg in neonates) for 14–21 days
HSV disease suppression	Aciclovir 400 mg twice daily Famciclovir 250 mg twice daily Valaciclovir 500 mg daily

(CNS = central nervous system; HSV = herpes simplex virus; VZV = varicella zoster virus)

Shingles (herpes zoster)

After initial infection, VZV persists in latent form in the dorsal root ganglion of sensory nerves and can reactivate in later life.

Clinical features

Burning discomfort occurs in the affected dermatome following reactivation and discrete vesicles appear 3–4 days later. This is associated with a brief viraemia, which can produce distant satellite ‘chickenpox’ lesions. Occasionally, paraesthesia occurs without rash (‘zoster sine herpete’). Severe disease, a prolonged duration of rash, multiple dermatomal involvement or recurrence suggests underlying immune deficiency, including HIV. Chickenpox may be contracted from a case of shingles but not vice versa.

Although thoracic dermatomes are most commonly involved (Fig. 11.10B), the ophthalmic division of the trigeminal nerve is also frequently affected; vesicles may appear on the cornea and lead to ulceration. This condition can lead to blindness and urgent ophthalmology review is required. Geniculate ganglion involvement causes the Ramsay Hunt syndrome of facial palsy, ipsilateral loss of taste and buccal ulceration, plus a rash in the external auditory canal. This may be mistaken for Bell’s palsy (p. 1082). Bowel and bladder dysfunction occur with sacral nerve root involvement. The virus occasionally causes cranial nerve palsy, myelitis or encephalitis. Granulomatous cerebral angiitis is a cerebrovascular complication that leads to a stroke-like syndrome in association with shingles, especially in an ophthalmic distribution.

Post-herpetic neuralgia causes troublesome persistence of pain for 1–6 months or longer, following healing of the rash. It is more common with advanced age.

i 11.31 Indications for varicella zoster immunoglobulin (VZIG) in adults

An adult should satisfy all three of the following conditions:

1. Significant contact

Contact with chickenpox (any time from 48 hrs before the rash until crusting of lesions) or zoster (exposed, disseminated or, with immunocompromised contacts, localised zoster; between development of the rash until crusting) defined as:
- Prolonged household contact, sharing a room for ≥15 mins or face-to-face contact (includes direct contact with zoster lesions)
- Hospital contact with chickenpox in another patient, health-care worker or visitor
- Intimate contact (e.g. touching) with person with shingles lesions
- Newborn whose mother develops chickenpox no more than 5 days before delivery or 2 days after delivery

2. Susceptible contact

- Individual with no history of chickenpox, ideally confirmed by negative test for VZV IgG

3. Predisposition to severe chickenpox

- Immunocompromised due to disease (e.g. acute leukaemia, HIV, other primary or secondary immunodeficiency)
- Medically immunosuppressed (e.g. following solid organ transplant; current or recent (<6 months) cytotoxic chemotherapy or radiotherapy; current or recent (<3 months) high-dose glucocorticoids; haematopoietic stem cell transplant)
- Pregnant (any stage)
- Infants: newborn whose mother has had chickenpox as above; premature infants <28 weeks

Management

Early therapy with aciclovir or related agents has been shown to reduce both early- and late-onset pain, especially in patients over 65 years. Post-herpetic neuralgia requires aggressive analgesia, along with agents such as amitriptyline 25–100 mg daily, gabapentin (commencing at 300 mg daily and building slowly to 300 mg twice daily or more) or pregabalin (commencing at 75 mg twice daily and building up to 100 mg or 200 mg 3 times daily if tolerated). Capsaicin cream (0.075%) may be helpful. Although controversial, glucocorticoids have not been demonstrated to reduce post-herpetic neuralgia to date.

Enteroviral exanthems

Coxsackie or echovirus infections can lead to a maculopapular eruption or roseola-like rash that occurs after fever falls. Enteroviral infections are discussed further under viral infections of the skin (see below).

Systemic viral infections without exanthem

Other systemic viral infections present with features other than a rash suggestive of exanthem. Rashes may occur in these conditions but differ from those seen in exanthems or are not the primary presenting feature.

Mumps

Mumps is a systemic viral infection characterised by swelling of the parotid glands. Infection is endemic worldwide and peaks at 5–9 years of age. Vaccination has reduced the incidence in children but incomplete coverage and waning immunity with

Fig. 11.11 Typical unilateral mumps. A Note the loss of angle of the jaw on the affected (right) side. B Comparison showing normal (left) side.

time have led to outbreaks in young adults. Infection is spread by respiratory droplets.

Clinical features

The median incubation period is 19 days, with a range of 15–24 days. Classical tender parotid enlargement, which is bilateral in 75%, follows a prodrome of pyrexia and headache (Fig. 11.11). Meningitis complicates up to 10% of cases. The CSF reveals a lymphocytic pleocytosis or, less commonly, neutrophils. Rare complications include encephalitis, transient hearing loss, labyrinthitis, electrocardiographic abnormalities, pancreatitis and arthritis.

Approximately 25% of post-pubertal males with mumps develop epididymo-orchitis but, although testicular atrophy occurs, sterility is unlikely. Oophoritis is less common. Abortion may occur if infection takes place in the first trimester of pregnancy. Complications may occur in the absence of parotitis.

Diagnosis

The diagnosis is usually clinical. In atypical presentations without parotitis, serology for mumps-specific IgM or IgG seroconversion (fourfold rise in IgG convalescent titre) confirms the diagnosis. Virus can also be cultured from urine in the first week of infection or detected by PCR in urine, saliva or CSF.

Management and prevention

Treatment is with analgesia. There is no evidence that glucocorticoids are of value for orchitis. Mumps vaccine is one of the components of the combined MMR vaccine.

Influenza

Influenza is an acute systemic viral infection that primarily affects the respiratory tract and carries a significant mortality. It is caused by influenza A virus or, in milder form, influenza B virus. Infection is seasonal, and variation in the haemagglutinin (H) and neuraminidase (N) glycoproteins on the surface of the virus leads to disease of variable intensity each year. Minor changes in haemagglutinin are known as 'genetic drift', whereas a switch in the haemagglutinin or neuraminidase antigen is termed 'genetic shift'. Nomenclature of influenza strains is based on these glycoproteins, e.g. H1N1, H3N2 etc. Genetic shift results in the circulation of a new influenza strain within a community to

which few people are immune, potentially initiating an influenza epidemic or pandemic in which there is a high attack rate and there may be increased disease severity.

Clinical features

After an incubation period of 1–3 days, uncomplicated disease leads to fever, malaise and cough. Viral pneumonia may occur, although pulmonary complications are most often due to superinfection with *Strep. pneumoniae*, *Staph. aureus* or other bacteria. Rare extrapulmonary manifestations include myositis, myocarditis, pericarditis and neurological complications (Reye's syndrome in children, encephalitis or transverse myelitis). Mortality is greatest in the elderly, those with medical comorbidities and pregnant women. Polymorphisms in the gene encoding an antiviral protein, interferon-induced transmembrane protein 3 (IFITM3), are associated with more severe influenza.

Diagnosis

Acute infection is diagnosed by viral antigen or RNA detection in a nasopharyngeal sample. The disease may also be diagnosed retrospectively by serology.

Management and prevention

Management involves early microbiological identification of cases and good infection control, with an emphasis on hand hygiene and preventing dissemination of infection by coughing and sneezing. Administration of neuraminidase inhibitor, oral oseltamivir (75 mg twice daily) or inhaled zanamivir (10 mg twice daily) for 5 days, can reduce the severity of symptoms if started within 48 hours of symptom onset (or possibly later in immunocompromised individuals). These agents have superseded routine use of amantadine and rimantadine. Antiviral drugs can also be used as prophylaxis in high-risk individuals during the 'flu' season. Resistance can emerge to all of these agents and so updated local advice should be followed with regard to the sensitivity to antivirals of the circulating strain.

Prevention relies on seasonal vaccination of the elderly, children 2–7 years of age and individuals with chronic medical illnesses that place them at increased risk of the complications of influenza, such as chronic cardiopulmonary diseases or immune compromise, as well as their health-care workers. The vaccine composition changes each year to cover the 'predicted' seasonal strains but vaccination may fail when a new pandemic strain emerges.

Avian influenza

Avian influenza is caused by transmission of avian influenza A viruses to humans. Avian viruses, such as H5N1, possess alternative haemagglutinin antigens to seasonal influenza strains. Most cases have had contact with sick poultry, predominantly in South-east Asia, and person-to-person spread has been limited to date. Infections with H5N1 viruses have been severe, with enteric features and respiratory failure. Treatment depends on the resistance pattern but often involves oseltamivir. Vaccination against seasonal 'flu' does not adequately protect against avian influenza. There is a concern that adaptation of an avian strain to allow effective person-to-person transmission is likely to lead to a global pandemic of life-threatening influenza.

Swine influenza

Re-assortment of swine, avian and human influenza strains can occur in pigs and lead to outbreaks of swine 'flu' in humans, as occurred in 2009, when an outbreak of H1N1pdm2009 influenza spread around the world from Mexico. Cases were still occurring in the Indian subcontinent in 2014–16. Symptoms included more gastrointestinal symptoms than with seasonal influenza, respiratory failure and seizures or encephalitis. Severe disease was a feature of infants, adults less than 50 years, those with chronic lung or neurological disease, obese patients and pregnant women, but with time the clinical features have become indistinguishable from those of seasonal influenza.

Infectious mononucleosis and Epstein–Barr virus

Infectious mononucleosis (IM) is a clinical syndrome characterised by pharyngitis, cervical lymphadenopathy, fever and lymphocytosis (known colloquially as glandular fever). It is most often caused by Epstein–Barr virus (EBV) but other infections can produce a similar clinical syndrome (Box 11.32).

EBV is a gamma herpesvirus. In developing countries, subclinical infection in childhood is virtually universal. In developed countries, primary infection may be delayed until adolescence or early adult life. Under these circumstances, about 50% of infections result in typical IM. The virus is usually acquired from asymptomatic excreters via saliva, either by droplet infection or environmental contamination in childhood, or by kissing among adolescents and adults. EBV is not highly contagious and isolation of cases is unnecessary.

Clinical features

EBV infection has a prolonged but undetermined incubation period, followed in some cases by a prodrome of fever, headache and malaise. This is followed by IM with severe pharyngitis, which may include tonsillar exudates and non-tender anterior and posterior cervical lymphadenopathy. Palatal petechiae, periorbital oedema, splenomegaly, inguinal or axillary lymphadenopathy, and macular, petechial or erythema multiforme rashes may occur. In most cases, fever resolves over 2 weeks, and fatigue and other abnormalities settle over a further few weeks. Complications are listed in Box 11.33. Death is rare but can occur due to respiratory obstruction, haemorrhage from splenic rupture, thrombocytopenia or encephalitis.

The diagnosis of EBV infection outside the usual age in adolescence and young adulthood is more challenging. In children under 10 years the illness is mild and short-lived, but in adults over 30 years of age it can be severe and prolonged. In both groups, pharyngeal symptoms are often absent. EBV may present with jaundice, as a PUO or with a complication.

Long-term complications of EBV infection

Lymphoma complicates EBV infection in immunocompromised hosts, and some forms of Hodgkin lymphoma are EBV-associated (p. 961). The endemic form of Burkitt's lymphoma complicates EBV infection in areas of sub-Saharan Africa where *falciparum* malaria is endemic. Nasopharyngeal carcinoma is a geographically restricted tumour seen in China and Alaska that is associated with EBV infection. X-linked lymphoproliferative (Duncan's) syndrome is a familial lymphoproliferative disorder that follows primary EBV infection in boys without any other history of immunodeficiency;

11.32 Causes of infectious mononucleosis syndrome

- Epstein–Barr virus infection
- Cytomegalovirus
- Human herpesvirus-6 or 7
- HIV-1 primary infection (p. 311)
- Toxoplasmosis

it is due to mutation of the *SAP* gene, causing failure of T-cell and NK-cell activation and inability to contain EBV infection.

Investigations

Atypical lymphocytes are common in EBV infection but also occur in other causes of IM, acute retroviral syndrome with HIV infection, viral hepatitis, mumps and rubella (Fig. 11.12A). They are also a feature of dengue, malaria and other geographically restricted infections (see Box 11.19). A 'heterophile' antibody is present during the acute illness and convalescence, which is detected by the Paul–Bunnell or 'Monospot' test. (A heterophile antibody is an antibody that has affinity for antigens other than the specific one, in this case animal immunoglobulins; the Paul–Bunnell and Monospot tests exploit this feature by detecting the ability of test serum to agglutinate sheep and horse red blood cells, respectively.). Sometimes antibody production is delayed, so an initially negative test should be repeated. However, many children and 10% of adolescents with IM do not produce heterophile antibody at any stage.

Specific EBV serology confirms the diagnosis. Acute infection is characterised by IgM antibodies against the viral capsid, antibodies to EBV early antigen and the initial absence of antibodies to EBV nuclear antigen (anti-EBNA). Seroconversion of anti-EBNA at approximately 1 month after the initial illness may confirm the diagnosis in retrospect. CNS infections may be diagnosed by detection of viral DNA in CSF.

11.33 Complications of Epstein–Barr virus infection

Common	
• Severe pharyngeal oedema • Antibiotic-induced rash (80–90% with ampicillin) • Hepatitis (80%)	• Prolonged post-viral fatigue (10%) • Jaundice (<10%)
Uncommon	
Neurological	
• Cranial nerve palsies • Polyneuritis	• Transverse myelitis • Meningoencephalitis
Haematological	
• Haemolytic anaemia	• Thrombocytopenia
Renal	
• Abnormalities on urinalysis	• Interstitial nephritis
Cardiac	
• Myocarditis • ECG abnormalities	• Pericarditis
Rare	
• Ruptured spleen • Respiratory obstruction • Agranulocytosis	• X-linked lymphoproliferative syndrome
EBV-associated malignancy	
• Nasopharyngeal carcinoma • Burkitt's lymphoma • Hodgkin lymphoma (certain subtypes only)	• Primary CNS lymphoma • Lymphoproliferative disease in immunocompromised

Management

Treatment is largely symptomatic. If a throat culture yields a β-haemolytic streptococcus, penicillin should be given. Administration of ampicillin or amoxicillin in this condition commonly causes an itchy macular rash and should be avoided (Fig. 11.12B). When pharyngeal oedema is severe, a short course of glucocorticoids, e.g. prednisolone 30 mg daily for 5 days, may help. Current antiviral drugs are not active against EBV.

Return to work or school is governed by physical fitness rather than laboratory tests; contact sports should be avoided until splenomegaly has resolved because of the danger of splenic rupture. Unfortunately, about 10% of patients with IM suffer a chronic relapsing syndrome.

Cytomegalovirus

Cytomegalovirus (CMV), like EBV, circulates readily among children. A second period of virus acquisition occurs among teenagers and young adults, peaking between the ages of 25 and 35 years, rather later than with EBV infection. CMV infection is persistent, and is characterised by subclinical cycles of active virus replication and by persistent low-level virus shedding. Most post-childhood infections are therefore acquired from asymptomatic excreters who shed virus in saliva, urine, semen and genital secretions. Sexual transmission and oral spread are common among adults but infection may also be acquired by women caring for children with asymptomatic infections.

Clinical features

Most post-childhood CMV infections are subclinical, although some young adults develop an IM-like syndrome and some have a prolonged influenza-like illness lasting 2 weeks or more. Physical signs resemble those of IM but in CMV infections hepatomegaly is

A B

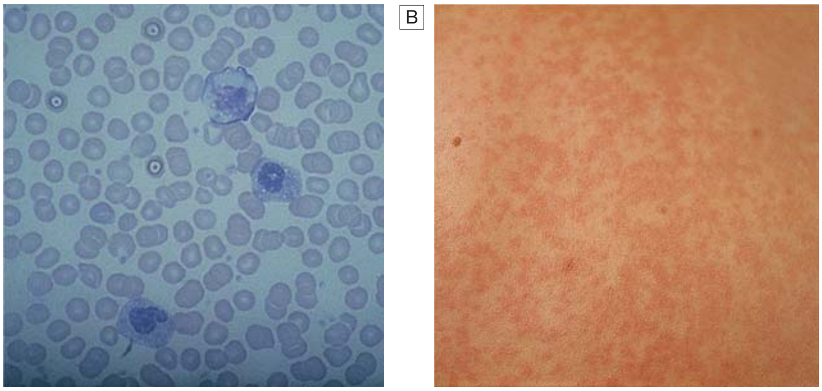

Fig. 11.12 Features of infectious mononucleosis. A Atypical lymphocytes in peripheral blood. B Skin reaction to ampicillin.

more common, while lymphadenopathy, splenomegaly, pharyngitis and tonsillitis occur less often. Jaundice is uncommon and usually mild. Complications include meningoencephalitis, Guillain–Barré syndrome, autoimmune haemolytic anaemia, thrombocytopenia, myocarditis and skin eruptions, such as ampicillin-induced rash. Immunocompromised patients can develop hepatitis, oesophagitis, colitis, pneumonitis, retinitis, encephalitis and polyradiculitis.

Women who develop a primary CMV infection during pregnancy have about a 40% chance of passing CMV to the fetus, causing congenital infection and disease at any stage of gestation. Features include petechial rashes, hepatosplenomegaly and jaundice; 10% of infected infants will have long-term CNS sequelae, such as microcephaly, cerebral calcifications, chorioretinitis and deafness. Infections in the newborn usually are asymptomatic or have features of an IM-like illness, although some studies suggest that subtle sequelae affecting hearing or mental development may occur.

Investigations

Atypical lymphocytosis is not as prominent as in EBV infection and heterophile antibody tests are usually negative. LFTs are often abnormal, with an alkaline phosphatase level raised out of proportion to transaminases. Serological diagnosis depends on the detection of CMV-specific IgM antibody plus a fourfold rise or seroconversion of IgG. In the immunocompromised, antibody detection is unreliable and detection of CMV in an involved organ by PCR, antigen detection, culture or histopathology establishes the diagnosis. Detection of CMV in the blood may be useful in transplant populations but not in HIV-positive individuals, since in HIV infection CMV reactivates at regular intervals, but these episodes do not correlate well with episodes of clinical disease. Detection of CMV in urine is not helpful in diagnosing infection, except in neonates, since CMV is intermittently shed in the urine throughout life following infection.

Management

Only symptomatic treatment is required in the immunocompetent patient. Immunocompromised individuals are treated with ganciclovir 5 mg/kg IV twice daily or with oral valganciclovir 900 mg twice daily for at least 14 days. Foscarnet or cidofovir is also used in CMV treatment of immunocompromised patients who are resistant to or intolerant of ganciclovir-based therapy. They can be given intravitreally if required.

Dengue

Dengue is a febrile illness caused by a flavivirus transmitted by mosquitoes. It is endemic in Asia, the Pacific, Africa and the Americas (Fig. 11.13). Approximately 400 million infections and 100 million clinically apparent infections occur annually, and dengue is the most rapidly spreading mosquito-borne viral illness. The principal vector is the mosquito *Aedes aegypti*, which breeds in standing water; collections of water in containers, water-based air coolers and tyre dumps are a good environment for the vector in large cities. *Aedes albopictus* is a vector in some South-east Asian countries. There are four serotypes of dengue virus, all producing a similar clinical syndrome; type-specific immunity is life-long but immunity against the other serotypes lasts only a few months. Dengue haemorrhagic fever (DHF) and dengue shock syndrome (DSS) occur in individuals who are immune to one dengue virus serotype and are then infected with another. Prior immunity results in increased uptake of virus by cells expressing the antibody Fc receptor and increased T-cell activation with resultant cytokine release, causing capillary leak and disseminated intravascular coagulation (DIC; p. 978). Previously, dengue was seen in small children and DHF/DSS in children 2–15 years old, but these conditions are now being seen in children less than 2 years old, and most frequently in those 16–45 years of age or older, in whom severe organ dysfunction is more common. Other epidemiological changes include the spread of dengue into rural communities and greater case fatality in women.

Clinical features

Many cases of dengue infection are asymptomatic in children. Clinical disease presents with undifferentiated fever termed dengue-like illness. When dengue infection occurs with characteristic symptoms or signs it is termed 'dengue' (Box 11.34). A rash frequently follows the initial febrile phase as the fever settles. Laboratory features include leucopenia, neutropenia,

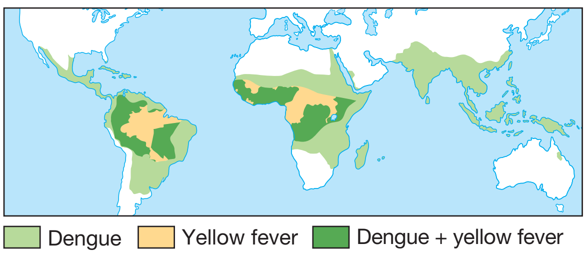

Fig. 11.13 Endemic zones of yellow fever and dengue.

11.34 Clinical features of dengue fever

Incubation period
• 2–7 days
Prodrome
• 2 days of malaise and headache
Acute onset
• Fever, backache, arthralgias, headache, generalised pains ('break-bone fever'), pain on eye movement, lacrimation, scleral injection, anorexia, nausea, vomiting, pharyngitis, upper respiratory tract symptoms, relative bradycardia, prostration, depression, hyperaesthesia, dysgeusia, lymphadenopathy
Fever
• Continuous or 'saddle-back', with break on 4th or 5th day and then recrudescence; usually lasts 7–8 days
Rash
• Initial flushing faint macular rash in first 1–2 days. Maculopapular, scarlet morbilliform blanching rash from days 3–5 on trunk, spreading centrifugally and sparing palms and soles; onset often with fever defervescence. May desquamate on resolution or give rise to petechiae on extensor surfaces
Convalescence
• Slow and may be associated with prolonged fatigue syndrome, arthralgia or depression
Complications
• Dengue haemorrhagic fever and disseminated intravascular coagulation • Dengue shock syndrome • Severe organ involvement • Vertical transmission if infection within 5 weeks of delivery

thrombocytopenia and elevated alanine aminotransferase (ALT) or aspartate aminotransferase (AST). Many symptomatic infections run an uncomplicated course but complications or a protracted convalescence may ensue. Warning signs justify intense medical management and monitoring for progression to severe dengue. Atypical clinical features of dengue are increasingly common, especially in infants or older patients (Box 11.35). These, along with DHF or DSS, are recognised as features of severe dengue in the 2015 case definition.

The period 3–7 days after onset of fever is termed the 'critical' phase, during which signs of DHF or DSS may develop. In mild forms, petechiae occur in the arm when a blood pressure cuff is inflated to a point between systolic and diastolic blood pressure and left for 5 minutes (the positive 'tourniquet test') – a non-specific test of capillary fragility and thrombocytopenia. As the extent of capillary leak increases, DSS develops, with a raised haematocrit, tachycardia and hypotension, pleural effusions and ascites. This may progress to metabolic acidosis and multi-organ failure, including acute respiratory distress syndrome (ARDS; p. 198). Minor (petechiae, ecchymoses, epistaxis) or major (gastrointestinal or vaginal) haemorrhage, a feature of DHF, may occur. Cerebrovascular bleeding may be a complication of severe dengue.

i 11.35 WHO case definitions of dengue, 2015

Probable dengue fever

- Exposure in an endemic area
- Fever
- Two of:
  - Nausea/vomiting
  - Rash
  - Aches/pains
  - Positive tourniquet test
  - Leucopenia
  - Any warning sign

Laboratory confirmation important

Needs regular medical observation and instruction in the warning signs

If there are no warning signs, need for hospitalisation is influenced by age, comorbidities, pregnancy and social factors

Dengue with warning signs

- Probable dengue plus one of:
  - Abdominal pain or tenderness
  - Persistent vomiting
  - Signs of fluid accumulation, e.g. pleural effusion or ascites
  - Mucosal bleed
  - Hepatomegaly >2 cm
  - Rapid increase in haematocrit with fall in platelet count

Needs medical intervention, e.g. intravenous fluid

Severe dengue

- Severe plasma leakage leading to:
  - Shock (dengue shock syndrome)
  - Fluid accumulation with respiratory distress
- Severe haemorrhagic manifestations, e.g. gastrointestinal haemorrhage
- Severe organ involvement (atypical features):
  - Liver AST or ALT ≥1000 U/L
  - CNS: impaired consciousness, meningoencephalitis, seizures
  - Cardiomyopathy, conduction defects, arrhythmias
  - Other organs, e.g. acute kidney injury, pancreatitis, acute lung injury, disseminated intravascular coagulopathy, rhabdomyolysis

Needs emergency medical treatment and specialist care with intensive care input

(ALT = alanine aminotransferase; AST = aspartate aminotransferase)
Adapted from https://wwwn.cdc.gov/nndss/conditions/dengue-virus-infections/case-definition/2015/

Diagnosis

In endemic areas, mild dengue must be distinguished from other viral infections. The diagnosis can be confirmed by seroconversion of IgM or a fourfold rise in IgG antibody titres. Serological tests may detect cross-reacting antibodies from infection or vaccination against other flaviviruses, including yellow fever virus, Japanese encephalitis virus and West Nile virus. Isolation of dengue virus or detection of dengue virus RNA by PCR (p. 106) in blood or CSF is available in specialist laboratories. Commercial enzyme-linked immunosorbent assay (ELISA) kits to detect the NS1 viral antigen, although less sensitive than PCR, are available in many endemic areas.

Management and prevention

Treatment is supportive, emphasising fluid replacement and appropriate management of shock and organ dysfunction, which is a major determinant of morbidity and mortality. With intensive care support, mortality rates are 1% or less. Aspirin should be avoided due to bleeding risk. Glucocorticoids have not been shown to help. No existing antivirals are effective.

Breeding places of *Aedes* mosquitoes should be abolished and the adults destroyed by insecticides. A recently licensed vaccine is available.

Yellow fever

Yellow fever is a haemorrhagic fever of the tropics, caused by a flavivirus. It is a zoonosis of monkeys in West and Central African, and South and Central American tropical rainforests, where it may cause devastating epidemics (Fig. 11.13). Transmission is by tree-top mosquitoes, *Aedes africanus* (Africa) and *Haemagogus* spp. (America). The infection is introduced to humans either by infected mosquitoes when trees are felled, or by monkeys raiding human settlements. In towns, yellow fever may be transmitted between humans by *Aedes aegypti*, which breeds efficiently in small collections of water. The distribution of this mosquito is far wider than that of yellow fever, and more widespread infection is a continued threat.

Yellow fever causes approximately 200 000 infections each year, mainly in sub-Saharan Africa, and the number is increasing. Overall mortality is around 15%, although this varies widely. Humans are infectious during the viraemic phase, which starts 3–6 days after the bite of the infected mosquito and lasts for 4–5 days.

Clinical features

After an incubation period of 3–6 days, yellow fever is often a mild febrile illness lasting less than 1 week, with headache, myalgia, conjunctival erythema and bradycardia. This is followed by fever resolution (defervescence) but, in some cases, fever recurs after a few hours to days. In more severe disease, fever recrudescence is associated with lower back pain, abdominal pain and somnolence, prominent nausea and vomiting, bradycardia and jaundice. Liver damage and DIC lead to bleeding with petechiae, mucosal haemorrhages and gastrointestinal bleeding. Shock, hepatic failure, renal failure, seizures and coma may ensue.

Diagnosis

The differential diagnosis includes malaria, typhoid, viral hepatitis, leptospirosis, haemorrhagic fevers and aflatoxin poisoning. Diagnosis of yellow fever can be confirmed by detection of virus in the blood in the first 3–4 days of illness (e.g. by culture or reverse transcription polymerase chain reaction (RT-PCR)), the presence of IgM or a fourfold rise in IgG antibody titre. Leucopenia is characteristic. Liver biopsy should be avoided in life due to the risk of fatal bleeding. Postmortem features, such as acute mid-zonal necrosis and Councilman bodies with minimal inflammation in the liver, are suggestive but not specific. Immunohistochemistry for viral antigens improves specificity.

Management and prevention

Treatment is supportive, with meticulous attention to fluid and electrolyte balance, urine output and blood pressure. Blood transfusions, plasma expanders and peritoneal dialysis may be necessary. Patients should be isolated, as their blood and body products may contain virus particles.

A single vaccination with a live attenuated vaccine gives full protection for at least 10 years and many travellers do not require a booster unless specified by individual countries' travel requirements. Potential side-effects include hypersensitivity, encephalitis and systemic features of yellow fever (viscerotropic disease) caused by the attenuated virus. Vaccination is not recommended in people who are significantly immunosuppressed. The risk of vaccine side-effects must be balanced against the risk of infection for less immunocompromised hosts, pregnant women and older patients. An internationally recognised certificate of vaccination is sometimes necessary when crossing borders.

Viral haemorrhagic fevers

Viral haemorrhagic fevers (VHFs) are zoonoses caused by several different viruses (Box 11.36). They are geographically restricted and previously occurred in rural settings or in health-care facilities. The largest outbreak of VHF to date started in 2014, with Ebola

11.36 Viral haemorrhagic fevers

Disease	Reservoir	Transmission	Incubation period	Geography	Mortality rate	Clinical features of severe disease[1]
Lassa fever	Multimammate rats (*Mastomys natalensis*)	Urine from rat Body fluids from patients	6–21 days	West Africa	15%	Haemorrhage, shock, encephalopathy, ARDS (responds to ribavirin), deafness in survivors
Ebola fever	Fruit bats (*Pteropodidae* family) and bush meat	Body fluids from patients Handling infected primates	2–21 days	Central Africa Outbreaks as far north as Sudan	25–90%	Haemorrhage and/or diarrhoea, hepatic failure and acute kidney injury
Marburg fever	Undefined	Body fluids from patients Handling infected primates	3–9 days	Central Africa Outbreak in Angola	25–90%	Haemorrhage, diarrhoea, encephalopathy, orchitis
Yellow fever	Monkeys	Mosquitoes	3–6 days	See Figure 11.13	~15%	Hepatic failure, acute kidney injury, haemorrhage
Dengue	Humans	*Aedes aegypti*	2–7 days	See Figure 11.13	<10%[2]	Haemorrhage, shock
Crimean–Congo haemorrhagic fever	Small vertebrates Domestic and wild animals	*Ixodes* tick Body fluids	1–3 days up to 9 days 3–6 days up to 13 days	Africa, Asia, Eastern Europe	30%	Encephalopathy, early haemorrhage, hepatic failure, acute kidney injury, ARDS
Rift Valley fever	Domestic livestock	Contact with animals, mosquito or other insect bites	2–6 days	Africa, Arabian peninsula	1%	Haemorrhage, blindness, meningoencephalitis (complications only in a minority)
Kyasanur fever	Monkeys	Ticks	3–8 days	Karnataka State, India	5–10%	Haemorrhage, pulmonary oedema, neurological features, iridokeratitis in survivors
Bolivian and Argentinian haemorrhagic fever (Junin and Machupo viruses)	Rodents (*Calomys* spp.)	Urine, aerosols Body fluids from case (rare)	5–19 days (3–6 days for parenteral)	South America	15–30%	Haemorrhage, shock, cerebellar signs (may respond to ribavirin)
Haemorrhagic fever with renal syndrome (Hantaan fever)	Rodents	Aerosols from faeces	5–42 days (typically 14 days)	Northern Asia, northern Europe, Balkans	5%	Acute kidney injury, cerebrovascular accidents, pulmonary oedema, shock (hepatic failure and haemorrhagic features only in some variants)

[1]All potentially have circulatory failure. [2]Mortality of uncomplicated and haemorrhagic dengue fever, respectively.
(ARDS = acute respiratory distress syndrome)

circulating in Guinea, Liberia and Sierra Leone. The outbreak resulted in over 28 000 cases by 2016.

Serological surveys have shown that Lassa fever is widespread in West Africa and may lead to up to 500 000 infections annually. Mortality overall may be low, as 80% of cases are asymptomatic, but in hospitalised cases mortality averages 15%. Ebola outbreaks have occurred at a rate of approximately one per year in Africa, involving up to a few hundred cases prior to the 2014 outbreak. Marburg has been documented less frequently, with outbreaks in the Democratic Republic of Congo and Uganda, but the largest outbreak to date involved 163 cases in Angola in 2005. Mortality rates of Ebola and Marburg are high.

VHFs have extended into Europe, with an outbreak of Congo–Crimean haemorrhagic fever (CCHF) in Turkey in 2006, and cases of haemorrhagic fever with renal syndrome in the Balkans and Russia. An outbreak of CCHF in 2011 in Gujarat, India, involved several health-care workers and emphasised the importance of maintaining a high index of suspicion for VHF and implementing appropriate infection control measures at the first opportunity. Kyasanur forest disease is a tick-borne VHF currently confined to a small focus in Karnataka, India; there are about 500 cases annually. Monkeys are the principal hosts but, with forest felling, there are fears that this disease will increase.

New outbreaks and new agents are identified sporadically. Details on recent disease outbreaks can be found at the WHO website (see 'Further information').

Clinical features

VHFs present with non-specific fever, malaise, body pains, sore throat and headache. On examination, conjunctivitis, throat injection, an erythematous or petechial rash, haemorrhage, lymphadenopathy and bradycardia may be noted. The viruses cause endothelial dysfunction with the development of capillary leak. Bleeding is due to endothelial damage and platelet dysfunction. Hypovolaemic shock and ARDS may develop (p. 198).

Haemorrhage is a late feature of most VHFs and most patients present with earlier features. In Lassa fever, joint and abdominal pain is prominent. A macular blanching rash may be present but bleeding is unusual, occurring in only 20% of hospitalised patients. Encephalopathy may develop and deafness affects 30% of survivors. In CCHF, bleeding, manifest by haematemesis or bleeding per rectum, may be an early feature, accompanied by derangement of LFTs.

The clue to the viral aetiology comes from the travel and exposure history. Travel to an outbreak area, activity in a rural environment and contact with sick individuals or animals within 21 days all increase the risk of VHF. Enquiry should be made about insect bites, hospital visits and attendance at ritual funerals (Ebola virus infection). For Lassa fever, retrosternal pain, pharyngitis and proteinuria have a positive predictive value of 80% in West Africa.

Investigations and management

Non-specific findings include leucopenia, thrombocytopenia and proteinuria. In Lassa fever, an AST of >150 U/L is associated with a 50% mortality. It is important to exclude other causes of fever, especially malaria, typhoid and respiratory tract infections. Most patients suspected of having a VHF in the UK turn out to have malaria.

A febrile patient from an endemic area within the 21-day incubation period, who has specific epidemiological risk factors (see Fig. 11.6) or signs of organ failure or haemorrhage, should be treated as being at high risk of VHF; appropriate infection control measures must be implemented and the patient transferred to a centre with biosafety level (BSL) 4 facilities if testing positive. Individuals with a history of travel within 21 days and fever, but without the relevant epidemiological features or signs of VHF, are classified as medium-risk and should have an initial blood sample tested to exclude malaria. If this is negative, relevant specimens (blood, throat swab, urine and pleural fluid, if available) are collected and sent to an appropriate reference laboratory for nucleic acid detection (PCR), virus isolation and serology. If patients are still felt to be at significant risk of VHF or if infection is confirmed, they should be transferred to a specialised high-security infectious disease unit. All further laboratory tests should be performed at BSL 4. Transport requires an ambulance with BSL 3 facilities.

In addition to general supportive measures, ribavirin is given intravenously (100 mg/kg, then 25 mg/kg daily for 3 days and 12.5 mg/kg daily for 4 days) when Lassa fever or South American haemorrhagic fevers are suspected.

Prevention

Ribavirin has been used as prophylaxis in close contacts in Lassa fever but there are no formal trials of its efficacy.

Ebola virus disease (EVD)

Ebola virus disease (EVD) is thought to spread to human populations from fruit bats, sometimes indirectly via contact with infected primates or other animals. Person-to-person spread, via contact with blood, secretions or body parts, establishes EVD in populations. Family members, health-care workers and people performing traditional burials are at particular risk. The 2014 outbreak involved the Zaire strain of Ebola virus.

Clinical features

The incubation period is 2–21 days but typically 8–10 days. Fever and non-specific signs are accompanied by abdominal pain, diarrhoea, vomiting and hiccups. A maculopapular rash occurs after 5–7 days in some. Although bleeding from the gums or venepuncture sites or in the stool occurs, haemorrhage may be less prominent than in other VHFs and is often a terminal event, as observed in the 2014 epidemic. In contrast, fluid losses from diarrhoea are more marked and reach 10 L a day. Complications include meningoencephalitis, uveitis and miscarriages in pregnant women.

Investigations

Lymphopenia occurs, followed by neutrophilia, atypical lymphocytes, thrombocytopenia and coagulation abnormalities. Elevations of AST/ALT, features of acute kidney injury, electrolyte disturbances and proteinuria are also observed. The virus is detected by a PCR in blood or body fluids, but may need retesting if the duration of symptoms is less than 3 days. Serology provides a retrospective diagnosis.

Management

Treatment is supportive and aimed at fluid replacement. Bacterial super-infections should be promptly treated. A cocktail of monoclonal antibodies against Ebola virus, ZMapp, has been used in a few cases, but efficacy requires further studies. Mortality is approximately 40%. Survivors recover from the second week of illness but experience late sequelae, including arthritis (76%), uveitis (60%) and deafness (24%), while skin sloughing is common. Relapse with meningitis is reported months after recovery.

Prevention

Ebola virus may be detected in the semen months after recovery. Male survivors are therefore encouraged to practise safe sex for 12 months after symptom onset or until semen tests negative on two occasions, but recommendations are evolving. Public health measures are essential for outbreak control and involve contact surveillance and monitoring through the incubation period, separating healthy from sick individuals, practising safe burial methods and ensuring appropriate infection control measures to protect health-care and laboratory workers, including provision of personal protective equipment such as gloves, gowns and full-face protection (face shield or masks combined with goggles). An Ebola glycoprotein vaccine, rVZV-ZEBOV, was shown to be effective in 2016 after a trial in West Africa.

Zika virus

Zika virus is a flavivirus spread from primate hosts by *Aedes aegypti* and *Aedes albopictus*, which bite during the day. Described in Africa and Asia since 2015, it has been epidemic in the Caribbean and Central and South America, where a mosquito–man–mosquito transmission cycle is established. It also can be transmitted in semen.

Clinical features

The incubation period is 3–12 days. Infection is asymptomatic or mild, resembling dengue with fever, arthralgia, conjunctivitis and maculopapular rash. Complications include increased reports of Guillain–Barré syndrome. The major concern has been a marked increase in microcephaly in pregnant women infected with Zika virus, as well as increased rates of cerebral calcification, deafness, visual problems such as chorioretinal scarring, joint contractures (arthrogryposis), hydrops fetalis and growth retardation. Zika virus appears to infect neural progenitor cells.

Investigations

Routine blood tests are usually normal but may show leucopenia, thrombocytopenia or increased transaminases. PCR detects virus in the first week of illness or in urine up to 14 days. Serology provides a retrospective diagnosis but cross-reacts with other flaviruses. Plaque-reduction neutralisation testing can be used to detect virus-specific neutralising antibodies and distinguish between cross-reacting antibodies in primary flavivirus infections.

Prevention

Prevention focuses on avoiding mosquito bites. Since Zika virus may be found in the semen or genital secretions for prolonged periods, infected individuals should practise safe sex for at least 6 months and planned pregnancy should be postponed for at least 6 months. Individuals who have travelled to an endemic area but are asymptomatic should practise safe sex and avoid pregnancy for at least 2 months. As this is an evolving area, updated guidance should be sought. There is currently no vaccine.

Viral infections of the skin

Herpes simplex virus 1 and 2

Herpes simplex viruses (HSVs) cause recurrent mucocutaneous infection; HSV-1 typically involves the mucocutaneous surfaces of the head and neck (Fig. 11.14), while HSV-2 predominantly involves the genital mucosa (pp. 333 and 336), although there is overlap (see Box 11.29). The seroprevalence of HSV-1 is 30–100%, varying by socioeconomic status, while that of HSV-2 is 20–60%. Infection is acquired by inoculation of viruses shed by an infected individual on to a mucosal surface in a susceptible person. The virus infects sensory and autonomic neurons and establishes latent infection in the nerve ganglia. Primary infection is followed by episodes of reactivation throughout life.

Clinical features

Primary HSV-1 or 2 infection is more likely to be symptomatic later in life, causing gingivostomatitis, pharyngitis or painful genital tract lesions. The primary attack may be associated with fever and regional lymphadenopathy.

Recurrence

Recurrent attacks occur throughout life, most often in association with concomitant medical illness, menstruation, mechanical trauma, immunosuppression, psychological stress or, for oral lesions, ultraviolet light exposure. HSV reactivation in the oral mucosa produces the classical ‘cold sore’ or ‘herpes labialis’. Prodromal hyperaesthesia is followed by rapid vesiculation, pustulation and crusting. Recurrent HSV genital disease is a common cause of recurrent painful ulceration (pp. 333 and 336). An inoculation lesion on the finger gives rise to a paronychia, termed a ‘whitlow’, in contacts of patients with herpetic lesions (Fig. 11.14B).

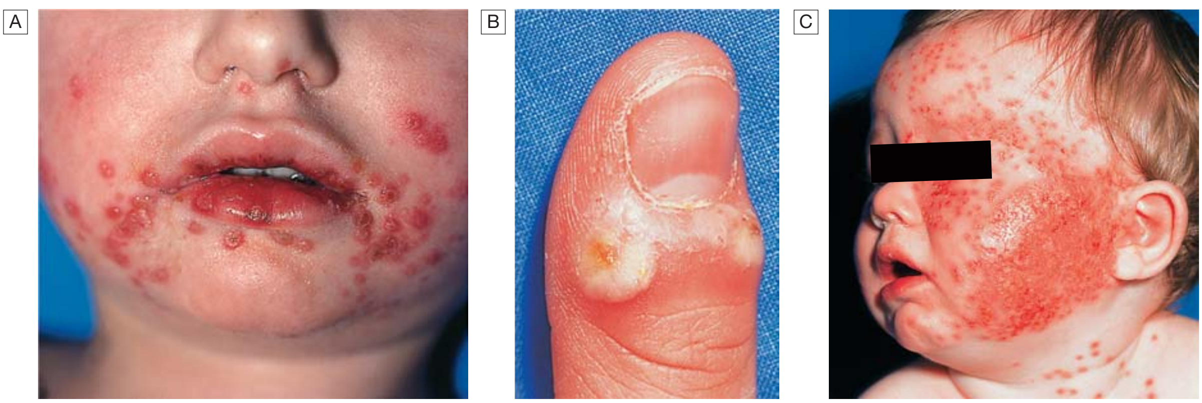

Fig. 11.14 Cutaneous manifestations of herpes simplex virus 1 (HSV-1). **A** Acute HSV-1. There were also vesicles in the mouth – herpetic stomatitis. **B** Herpetic whitlow. **C** Eczema herpeticum. HSV-1 infection spreads rapidly in eczematous skin.

Complications

Disseminated cutaneous lesions can occur in individuals with underlying dermatological diseases, such as eczema (eczema herpeticum) (Fig. 11.14C). Herpes keratitis presents with pain and blurring of vision; characteristic dendritic ulcers are visible on slit-lamp examination and may produce corneal scarring and permanent visual impairment.

Primary HSV-2 can cause meningitis or transverse myelitis. HSV is the leading cause of sporadic viral encephalitis (p. 1121); this follows either primary or secondary disease, usually with HSV-1. A haemorrhagic necrotising temporal lobe cerebritis produces temporal lobe epilepsy and altered consciousness/coma. Without treatment, mortality is 80%. HSV is also implicated in the pathogenesis of Bell's palsy with a lower motor neuron 7th nerve palsy, although antivirals have not been demonstrated to improve outcome.

Neonatal HSV disease is usually associated with primary infection of the mother at term (see Box 11.26). In excess of two-thirds of cases develop disseminated disease with cutaneous lesions, hepatitis, pneumonitis and frequently encephalitis.

Immunocompromised hosts can develop visceral disease with oesophagitis, hepatitis, pneumonitis, encephalitis or retinitis.

Diagnosis

Differentiation from other vesicular eruptions is achieved by demonstration of virus in vesicular fluid, usually by direct immunofluorescence or PCR. HSV encephalitis is diagnosed by a positive PCR for HSV in CSF. Serology is of limited value.

Management

Therapy of localised disease must commence in the first 48 hours of clinical disease (primary or recurrent); thereafter it is unlikely to influence clinical outcome. Oral lesions in an immunocompetent individual may be treated with topical aciclovir. All severe manifestations should be treated, regardless of the time of presentation (see Box 11.30). Suspicion of HSV encephalopathy requires immediate empirical antiviral therapy. Aciclovir resistance is encountered occasionally in immunocompromised hosts, in which case foscarnet is the treatment of choice.

Human herpesvirus 8

Human herpesvirus 8 (HHV-8) (see Box 11.29) causes Kaposi's sarcoma in both AIDS-related and endemic non-AIDS-related forms (p. 314). HHV-8 is spread via saliva, and men who have sex with men have an increased incidence of infection. Seroprevalence varies widely, being highest in sub-Saharan Africa. HHV-8 also causes two rare haematological malignancies: primary effusion lymphoma and multicentric Castleman's disease. Current antivirals are not effective.

Enterovirus infections

Hand, foot and mouth disease

This systemic infection is caused by Coxsackie viruses usually, or occasionally by echoviruses. It affects children and occasionally adults, resulting in local or household outbreaks, particularly in the summer months. A relatively mild illness with fever and lymphadenopathy develops after an incubation period of approximately 10 days; 2–3 days later, a painful papular or vesicular rash appears on palmoplantar surfaces of hands and feet, with associated oral lesions on the buccal mucosa and tongue that ulcerate rapidly. A papular erythematous rash may appear on buttocks and thighs. Antiviral treatment is not available and management consists of symptom relief with analgesics.

Herpangina

This infection, caused by Coxsackie viruses, primarily affects children and teenagers in the summer months. It is characterised by a small number of vesicles at the soft/hard palate junction, often associated with high fever, an extremely sore throat and headache. The lesions are short-lived, rupturing after 2–3 days and rarely persisting for more than 1 week. Treatment is with analgesics if required. Culture of the virus from vesicles or DNA detection by PCR differentiates herpangina from HSV.

Poxviruses

These DNA viruses are rare but potentially important pathogens.

Smallpox (variola)

Smallpox, which has high mortality, was eradicated worldwide by a global vaccination programme but interest has re-emerged due to its potential as a bioweapon. The virus is spread by the respiratory route or contact with lesions, and is highly infectious.

The incubation period is 7–17 days. A prodrome with fever, headache and prostration leads, in 1–2 days, to the rash, which develops through macules and papules to vesicles and pustules, worst on the face and distal extremities. Lesions in one area are all at the same stage of development with no cropping (unlike chickenpox). Vaccination can lead to a modified course of disease with milder rash and lower mortality.

If a case of smallpox is suspected, national public health authorities must be contacted. Electron micrography (like Fig. 11.15) and DNA detection tests (PCR) are used to confirm diagnosis.

Monkeypox

Despite the name, the animal reservoirs for this virus are probably small squirrels and rodents. It causes a rare zoonotic infection in communities in the rainforest belt of Central Africa, producing a vesicular rash that is indistinguishable from smallpox, but differentiated by the presence of lymphadenopathy. Little person-to-person transmission occurs. Outbreaks outside

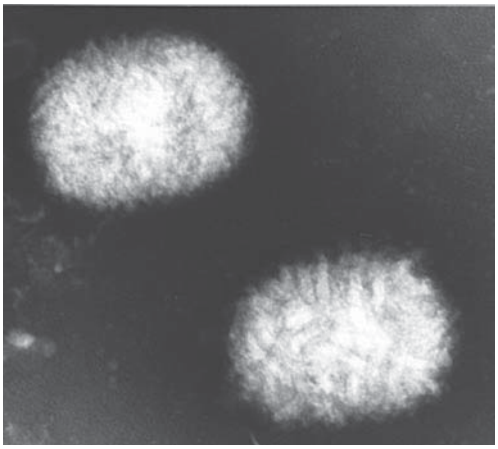

Fig. 11.15 Electron micrograph of molluscum contagiosum, a poxvirus. *Courtesy of Prof. Goura Kudesia, Northern General Hospital, Sheffield.*

Africa have been linked to importation of African animals as exotic pets. Diagnosis is by electron micrography or DNA detection (PCR).

Cowpox

Humans in contact with infected cows develop large vesicles, usually on the hands or arms and associated with fever and regional lymphadenitis. The reservoir is thought to be wild rodents.

Vaccinia virus

This laboratory strain is the basis of the existing vaccine to prevent smallpox. Widespread vaccination is no longer recommended due to the likelihood of local spread from the vaccination site (potentially life-threatening in those with eczema (eczema vaccinatum) or immune deficiency) and of encephalitis. However, vaccination may still be recommended for key medical staff.

Other poxviruses: orf and molluscum contagiosum

See page 1239 and Figure 11.15.

Gastrointestinal viral infections

Norovirus (Norwalk agent)

Norovirus is the most common cause of infectious gastroenteritis in the UK and leads to outbreaks in hospital wards, cruise ships and military camps. Food handlers may transmit this virus, which is relatively resistant to decontamination procedures. The incubation period is 24–48 hours. High attack rates and prominent vomiting are characteristic. Diagnosis may be achieved by electron microscopy, antigen or DNA detection (PCR) in stool samples, although the characteristic clinical and epidemiological features mean that microbiological confirmation is not always necessary. The virus is highly infectious and cases should be isolated and environmental surfaces cleaned with detergents and disinfected with bleach.

Astrovirus

Astroviruses cause diarrhoea in small children and occasionally in immunocompromised adults.

Rotavirus

Rotaviruses infect enterocytes and are a major cause of diarrhoeal illness in young children worldwide. There are winter epidemics in developed countries, particularly in nurseries. Adults in close contact with cases may develop disease. The incubation period is 48 hours and patients present with watery diarrhoea, vomiting, fever and abdominal pain. Dehydration is prominent. Diagnosis is aided by commercially available enzyme immunoassay kits, which require fresh or refrigerated stool samples. Immunity develops to natural infection. Monovalent and multivalent vaccines have been licensed in many countries and have now demonstrated efficacy in large trials in Africa and the Americas.

Hepatitis viruses (A–E)

See Chapter 22.

Other viruses

Adenoviruses are frequently identified from stool culture and implicated as a cause of diarrhoea in children. They have also been linked to cases of intussusception.

Respiratory viral infections

These infections are described on page 581.

Adenoviruses, rhinoviruses and enteroviruses (Coxsackie viruses and echoviruses) often produce non-specific upper respiratory tract symptoms but may cause viral pneumonia. Parainfluenza and respiratory syncytial viruses cause upper respiratory tract disease, croup and bronchiolitis in small children and pneumonia in the immunocompromised. Respiratory syncytial virus also causes pneumonia in nursing home residents and may be associated with nosocomial pneumonia. Metapneumovirus and bocavirus cause upper and occasionally lower respiratory tract infection, especially in immunosuppressed individuals. The severe acute respiratory syndrome (SARS), caused by the SARS coronavirus, emerged as a major respiratory pathogen during an outbreak in 2002–2003, with 8000 cases and 10% mortality (p. 582).

Middle East respiratory syndrome coronavirus (MERS-CoV)

11

In 2012, a novel coronavirus, distantly related to the SARS coronavirus, caused several deaths connected with pneumonia in patients originating from the Middle East. The Middle East respiratory syndrome coronavirus (MERS-CoV) appears to be a zoonosis, involving transmission from bats to camels and then to humans. Over 20 countries have reported cases, although most cases have a history of travel to Saudi Arabia or other countries in the Arabian Peninsula. By 2016 there had been over 1700 reported cases.

Clinical features

The incubation period in person-to-person transmission is 2–14 (average 5) days. Any age may be infected but the severe form of MERS-CoV mainly occurs in patients over 50 with medical comorbidities. Initial symptoms are fever, chills, headache, myalgia, dry cough and dyspnoea. Abdominal pain and diarrhoea may be prominent. The mean period from symptom onset to hospitalisation is 4 days, and 5 days to intensive care unit admission. Illness is complicated by rapid development of respiratory failure and features of ARDS and multi-organ failure. Mortality is 35%.

Diagnosis and management

Laboratory features include lymphopenia, thrombocytopenia and raised lactate dehydrogenase (LDH). Diagnosis is confirmed by PCR of serum, nasopharyngeal or other respiratory samples. Serology may also be useful. Treatment is supportive. Strict infection control measures should be implemented for anyone with fever, severe respiratory illness and epidemiological risk factors. Patients should be managed in an airborne infection isolation room with contact and airborne infection control measures, including personal protective equipment for health-care workers.

Viral infections with neurological involvement

See also page 1121.

Japanese B encephalitis

This flavivirus is an important cause of endemic encephalitis in Japan, China, Russia, South-east Asia, India and Pakistan; outbreaks also occur elsewhere. There are 10 000–20 000 cases reported to the WHO annually. Pigs and aquatic birds are the

virus reservoirs and transmission is by mosquitoes. Exposure to rice paddies is a recognised risk factor.

Clinical features

The incubation period is 4–21 days. Most infections are subclinical in childhood and 1% or less of infections lead to encephalitis. Initial systemic illness with fever, malaise and anorexia is followed by headache, photophobia, vomiting and changes in brainstem function. Other neurological features include meningism, seizures, cranial nerve palsies, flaccid or spastic paralysis and extrapyramidal syndromes. Mortality with neurological disease is 25%. Most children die from respiratory failure. Some 50% of survivors have neurological sequelae.

Investigations, management and prevention

Other infectious causes of encephalitis should be excluded (p. 1121). There is neutrophilia and often hyponatraemia. CSF analysis reveals lymphocytosis and elevated protein. Serological testing of serum and CSF aids diagnosis but may cross-react with dengue and other flaviviruses.

Treatment is supportive. Vaccination is recommended for travellers to endemic areas during the monsoon. Some endemic countries include vaccination in their childhood schedules.

West Nile virus

This flavivirus is an important cause of neurological disease in an area that extends from Australia, India and Russia through Africa and Southern Europe and across to North America. The disease has an avian reservoir and a mosquito vector. Older people are at increased risk of neurological disease.

Clinical features

Most infections are asymptomatic. After 2–6 days' incubation, a mild febrile illness and arthralgia may occur. A prolonged incubation may be seen in immunocompromised individuals. Children may develop a maculopapular rash. Neurological disease is seen in 1% and is characterised by encephalitis, meningitis or asymmetric flaccid paralysis with 10% mortality.

Diagnosis and management

Diagnosis is by serology or detection of viral RNA in blood or CSF. Serological tests may show cross-reactivity with other flaviviruses, including vaccine strains. Treatment is supportive.

Enterovirus 71

Enterovirus 71 has caused outbreaks around the globe of enteroviral disease with hand, foot and mouth disease (p. 248) and aseptic meningitis. Some cases have been complicated by encephalitis with flaccid paralysis or by brainstem involvement and death. The virus can be isolated from vesicle fluid, stool or CSF, and viral RNA can be detected in CSF by RT-PCR.

Nipah virus encephalitis

Nipah virus is a paramyxovirus in the Henipavirus genus, which caused an epidemic of encephalitis amongst Malaysian pig farmers in 1999 and subsequently caused outbreaks in Bangladesh and India. Mortality is around 30%. Diagnosis is by PCR or serology.

Human T-cell lymphotropic virus type I

Human T-cell lymphotropic virus type I (HTLV-1) is a retrovirus that causes chronic infection with development of adult T-cell leukaemia/lymphoma (ATL) or HTLV-1-associated myelopathy (HAM) in a subset of those infected (see Box 23.57, p. 964). It is found mainly in Japan, the Caribbean, Central and South America, and the Seychelles. HAM or tropical spastic paraparesis occurs in less than 5% of those with chronic infection, and presents with gait disturbance, spasticity of the lower extremities, urinary incontinence, impotence and sensory disturbance. Myositis and uveitis may also occur with HTLV-1 infection. Serology, sometimes confirmed with PCR, establishes the diagnosis. Treatment is usually supportive.

Viral infections with rheumatological involvement

Rheumatological syndromes characterise a variety of viral infections ranging from exanthems, such as rubella and parvovirus B19 (p. 237), to blood-borne viruses, such as HBV and HIV-1 and the sequelae of EVD.

Chikungunya virus

Chikungunya is an alphavirus that causes fever, rash and arthropathy. It is found principally in Africa and Asia, including India. Humans and non-human primates are the main reservoir and the main vector is the *Aedes aegypti* mosquito. Cases occur in epidemics on a background of sporadic cases. In 2007, an outbreak extended as far north as Italy.

The incubation period is 2–12 days. A period of fever may be followed by an afebrile phase and then recrudescence of fever. Children may develop a maculopapular rash. Adults are susceptible to arthritis, which causes early morning pain and swelling, most often in the small joints. Arthritis can persist for months and may become chronic in individuals who are positive for human leucocyte antigen (HLA)-B27. Related alphaviruses causing similar syndromes include Sindbis virus (Scandinavia and Africa), O'nyong-nyong virus (Central Africa), Ross River virus (Australia) and Mayaro virus (Caribbean and South America).

Diagnosis is by serology but cross-reactivity between alphaviruses occurs. Treatment is symptomatic.

Prion diseases

Prions cause transmissible spongiform encephalopathies and are discussed on page 1126.

Bacterial infections

Bacterial infections of the skin, soft tissues and bones

Most infections of the skin, soft tissues and bone are caused by either *Staph. aureus* or streptococci (mainly *Strep. pyogenes*) (see pp. 1019 and 1237).

Staphylococcal infections

Staphylococci are usually found colonising the anterior nares and skin. Some staphylococci produce coagulase, an enzyme that converts fibrinogen to fibrin in rabbit plasma, causing it to clot. *Staph. aureus* is coagulase-positive, and most other species are coagulase-negative. In modern laboratory practice, however, the identification of *Staph. aureus* rarely involves the coagulase test.

Staph. aureus is the main cause of staphylococcal infections. *Staph. intermedius* is another coagulase-positive staphylococcus, which causes infection following dog bites. Among coagulase-negative organisms, *Staph. epidermidis* is the predominant commensal organism of the skin, and can cause severe infections in those with central venous catheters or implanted prosthetic materials. *Staph. saprophyticus* is part of the normal vaginal flora and causes urinary tract infections in sexually active young women. Others implicated in human infections include *Staph. lugdunensis*, *Staph. schleiferi*, *Staph. haemolyticus* and *Staph. caprae.* Coagulase-negative staphylococci are not usually identified to species level.

Staphylococci are particularly dangerous if they gain access to the blood stream, having the potential to disseminate widely (Fig. 11.16). In any patient with staphylococcal bacteraemia, especially injection drug-users, the possibility of endocarditis must be considered (p. 527). Growth of *Staph. aureus* in blood cultures should not be dismissed as a 'contaminant' unless all possible underlying sources have been excluded and repeated blood culture is negative. Any evidence of spreading cellulitis indicates the urgent need for an antistaphylococcal antibiotic, such as flucloxacillin (unless there is a likely risk of MRSA). This is particularly true for mid-facial cellulitis, which can result in cavernous sinus thrombophlebitis.

In addition, *Staph. aureus* can cause severe systemic disease due to the effects of toxin produced at superficial sites in the absence of tissue invasion by bacteria.

Skin infections

Staphylococcal infections cause ecthyma, folliculitis, furuncles, carbuncles, bullous impetigo and the scalded skin syndrome (pp. 1235–1237). They may also be involved in necrotising infections of the skin and subcutaneous tissues (p. 226).

Wound infections

Many wound infections are caused by staphylococci, which may significantly prolong post-operative hospital stays (Fig. 11.17A). Prevention involves careful attention to hand hygiene, skin preparation and aseptic technique, and the use of topical and systemic antibiotic prophylaxis.

Treatment is by drainage of any abscesses plus adequate dosage of antistaphylococcal antibiotics, done early, particularly if prosthetic implants have been inserted.

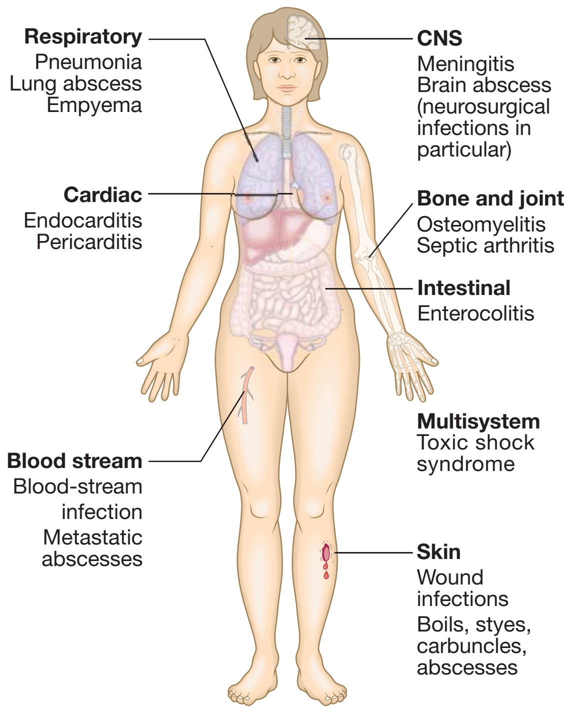

Fig. 11.16 Infections caused by *Staphylococcus aureus*.

Cannula-related infection

Staphylococcal infection associated with cannula sepsis (Fig. 11.17B and p. 196) and thrombophlebitis is an important and common reason for morbidity following hospital admission. The Visual Infusion Phlebitis (VIP) score aids cannula evaluation (Box 11.37). Staphylococci have a predilection for plastic, rapidly

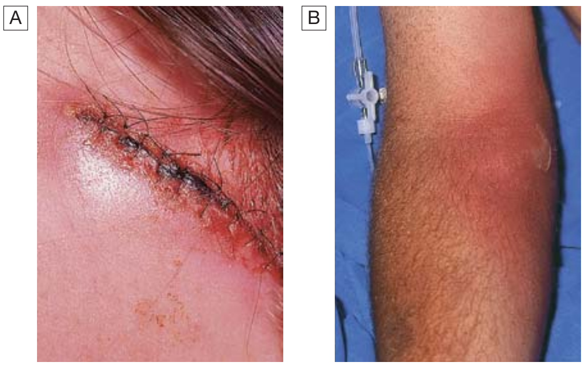

Fig. 11.17 Manifestations of skin infection with *Staphylococcus aureus.* A Wound infection. B Cannula-related infection.

11.37 How to assess an intravenous cannula using the Visual Infusion Phlebitis (VIP) score

Clinical features	Score	Assessment and management
IV site appears healthy	0	**No signs of phlebitis** Observe cannula
One of the following is evident: Slight pain near IV site Slight redness near IV site	1	**Possible first signs of phlebitis** Observe cannula
Two of the following are evident: Pain near IV site Erythema Swelling	2	**Early stage of phlebitis** Resite cannula
ALL of the following are evident and extensive: Pain along path of cannula Erythema Induration	3	**Medium stage of phlebitis** Resite cannula Consider treatment
ALL of the following are evident and extensive: Pain along path of cannula Erythema Induration Palpable venous cord	4	**Advanced stage of phlebitis or start of thrombophlebitis** Resite cannula Consider treatment
ALL of the following are evident: Pain along path of cannula Erythema Induration Palpable venous cord Pyrexia	5	**Advanced stage of thrombophlebitis** Initiate treatment Resite cannula

Adapted from Jackson A. Nursing Times 1997; 94:68–71.

forming a biofilm on cannulae, which remains as a source of bacteraemia. Local poultice application may relieve symptoms but cannula removal and antibiotic treatment with flucloxacillin (or a glycopeptide if MRSA is suspected) are necessary if there is any suggestion of spreading infection.

Meticillin-resistant Staph. aureus

Resistance to meticillin is due to a penicillin-binding protein mutation in *Staph. aureus*. Resistance to vancomycin/teicoplanin (glycopeptides) in either glycopeptide intermediate *Staph. aureus* (GISA) or, rarely, vancomycin-resistant (VRSA) strains threatens the ability to manage serious infections produced by such organisms. Meticillin-resistant *Staph. aureus* (MRSA) is now a major worldwide health care-acquired pathogen, accounting for up to 40% of staphylococcal bacteraemia in developed countries. Community-acquired MRSA (c-MRSA) currently accounts for 50% of all MRSA infections in the USA. These organisms have also acquired other toxins, such as Panton–Valentine leukocidin (PVL), and cause rapidly fatal infection in young people. Clinicians must be aware of the potential danger of these infections and be prepared to take whatever appropriate infection control measures are locally advised (p. 111).

Treatment options for MRSA are shown in Box 6.16 (p. 117). Treatment should always be based on the results of antimicrobial susceptibility testing, since resistance to all these agents occurs. Milder MRSA infections may be treated with clindamycin, tetracyclines or co-trimoxazole. Glycopeptides, linezolid and daptomycin are reserved for treatment of more severe infections. Toxin-producing MRSA infections should be treated with protein-inhibiting antibiotics (clindamycin, linezolid).

Staphylococcal toxic shock syndrome

Staphylococcal toxic shock syndrome (TSS) is a serious and life-threatening disease associated with infection by *Staph. aureus*, which produces a specific toxin (toxic shock syndrome toxin 1, TSST1). It was formerly seen in young women in association with the use of highly absorbent intravaginal tampons but can occur with any *Staph. aureus* infection involving a relevant toxin-producing strain. The toxin acts as a 'super-antigen', triggering significant T-cell activation and massive cytokine release.

TSS has an abrupt onset with high fever, generalised systemic upset (myalgia, headache, sore throat and vomiting), a widespread erythematous blanching rash resembling scarlet fever, and hypotension. It rapidly progresses over a few hours to multi-organ failure, leading to death in 10–20%. Recovery is accompanied at 7–10 days by desquamation (Fig. 11.18).

The diagnosis is clinical and may be confirmed in menstrual cases by finding a retained tampon with staphylococci on Gram stain. Subsequent culture and demonstration of toxin production are confirmatory.

Management

Treatment is with immediate and aggressive fluid resuscitation and an intravenous antistaphylococcal antimicrobial (flucloxacillin or vancomycin), usually with the addition of a protein synthesis inhibitor (e.g. clindamycin) to inhibit toxin production. Intravenous immunoglobulin is occasionally added in the most severe cases. Women who recover from tampon-associated TSS should avoid tampons for at least 1 year and be advised that the condition can recur.

Fig. 11.18 **Full-thickness desquamation after staphylococcal toxic shock syndrome.**

Streptococcal infections

Streptococci are oropharyngeal and gut commensals, which appear as Gram-positive cocci in chains (see Fig. 6.3, p. 102). They are classified by the pattern of haemolysis they produce on blood agar (see Fig. 6.4, p. 102), by their 'Lancefield groups' (Box 11.38) and more recently by speciation on matrix-assisted laser desorption/ionisation time-of-flight (MALDI-TOF) mass spectometry. Some streptococci (e.g. *Strep. milleri* group) defy simple classification.

Group A streptococci (GAS) are the leading cause of bacterial pharyngitis. Although the presence of fever, tender anterior lymphadenopathy and purulent tonsillar exudate and the absence of cough make streptococcal pharyngitis more likely than viral infection, clinical features alone are unreliable for diagnosing streptococcal pharyngitis. GAS are also the major cause of cellulitis, erysipelas and impetigo (pp. 1237 and 1235). Groups C and G streptococci cause cellulitis, particularly in elderly, diabetic or immunocompromised patients. Group B streptococci (GBS) colonise the gut and vagina. They cause post-partum and neonatal sepsis, as well as other deep infections (infective endocarditis, septic arthritis, osteomyelitis etc.), especially in the elderly.

Streptococcal scarlet fever

Group A (or occasionally groups C and G) streptococci causing pharyngitis, tonsillitis or other infection may lead to scarlet fever, if the infecting strain produces a streptococcal pyrogenic exotoxin. Scarlet fever is most common in school-age children, but can also occur in young adults who have contact with young children. A diffuse erythematous rash occurs, which blanches on pressure (Fig. 11.19A), classically with circumoral pallor. The tongue, initially coated, becomes red and swollen ('strawberry tongue', Fig. 11.19B). The disease lasts about 7 days, the rash disappearing in 7–10 days, followed by a fine desquamation. Residual petechial lesions in the antecubital fossa may be seen ('Pastia's sign', Fig. 11.19C).

Treatment involves intravenous benzylpenicillin or an oral penicillin plus symptomatic measures.

11.38 Streptococcal and related infections

β-haemolytic group A (*Strep. pyogenes*)	
• Skin and soft tissue infection (including erysipelas, impetigo, necrotising fasciitis) • Streptococcal toxic shock syndrome	• Puerperal sepsis • Scarlet fever • Glomerulonephritis • Rheumatic fever • Bone and joint infection • Tonsillitis
β-haemolytic group B (*Strep. agalactiae*)	
• Neonatal infections, including meningitis	• Female pelvic infections • Cellulitis
β-haemolytic group C (various zoonotic streptococci)	
• Cellulitis • Endocarditis	• Pharyngitis • Septic arthritis
α-, β- or non-haemolytic group D (*Enterococcus faecalis, E. faecium*)	
• Endocarditis • Intra-abdominal infections	• Urinary tract infection
α- or non-haemolytic group D (*Strep. gallolyticus* subsp. *gallolyticus*/*S. bovis* biotype I)	
• Bacteraemia/endocarditis associated with large bowel malignancy	
β-haemolytic group G streptococci	
• Cellulitis • Endocarditis	• Liver abscess • Septic arthritis
α-haemolytic optochin-resistant (viridans streptococci – *Strep. mitis*, *Strep. sanguis*, *Strep. mutans*, *Strep. salivarius*)	
• Sepsis in immunosuppressed	• Endocarditis
α-haemolytic optochin-sensitive (*Strep. pneumoniae*)	
• Pneumonia • Meningitis • Endocarditis • Otitis media	• Sepsis • Spontaneous bacterial peritonitis • Sinusitis
Variable haemolysis (*Strep. milleri* group – *Strep. anginosus*, *Strep. intermedius*, *Strep. constellatus*)	
• Endocarditis • Intra-abdominal infections	• Urinary tract infection
Anaerobic streptococci (*Peptostreptococcus* spp.)	
• Sepsis in immunosuppressed	• Endocarditis

N.B. All streptococci can cause sepsis.

Streptococcal toxic shock syndrome

Group A (or occasionally group C or G) streptococci can produce one of a variety of toxins, such as pyogenic exotoxin A. Like staphylococcal TSST1 (see above), these act as super-antigens. Initially, an influenza-like illness occurs, with signs of localised infection in 50% of cases, most often involving the skin and soft tissues. A faint erythematous rash, mainly on the chest, rapidly progresses to circulatory shock. Without aggressive management, multi-organ failure will develop.

Fluid resuscitation must be undertaken, along with parenteral antistreptococcal antibiotic therapy, usually with benzylpenicillin and clindamycin, to inhibit toxin production. Intravenous immunoglobulin is often administered. If necrotising fasciitis is present, it should be treated as described on page 227 with urgent débridement.

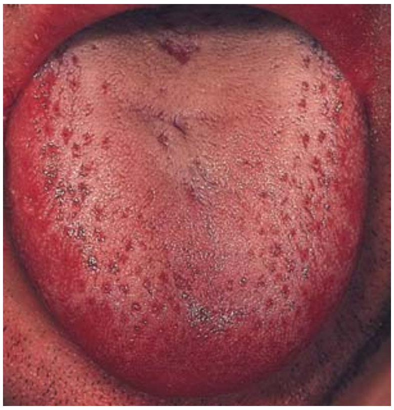
Treponematoses

Syphilis

This disease is described on page 337.

Endemic treponematoses

Yaws



Yaws is a granulomatous disease, mainly involving the skin and bones; it is caused by *Treponema pertenue*, morphologically and serologically indistinguishable from the causative organisms of syphilis and pinta. It is important to establish the geographical origin and sexual history of patients to exclude false-positive syphilis serology due to endemic treponemal infections. Between 1950 and 1960, WHO campaigns treated over 60 million people and eradicated yaws from many areas, but the disease has persisted patchily throughout the tropics; there was a resurgence in the 1980s and 1990s in West and Central Africa and the South Pacific.

Organisms are transmitted by bodily contact from a patient with infectious yaws through minor abrasions of the skin of another patient, usually a child. After an incubation period of 3–4 weeks, a proliferative granuloma containing numerous treponemes develops at the site of inoculation. This primary lesion is followed by secondary eruptions. In addition, there may be hypertrophic periosteal lesions of many bones, with underlying cortical rarefaction. Lesions of late yaws are characterised

A

B

C

Fig. 11.19 Clinical features of scarlet fever. A Characteristic rash with blanching on pressure. B 'Strawberry tongue'. C Pastia's sign: a petechial rash in the cubital fossa.

i 11.39 Diagnosis and treatment of yaws, pinta and bejel

Diagnosis of early stages
- Detection of spirochaetes in exudate of lesions by dark ground microscopy

Diagnosis of latent and early stages
- Positive serological tests, as for syphilis (see Box 13.8, p. 339)

Treatment of all stages
- Single intramuscular injection of 1.2 g long-acting penicillin, e.g. benzathine benzylpenicillin

by destructive changes that closely resemble the osteitis and gummas of tertiary syphilis and that heal with scarring and deformity. Investigations and management are outlined in Box 11.39. Improved housing and hygiene, combined with mass chemotherapy programmes, have achieved dramatic success in the control of yaws.

Pinta and bejel

These two treponemal infections occur in poor rural populations with low standards of domestic hygiene but are found in separate parts of the world. They have features in common, notably that they are transmitted by contact, usually within the family and not sexually, and in the case of bejel, through common eating and drinking utensils. Their diagnosis and management are as for yaws (Box 11.39).

- *Pinta.* Pinta is found only in South and Central America, where its incidence is declining. The infection is confined to the skin. The early lesions are scaly papules or dyschromic patches on the skin. The late lesions are often depigmented and disfiguring.
- *Bejel.* Bejel is the Middle Eastern name for non-venereal syphilis, which has a patchy distribution across sub-Saharan Africa, the Middle East, Central Asia and Australia. It has been eradicated from Eastern Europe. Transmission is most commonly from the mouth of the mother or child and the primary mucosal lesion is seldom seen. The early and late lesions resemble those of secondary and tertiary syphilis (p. 337) but cardiovascular and neurological disease is rare.

Tropical ulcer

Tropical ulcer is due to a synergistic bacterial infection caused by a fusobacterium (*F. ulcerans*, an anaerobe) and *Treponema vincentii.* It is common in hot, humid regions. The ulcer is most common on the lower legs and develops as a papule that rapidly breaks down to a sharply defined, painful ulcer. The base of the ulcer has a foul slough. Penicillin and metronidazole are useful in the early stages but rest, elevation and dressings are the mainstays of treatment.

Buruli ulcer

This ulcer is caused by *Mycobacterium ulcerans* and occurs widely in tropical rainforests. In 1999, a survey in Ghana found 6500 cases; there are an estimated 10 000 cases in West Africa as a whole.

The initial lesion is a small subcutaneous nodule on the arm or leg. This breaks down to form a shallow, necrotic ulcer with deeply undermined edges, which extends rapidly. Healing may occur after 6 months but granuloma formation and the accompanying fibrosis cause contractures and deformity. Clumps of acid-fast bacilli can be detected in the ulcer floor.

A combination of rifampicin and streptomycin can cure the infection. Infected tissue should be removed surgically. Health campaigns in Ghana have successfully focused on early removal of the small, pre-ulcerative nodules.

Systemic bacterial infections

Brucellosis

Brucellosis is an enzootic infection (i.e. endemic in animals) caused by Gram-negative bacilli. The four species causing human disease and their animal hosts are: *Brucella melitensis* (goats, sheep and camels in Europe, especially the Mediterranean basin, the Middle East, Africa, India, Central Asia and South America), *B. abortus* (cattle, mainly in Africa, Asia and South America), *B. suis* (pigs in South Asia) and *B. canis* (dogs). *B. melitensis* causes the most severe disease; *B. suis* is often associated with abscess formation.

Infected animals may excrete *Brucella* spp. in their milk for prolonged periods and human infection is acquired by ingesting contaminated dairy products (especially unpasteurised milk), uncooked meat or offal. Animal urine, faeces, vaginal discharge and uterine products may transmit infection through abraded skin or via splashes and aerosols to the respiratory tract and conjunctiva.

Clinical features

Brucella spp. are intracellular organisms that survive for long periods within the reticulo-endothelial system. This explains the disease chronicity and tendency to relapse, even after antimicrobial therapy.

Acute illness is characterised by a high swinging temperature, rigors, lethargy, headache, joint and muscle pains, and scrotal pain. Occasionally, there is delirium, abdominal pain and constipation. Physical signs are non-specific, e.g. enlarged lymph nodes. Splenomegaly may cause thrombocytopenia.

Localised infection (Fig. 11.20), which occurs in about 30% of patients, is more likely if diagnosis and treatment are delayed.

Diagnosis

Definitive diagnosis depends on culture of the organism. Blood cultures are positive in 75–80% of *B. melitensis* and 50% of *B. abortus* infections. Bone marrow culture is not routine but may increase the diagnostic yield if antibiotics have been used prior to culture. CSF culture in neurobrucellosis is positive in about 30% of cases. The laboratory should be alerted to a suspected diagnosis of brucellosis, as the organism may infect laboratory workers and must be cultured at the appropriate biosafety level.

Serology may also aid diagnosis. In endemic areas, a single high antibody titre of more than 1/320 or a fourfold rise in titre is needed to support a diagnosis of acute infection. The test usually takes several weeks to become positive but should eventually detect 95% of acute infections.

Management

Aminoglycosides show synergistic activity with tetracyclines against brucellae. Treatment regimens for different forms of brucellosis are outlined in Box 11.40.

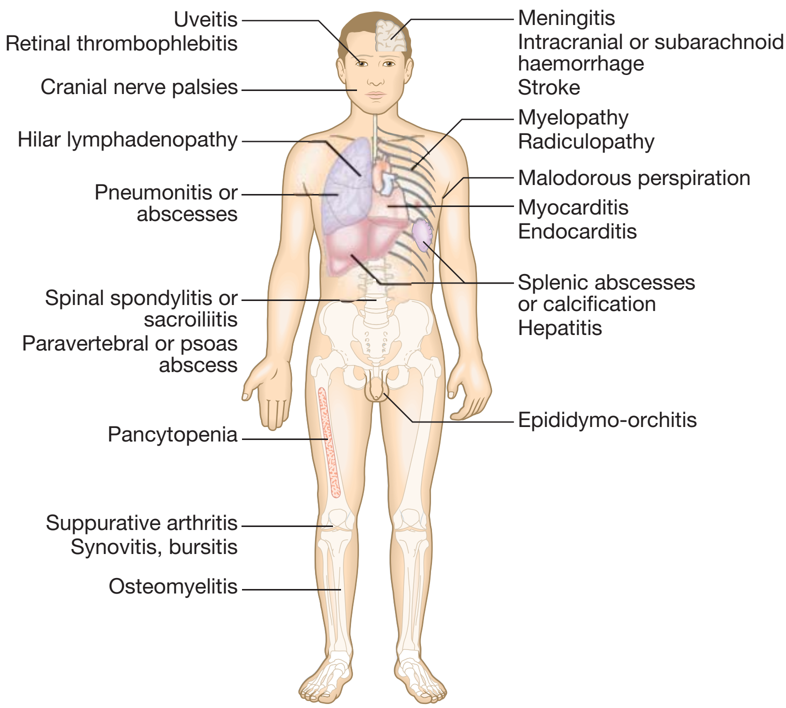


Fig. 11.20 **Clinical features of brucellosis.**

11

11.40 Treatment of brucellosis

Adults with non-localised disease
• Doxycycline 100 mg twice daily orally for 6 weeks *plus* gentamicin 5 mg/kg IV once daily for 7 days *or* • Doxycycline 100 mg twice daily *plus* rifampicin 600–900 mg orally once daily for 6 weeks
Bone disease
• Doxycycline 100 mg twice daily *plus* rifampicin 600–900 mg once daily orally for 6 weeks *plus* gentamicin 5 mg/kg IV once daily for 7 days *or* • Ciprofloxacin 750 mg twice daily orally *plus* rifampicin 600–900 mg orally once daily for 3 months
Neurobrucellosis
• Doxycycline 100 mg twice daily *plus* rifampicin 600–900 mg orally once daily for 6 weeks *plus* ceftriaxone 2vg IV twice daily until the cerebrospinal fluid is clear (though susceptibility should be confirmed because sensitivity to third-generation cephalosporins varies among strains)
Endocarditis
• Almost always needs surgical intervention *plus* • Doxycycline 100 mg twice daily, rifampicin 600–900 mg orally once daily and co-trimoxazole 5 mg/kg of trimethoprim component for 6 months *plus* gentamicin 5 mg/kg IV once daily for 2–4 weeks
Pregnancy
• Rifampicin 600–900 mg orally once daily and co-trimoxazole 5 mg/kg of trimethoprim component for 4 weeks, but caution in last week of pregnancy due to displacement of bilirubin from albumin by drugs and risk of kernicterus to the fetus

Borrelia infections

Borrelia are flagellated spirochaetal bacteria that infect humans after bites from ticks or lice. They cause a variety of human infections worldwide (Box 11.41).

Lyme disease

Lyme disease (named after the town of Old Lyme in Connecticut, USA) is caused by *B. burgdorferi,* which occurs in the USA, Europe, Russia, China, Japan and Australia. In Europe, two additional genospecies are also encountered, *B. afzelii* and *B. garinii.* The reservoir of infection is ixodid (hard) ticks that feed on a variety of large mammals, particularly deer. Birds may spread ticks over a wide area. The organism is transmitted to humans via the bite of infected ticks; larval, nymphal and adult forms are all capable of spreading infection.

Ehrlichiosis is a common co-infection with Lyme disease. Two forms occur: *Anaplasma phagocytophilum*, human granulocytic anaplasmosis (HGA); and *Ehrlichia chaffeensis*, human monocytic ehrlichiosis (HME).

Clinical features

There are three stages of disease. Progression may be arrested at any stage.

- *Early localised disease*. The characteristic feature is a skin reaction around the site of the tick bite, known as erythema migrans (Fig. 11.21). Initially, a red ‘bull’s eye’ macule or papule appears 2–30 days after the bite. It then enlarges peripherally with central clearing and may persist for months. Atypical forms are common. The lesion is not pathognomonic of Lyme disease since similar lesions can occur after tick bites. Acute manifestations, such as fever, headache and regional lymphadenopathy, may develop with or without the rash.

i 11.41 Clinical diseases caused by *Borrelia* spp.

Species	Vector	Geographical distribution
Lyme disease		
B. burgdorferi sensu stricto	Tick: *Ixodes scapularis*	Northern and eastern USA
	I. pacificus	Western USA
B. afzelii	*I. ricinus*	Europe
	I. persulcatus	Asia
B. garinii	*I. ricinus*	Europe
	I. persulcatus	Asia
Louse-borne relapsing fever		
B. recurrentis	Human louse: *Pediculus humanus corporis*	Worldwide
Tick-borne relapsing fever		
B. hermsii	Tick: *Ornithodoros hermsii*	Western North America
B. turicatae	*O. turicatae*	South-western North America and northern Mexico
B. venezuelensis	*O. rudis*	Central America and northern South America
B. hispanica	*O. erraticus*	Iberian peninsula and north-western Africa
B. crocidurae	*O. erraticus*	North Africa and Mediterranean region
B. duttonii	*O. moubata*	Central, eastern and southern Africa
B. persica	*O. tholozani*	Western China, India, Central Asia, Middle East
B. latyschewii	*O. tartakovskyi*	Tajikistan, Uzbekistan

Fig. 11.21 Rash of erythema migrans in Lyme disease with metastatic secondary lesions. *Courtesy of Dr Ravi Gowda, Royal Hallamshire Hospital, Sheffield.*

- *Early disseminated disease*. Dissemination occurs via the blood stream and lymphatics. There may be a systemic reaction with malaise, arthralgia and, occasionally, metastatic areas of erythema migrans (Fig. 11.21). Neurological involvement may follow weeks or months after infection. Common features include lymphocytic meningitis, cranial nerve palsies (especially unilateral or bilateral facial nerve palsy) and peripheral neuropathy. Radiculopathy, often painful, may present a year or more after initial infection. Carditis, sometimes accompanied by atrioventricular conduction defects, occurs in the USA but is rare in Europe.
- *Late disease*. Late manifestations include arthritis, polyneuritis and encephalopathy. Prolonged arthritis, particularly affecting large joints, and brain parenchymal involvement, causing neuropsychiatric abnormalities, may occur but are rare in the UK. Acrodermatitis chronica atrophicans is an uncommon late complication seen more frequently in Europe than North America. Doughy, patchy discoloration occurs on the peripheries, eventually leading to shiny atrophic skin. The lesions are easily mistaken for those of peripheral vascular disease. In patients coming from an endemic area or having risk factors, who have facial nerve palsy, Lyme disease should be considered.

Diagnosis

The diagnosis of early Lyme borreliosis is often clinical. Culture from biopsy material is not generally available, has a low yield and may take longer than 6 weeks. Antibody detection is frequently negative early in the course of the disease but sensitivity increases to 90–100% in disseminated or late disease. Immunofluorescence or ELISA can give false-positive reactions in a number of conditions, including other spirochaetal infections, infectious mononucleosis, rheumatoid arthritis and systemic lupus erythematosus (SLE). Immunoblot (Western blot) techniques are more specific and, although technically demanding, should be used to confirm the diagnosis. Microorganism DNA detection by PCR has been applied to blood, urine, CSF and biopsies of skin and synovium.

Management

Recent evidence suggests that asymptomatic patients with positive antibody tests should not be treated. However, erythema migrans always requires therapy because organisms may persist and cause progressive disease, even if the skin lesions resolve. Standard therapy consists of a 14-day course of doxycycline (200 mg daily) or amoxicillin (500 mg 3 times daily). Some 15% of patients with early disease will develop a mild Jarisch–Herxheimer reaction (JHR) during the first 24 hours of therapy (p. 339). In pregnant women and small children with penicillin allergy, or in those allergic to amoxicillin and doxycycline, 14-day treatment with cefuroxime axetil (500 mg twice daily) or erythromycin (250 mg 4 times daily) may be used.

Disseminated disease and arthritis require therapy for a minimum of 28 days. Arthritis may respond poorly and prolonged or repeated courses may be necessary. Neuroborreliosis is treated with parenteral β-lactam antibiotics for 3–4 weeks; third-generation cephalosporins such as ceftriaxone are the preferred therapy.

Prevention

Protective clothing and insect repellents should be used in tick-infested areas. Since the risk of borrelial transmission is lower in the first few hours of a blood feed, prompt removal of ticks is advisable. Unfortunately, larval and nymphal ticks are tiny and may not be noticed. Where risk of transmission is high, a single 200 mg dose of doxycycline, given within 72 hours of exposure, has been shown to prevent erythema migrans.

Louse-borne relapsing fever

The human body louse, *Pediculus humanus*, causes itching. Borreliae (*B. recurrentis*) are liberated from infected lice when they are crushed during scratching, which also inoculates the borreliae into the skin. The disease occurs worldwide, with epidemic relapsing fever most often seen in Central/East Africa and South America.

The borreliae multiply in the blood, where they are abundant in the febrile phases, and invade most tissues, especially the liver, spleen and meninges.

Clinical features

Onset is sudden with fever. The temperature rises to 39.5–40.5°C, accompanied by a tachycardia, headache, generalised aching, injected conjunctivae (Fig. 11.22) and herpes labialis. Thrombocytopenia is associated with a petechial rash and epistaxis. As the disease progresses tender hepatosplenomegaly, accompanied by jaundice and elevated transaminases, is common. There may be severe serosal and intestinal haemorrhage, delirium and meningism. The fever ends in crisis between the fourth and tenth days, often associated with profuse sweating, hypotension and circulatory and cardiac failure. There may be no further fever but, in a proportion of patients, after an afebrile period of about 7 days, there are one or more relapses, which are usually milder and less prolonged. In the absence of specific treatment, the mortality rate is up to 40%, especially among the elderly and malnourished.

Investigations and management

Dark ground microscopy of a wet film or Wright–Giemsa stained thick and thin films demonstrate the organism in blood from a febrile patient.

Treatment aims to eradicate the organism and prevent relapses, while minimising the severe JHR that inevitably follows successful chemotherapy. The safest treatment is procaine penicillin 300 mg IM, followed the next day by 0.5 g tetracycline. Tetracycline alone is effective and prevents relapse, but may give rise to a worse reaction. Doxycycline 200 mg once orally in place of tetracycline has the advantage of also being curative for typhus, which often accompanies epidemics of relapsing fever. JHR is best managed in a high-dependency unit with expert nursing and medical care.

The patient, clothing and all contacts must be freed from lice, as in epidemic typhus.

Fig. 11.22 Louse-borne relapsing fever. Injected conjunctivae.

Tick-borne relapsing fever

Soft ticks (*Ornithodoros* spp.) transmit *B. duttonii* (and other *Borrelia* species) through saliva while feeding on their host. People sleeping in mud houses are at risk, as the tick hides in crevices during the day and feeds on humans during the night. Rodents are the reservoir in all parts of the world except East Africa, where humans are the reservoir. Clinical manifestations are similar to those seen with the louse-borne disease but microorganisms are detected in fewer patients on dark field microscopy. A 7-day course (due to a higher relapse rate than in louse-borne relapsing fever) of treatment with either tetracycline (500 mg 4 times daily) or erythromycin (500 mg 4 times daily) is needed.

Leptospirosis

Microbiology and epidemiology

Leptospirosis is one of the most common zoonotic diseases, favoured by a tropical climate and flooding during the monsoon but occurring worldwide. Leptospires are tightly coiled, thread-like organisms about 5–7 μm in length, which are actively motile; each end is bent into a hook. *Leptospira interrogans* is pathogenic for humans. The genus can be separated into more than 200 serovars (subtypes) belonging to 23 serogroups.

11

Leptospirosis appears to be ubiquitous in wildlife and in many domestic animals. The organisms persist indefinitely in the convoluted tubules of the kidney and are shed into the urine in massive numbers, but infection is asymptomatic in the host. The most frequent hosts are rodents, especially the common rat (*Rattus norvegicus*). Particular leptospiral serogroups are associated with characteristic animal hosts; for example, *L. ictero-haemorrhagiae* is the classical parasite of rats and *L. canicola* of dogs. There is nevertheless considerable overlap in host–serogroup associations.

Leptospires can enter their human hosts through intact skin or mucous membranes but entry is facilitated by cuts and abrasions. Prolonged immersion in contaminated water will also favour invasion, as the spirochaete can survive in water for months. Leptospirosis is common in the tropics and also in freshwater sports enthusiasts.

Clinical features

After a relatively brief bacteraemia, invading organisms are distributed throughout the body, mainly in kidneys, liver, meninges and brain. The incubation period averages 1–2 weeks. Four main clinical syndromes can be discerned and clinical features can involve multiple different organ systems (Fig. 11.23).

Bacteraemic leptospirosis

Bacteraemia with any serogroup can produce a non-specific illness with high fever, weakness, muscle pain and tenderness (especially of the calf and back), intense headache and photophobia, and sometimes diarrhoea and vomiting. Conjunctival congestion is the only notable physical sign. The illness comes to an end after about 1 week, or else merges into one of the other forms of infection.

Aseptic meningitis

Classically associated with *L. canicola* infection, this illness is very difficult to distinguish from viral meningitis. The conjunctivae may be congested but there are no other differentiating signs. Laboratory clues include a neutrophil leucocytosis, abnormal LFTs, and the occasional presence of albumin and casts in the urine.

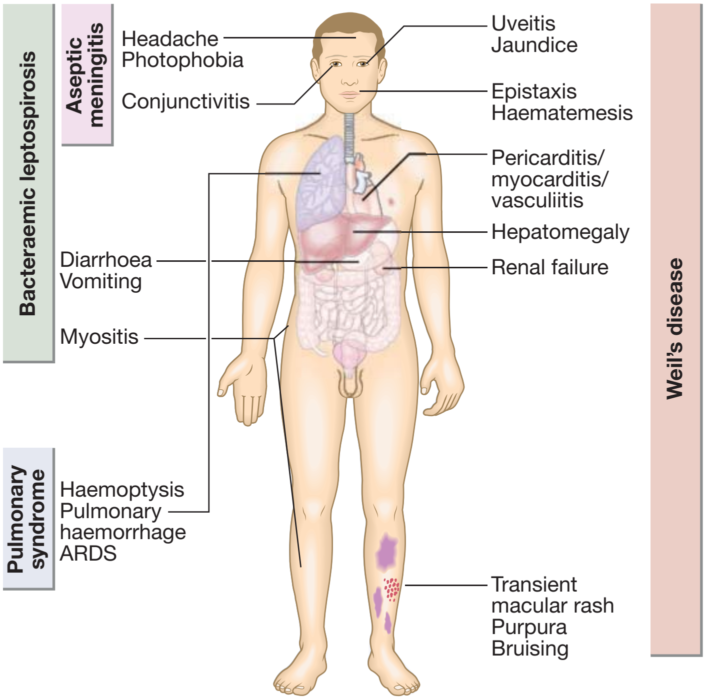

Fig. 11.23 Clinical syndromes of leptospirosis. (ARDS = acute respiratory distress syndrome)

Icteric leptospirosis (Weil's disease)

Fewer than 10% of symptomatic infections result in severe icteric illness. Weil's disease is a dramatic life-threatening event, characterised by fever, haemorrhages, jaundice and acute kidney injury. Conjunctival hyperaemia is a frequent feature. The patient may have a transient macular erythematous rash but the characteristic skin changes are purpura and large areas of bruising. In severe cases there may be epistaxis, haematemesis and melaena, or bleeding into the pleural, pericardial or subarachnoid spaces. Thrombocytopenia, probably related to activation of endothelial cells with platelet adhesion and aggregation, is present in 50% of cases. Jaundice is deep and the liver is enlarged but there is usually little evidence of hepatic failure or encephalopathy. Acute kidney injury, primarily caused by impaired renal perfusion and acute tubular necrosis, manifests as oliguria or anuria, with the presence of albumin, blood and casts in the urine.

Weil's disease may also be associated with myocarditis, encephalitis and aseptic meningitis. Uveitis and iritis may appear months after apparent clinical recovery.

Pulmonary syndrome

This syndrome has long been recognised in the Far East and has been described during an outbreak of leptospirosis in Nicaragua. It is characterised by haemoptysis, patchy lung infiltrates on chest X-ray, and respiratory failure. Total bilateral lung consolidation and ARDS (p. 324) with multi-organ dysfunction may develop, with a high mortality (over 50%).

Diagnosis

A polymorphonuclear leucocytosis is accompanied in severe infection by thrombocytopenia and elevated blood levels of creatine kinase. In jaundiced patients, there is hepatitis and the prothrombin time may be prolonged. The CSF in leptospiral meningitis shows a variable cellular response, a moderately elevated protein level and normal glucose content. Acute kidney injury due to interstitial nephritis is common.

In the tropics, dengue, malaria, typhoid fever, scrub typhus and hantavirus infection are important differential diagnoses.

Definitive diagnosis of leptospirosis depends on isolation of the organism, serological tests or detection of specific DNA. In general, however, it is probably under-diagnosed.

- Blood cultures are most likely to be positive if taken before the 10th day of illness. Special media are required and cultures may have to be incubated for several weeks.
- Leptospires appear in the urine during the second week of illness, and in untreated patients may be recovered on culture for several months.
- Serological tests are diagnostic if seroconversion or a fourfold increase in titre is demonstrated. The microscopic agglutination test (MAT) is the investigation of choice and can become positive by the end of the first week. IgM ELISA and immunofluorescent techniques are easier to perform, however, while rapid immunochromatographic tests are specific but of only moderate sensitivity in the first week of illness.
- Detection of leptospiral DNA by PCR is possible in blood in early symptomatic disease, and in urine from the eighth day of illness and for many months thereafter.

Management and prevention

The general care of the patient is critically important. Blood transfusion for haemorrhage and careful attention to renal function, the usual cause of death, are especially important. Acute kidney injury is potentially reversible with adequate support, such as dialysis. Most infections are self-limiting. Therapy with either oral doxycycline (100 mg twice daily for 1 week) or intravenous penicillin (900 mg 4 times daily for 1 week) is effective but may not prevent the development of renal failure. Parenteral ceftriaxone (1 g daily) is as effective as penicillin. JHR may occur but is usually

mild. Uveitis is treated with a combination of systemic antibiotics and local glucocorticoids. There is no role for the routine use of glucocorticoids in the management of leptospirosis.

Trials in military personnel have shown that infection with *L. interrogans* can be prevented by taking prophylactic doxycycline 200 mg weekly.

Plague

Plague is caused by *Yersinia pestis*, a small Gram-negative bacillus that is spread between rodents by their fleas. If domestic rats become infected, infected fleas may bite humans. Hunters and trappers can contract plague from handling rodents. In the late stages of human plague, *Y. pestis* may be expectorated and spread between humans by droplets, causing 'pneumonic plague'.

Epidemics of plague, such as the 'Black Death', have occurred since ancient times. It is often said that the first sign of plague is the appearance of dead rats. Plague foci are widely distributed throughout the world, including the USA; human cases are reported from about 10 countries per year (Fig. 11.24).

Y. pestis is a potential bioweapon because of the possibility of person-to-person spread and the high fatality rate associated with pneumonic plague.

Clinical features

Organisms inoculated through the skin are transported rapidly to the draining lymph nodes, where they elicit a severe inflammatory response that may be haemorrhagic. If the infection is not contained, sepsis ensues and necrotic, purulent or haemorrhagic lesions develop in many organs. Oliguria and shock follow, and disseminated intravascular coagulation may result in widespread haemorrhage. Inhalation of *Y. pestis* causes alveolitis. The incubation period is 3–6 days but shorter in pneumonic plague.

Bubonic plague

In this, the most common form of the disease, onset is usually sudden, with a rigor, high fever, dry skin and severe headache. Soon, aching and swelling at the site of the affected lymph nodes begin. The groin is the most common site of this 'bubo', made up of the swollen lymph nodes and surrounding tissue. Some infections are relatively mild but, in the majority of patients, toxaemia quickly increases, with a rapid pulse, hypotension and delirium. The spleen is usually palpable.

Septicaemic plague

Those not exhibiting a bubo usually deteriorate rapidly and have a high mortality. The elderly are more prone to this form of illness.

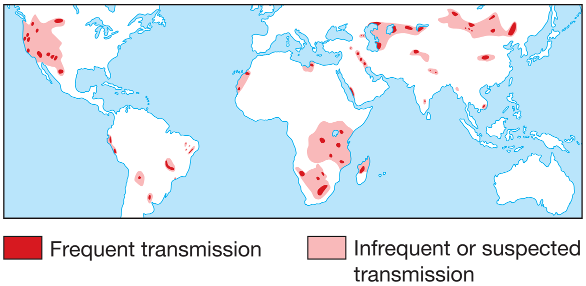

Fig. 11.24 Foci of the transmission of plague. *Reproduced by permission of the World Health Organisation.*

The patient is toxic and may have gastrointestinal symptoms, such as nausea, vomiting, abdominal pain and diarrhoea. DIC may occur, manifested by bleeding from various orifices or puncture sites, along with ecchymoses. Hypotension, shock, renal failure and ARDS may lead to further deterioration. Meningitis, pneumonia and expectoration of blood-stained sputum containing *Y. pestis* may complicate septicaemic, or occasionally bubonic, plague.

Pneumonic plague

Following primary infection in the lung, the onset of disease is very sudden, with cough and dyspnoea. The patient soon expectorates copious blood-stained, frothy, highly infective sputum, becomes cyanosed and dies. Chest radiology reveals bilateral infiltrates, which may be nodular and progress to an ARDS-like picture.

Investigations

The organism may be cultured from blood, sputum and bubo aspirates. For rapid diagnosis, Gram, Giemsa and Wayson's stains (the latter containing methylene blue) are applied to smears from these sites. *Y. pestis* is seen as bipolar staining coccobacilli, sometimes referred to as having a 'safety pin' appearance. Smears are also subjected to antigen detection by immunofluorescence, using *Y. pestis* F1 antigen-specific antibodies. The diagnosis may be confirmed by seroconversion or a single high titre (>128) of anti-F1 antibodies in serum. DNA detection by PCR is under evaluation.

Plague is a notifiable disease under international health regulations (p. 114).

Management

If the diagnosis is suspected on clinical and epidemiological grounds, treatment must be started as soon as, or even before, samples have been collected for laboratory diagnosis. Streptomycin (1 g twice daily) or gentamicin (1 mg/kg 3 times daily) is the drug of choice. Tetracycline (500 mg 4 times daily) and chloramphenicol (12.5 mg/kg 4 times daily) are alternatives. Fluoroquinolones (ciprofloxacin and levofloxacin) may be as effective but there is less clinical experience. Treatment may also be needed for acute circulatory failure, DIC and hypoxia.

Prevention and infection control

Rats and fleas should be controlled. In endemic areas, people should avoid handling and skinning wild animals. The patient should be isolated for the first 48 hours or until clinical improvement begins. Attendants must wear gowns, masks and gloves. Exposed symptomatic or asymptomatic people who have been in close contact with a patient with pneumonic plague should receive post-exposure antibiotic prophylaxis (doxycycline 100 mg or ciprofloxacin 500 mg twice daily) for 7 days.

A recombinant subunit vaccine (protein antigens F1 + V) is in development.

Listeriosis

Listeria monocytogenes is an environmental Gram-positive bacillus that can contaminate food. Outbreaks have been associated with raw vegetables, soft cheeses, under-cooked chicken, fish, meat and pâtés. The bacterium demonstrates 'cold enrichment', outgrowing other contaminating bacteria during refrigeration. Although food-borne outbreaks of gastroenteritis have been reported in immunocompetent individuals, *Listeria* causes more significant invasive infection, especially in pregnant women, older adults (over 55 years) and the immunocompromised.

11

In pregnancy, in addition to systemic symptoms of fever and myalgia, listeriosis causes chorioamnionitis, fetal deaths, abortions and neonatal infection. In other susceptible individuals, it causes systemic illness due to bacteraemia without focal symptoms. Meningitis, similar to other bacterial meningitis but with normal CSF glucose, is the next most common presentation; CSF usually shows increased neutrophils but occasionally only the mononuclear cells are increased (see Box 25.6, p. 1078).

Investigations and management

Diagnosis is made by blood and CSF culture. The organism grows readily in culture media.

The most effective regimen consists of a combination of intravenous amoxicillin or ampicillin plus an aminoglycoside. A sulfamethoxazole/trimethoprim combination can be used in those with penicillin allergy. Cephalosporins are of no use in this infection, as the organism is inherently resistant, an important consideration when treating meningitis empirically.

Proper treatment of foods before eating is the key to preventing listeriosis. Pregnant women are advised to avoid high-risk products, including soft cheeses.

Typhoid and paratyphoid (enteric) fevers

Typhoid and paratyphoid fevers, which are transmitted by the faecal–oral route, are important causes of fever in the Indian subcontinent, sub-Saharan Africa and Latin America. Elsewhere, they are relatively rare. Enteric fevers are caused by infection with *Salmonella* Typhi and *Salmonella* Paratyphi A and B. After a few days of bacteraemia, the bacilli localise, mainly in the lymphoid tissue of the small intestine, resulting in typical lesions in the Peyer's patches and follicles. These swell at first, then ulcerate and usually heal. After clinical recovery, about 5% of patients become chronic carriers (i.e. continue to excrete the bacteria after 1 year); the bacilli may live in the gallbladder for months or years and pass intermittently in the stool and, less commonly, in the urine.

Clinical features

Typhoid fever

Clinical features are outlined in Box 11.42. The incubation period is typically about 10–14 days but can be longer, and the onset may be insidious. The temperature rises in a stepladder fashion for 4 or 5 days with malaise, increasing headache, drowsiness and aching in the limbs. Constipation may be caused by swelling of lymphoid tissue around the ileocaecal junction, although in children diarrhoea and vomiting may be prominent early in the illness. The pulse is often slower than would be expected from the height of the temperature, i.e. a relative bradycardia.

At the end of the first week, a rash may appear on the upper abdomen and on the back as sparse, slightly raised, rose-red spots, which fade on pressure. It is usually visible only on white skin. Cough and epistaxis occur. Around the 7th–10th day, the spleen becomes palpable. Constipation is followed by diarrhoea and abdominal distension with tenderness. Bronchitis and delirium may develop. If untreated, by the end of the second week the patient may be profoundly ill.

Paratyphoid fever

The course tends to be shorter and milder than that of typhoid fever and the onset is often more abrupt with acute enteritis. The rash may be more abundant and the intestinal complications less frequent.

Complications

These are given in Box 11.43. Haemorrhage from, or a perforation of, the ulcerated Peyer's patches may occur at the end of the second week or during the third week of the illness. A drop in temperature to normal or subnormal levels may be falsely reassuring in patients with intestinal haemorrhage. Additional complications may involve almost any viscus or system because of the bacteraemia present during the first week. Bone and joint infection is common in children with sickle-cell disease.

Investigations

In the first week, diagnosis may be difficult because, in this invasive stage with bacteraemia, the symptoms are those of a generalised infection without localising features. Typically, there is a leucopenia. Blood culture establishes the diagnosis and multiple cultures increase the yield. Stool cultures are often positive in the second and third weeks. The Widal test detects antibodies to the O and H antigens but is not specific.

Management

Antibiotic therapy must be guided by in vitro sensitivity testing. Chloramphenicol (500 mg 4 times daily), ampicillin (750 mg 4 times daily) and co-trimoxazole (2 tablets or IV equivalent twice daily) are losing their effect due to resistance in many areas of the world, especially India and South-east Asia. Fluoroquinolones are the drugs of choice (e.g. ciprofloxacin 500 mg twice daily), if nalidixic acid screening predicts susceptibility, but resistance is common, especially in the Indian subcontinent and also in the UK. Extended-spectrum cephalosporins (ceftriaxone and cefotaxime) are useful alternatives but have a slightly increased

11.42 Clinical features of typhoid fever

First week

• Persistent gallbladder carriage	

treatment failure rate. Azithromycin (500 mg once daily) is an alternative when fluoroquinolone resistance is present but has not been validated in severe disease. Treatment should be continued for 14 days. Pyrexia may persist for up to 5 days after the start of specific therapy. Even with effective chemotherapy, there is still a danger of complications, recrudescence of the disease and the development of a carrier state.

Chronic carriers were formerly treated for 4 weeks with ciprofloxacin but may require an alternative agent and duration, as guided by antimicrobial sensitivity testing. Cholecystectomy may be necessary.

Prevention

Improved sanitation and living conditions reduce the incidence of typhoid. Travellers to countries where enteric infections are endemic should be inoculated with one of the three available typhoid vaccines (two inactivated injectable and one oral live attenuated).

Tularaemia

Tularaemia is primarily a zoonotic disease of the northern hemisphere. It is caused by a highly infectious Gram-negative bacillus, *Francisella tularensis*. *F. tularensis* is passed transovarially (ensuring transmission from parent to progeny) in ticks, which allows persistence in nature without the absolute requirement for an infected animal reservoir. It is a potential weapon for bioterrorism. Wild rabbits, rodents and domestic dogs or cats are potential reservoirs, and ticks, mosquitoes or other biting flies are the vectors.

Infection is introduced either through an arthropod or animal bite or via contact with infected animals, soil or water through skin abrasions. The most common 'ulceroglandular' variety of the disease (70–80%) is characterised by skin ulceration with regional lymphadenopathy. There is also a purely 'glandular' form. Alternatively, inhalation of the infected aerosols may result in pulmonary tularaemia, presenting as pneumonia. Rarely, the portal of entry of infection may be the conjunctiva, leading to a nodular, ulcerated conjunctivitis with regional lymphadenopathy (an 'oculoglandular' form). Typhoidal tularaemia is a rare and serious form of tularaemia with vomiting, diarrhoea and hepatosplenomegaly, which may be complicated by pneumonia and meningitis.

Investigations and management

Demonstration of a single high titre (≥1 : 160) or a fourfold rise in 2–3 weeks in the tularaemia tube agglutination test confirms the diagnosis. Bacterial yield from the lesions is extremely poor. DNA detection methods to enable rapid diagnosis are in development.

Treatment consists of a 10–21-day course of parenteral aminoglycosides, streptomycin (7.5–10 mg/kg twice daily) or gentamicin (1.7 mg/kg 3 times daily), with doxycycline or ciprofloxacin offered as alternatives.

Melioidosis

Melioidosis is caused by *Burkholderia pseudomallei*, a saprophyte found in soil and water (rice paddy fields). Infection is by inoculation or inhalation, leading to bacteraemia, which is followed by the formation of abscesses in the lungs, liver and spleen. Patients with diabetes, renal stones, thalassaemia or severe burns are particularly susceptible. The disease is most common in South-east Asia and northern Australia, and carries a significant mortality. Disease may present years or decades after the initial exposure.

Clinical features

Pneumonia is the most common feature but localised skin nodules and abscesses, or sepsis, especially in diabetics, may occur. Diarrhoea and hepatosplenomegaly may be observed. The chest X-ray can resemble cavitatory tuberculosis. In chronic forms, multiple abscesses occur in subcutaneous tissue, liver, spleen and bone, accompanied by profound weight loss.

Investigations and management

Culture of blood, sputum or pus on selective media, e.g. Ashdown agar, may yield *B. pseudomallei*. Latex agglutination has been developed as a rapid diagnostic test in Thailand and PCR-based tests are also available. Indirect haemagglutination testing can be helpful in travellers; however, most people in endemic areas are seropositive.

In the acute illness, prompt initiation of empirical therapy is life-saving. Ceftazidime 100 mg/kg (2 g 3 times daily) or meropenem (0.5–1 g 3 times daily) is given for 2–3 weeks, followed by maintenance therapy of co-trimoxazole (sulfamethoxazole 1600 mg plus trimethoprim 320 mg twice daily) or doxycycline 200 mg daily for 3–6 months. Abscesses should be drained surgically.

11

Actinomycete infections

Nocardiosis

Nocardiosis is an uncommon infection caused by aerobic Actinomycetes of the genus *Nocardia*, which are found in the soil. Infection occurs most frequently by direct traumatic inoculation or occasionally via inhalation or ingestion. Nocardiosis can result in localised cutaneous ulcers or nodules, most often in the lower limbs. Chronic destructive infection in tropical countries can result in actinomycetoma, involving soft tissues with occasional penetration to the bone. Actinomycetoma may also be caused by other aerobic Actinomycetes, and a similar clinical syndrome, eumycetoma, is caused by filamentous fungi. Both conditions are discussed on page 301. Systemic *Nocardia* infection, most commonly in immunocompromised individuals, results in suppurative disease with lung and brain abscesses.

On microscopy, *Nocardia* spp. appear as long, filamentous, branching Gram-positive rods, which are also weakly acid-fast. They are easily grown in culture but require prolonged incubation.

Treatment of systemic infection is guided by sensitivity testing and typically requires combinations of imipenem with ceftriaxone, amikacin or co-trimoxazole, often for 6–12 months or longer. Meropenem, tigecycline, linezolid and minocycline may also be used with severe disease or with allergy, or when intolerance prevents use of the preferred agents. Abscesses are drained surgically when this is feasible. Localised cutaneous infection is usually treated with a single agent for 1–3 months. Treatment of actinomycetoma is discussed on page 301.

Actinomyces *spp.*

Actinomyces are anaerobic Actinomycetes, which are predominantly commensals of the oral cavity. They are capable of causing deep, suppurating infection in the head and neck (cervicofacial actinomycosis) and the lungs (thoracic actinomycosis). They also cause suppurating disease in the pelvis, associated with intrauterine contraceptive devices (IUCDs). Modern diagnostic techniques demonstrate that actinomycosis

is caused by many different *Actinomyces* species, the most common of which is *Actinomyces israelii*. Treatment of established disease requires prolonged (about 6–12 months) of penicillin or doxycycline. Early disease may respond to shorter antibiotic courses.

Gastrointestinal bacterial infections

The approach to patients presenting with acute gastroenteritis is described on page 227.

Staphylococcal food poisoning

Staph. aureus is transmitted via the hands of food handlers to foodstuffs such as dairy products, including cheese, and cooked meats. Inappropriate storage of these foods allows growth of the organism and production of one or more heat-stable enterotoxins that cause the symptoms.

Nausea and profuse vomiting develop within 1–6 hours. Diarrhoea may not be marked. The toxins that cause the syndrome act as 'super-antigens' and induce a significant neutrophil leucocytosis that may be clinically misleading. Most cases settle rapidly but severe dehydration can occasionally be life-threatening.

Antiemetics and appropriate fluid replacement are the mainstays of treatment. Suspect food should be cultured for staphylococci and demonstration of toxin production. The public health authorities should be notified if food vending is involved.

Bacillus cereus food poisoning

Ingestion of the pre-formed heat-stable exotoxins of *B. cereus* causes rapid onset of vomiting and some diarrhoea within hours of food consumption, which resolves within 24 hours. Fried rice and freshly made sauces are frequent sources; the organism grows and produces enterotoxin during storage (Fig. 11.25). If viable bacteria are ingested and toxin formation takes place within the gut lumen, then the incubation period is longer (12–24 hours) and watery diarrhoea and cramps are the predominant symptoms. The disease is self-limiting but can be quite severe.

Rapid and judicious fluid replacement and appropriate notification of the public health authorities are all that is required.

Clostridium perfringens food poisoning

Spores of *C. perfringens* are widespread in the guts of large animals and in soil. If contaminated meat products are incompletely cooked and stored in anaerobic conditions, *C. perfringens* spores germinate and viable organisms multiply. Subsequent reheating of the food causes release of enterotoxin. Symptoms (diarrhoea and cramps) occur some 6–12 hours following ingestion. The illness is usually self-limiting.

Clostridial enterotoxins are potent and most people who ingest them will be symptomatic. 'Point source' outbreaks, in which a number of cases all become symptomatic following ingestion, classically occur after school or canteen lunches where meat stews are served.

Clostridial necrotising enteritis (CNE) or pigbel is an often-fatal type of food poisoning caused by a β-toxin of *C. perfringens*, type C. The toxin is normally inactivated by certain proteases or by normal cooking. Pigbel is more likely in protein malnutrition or in the presence of trypsin inhibitors, either in foods such as sweet potatoes or during infection with *Ascaris* sp. roundworms.

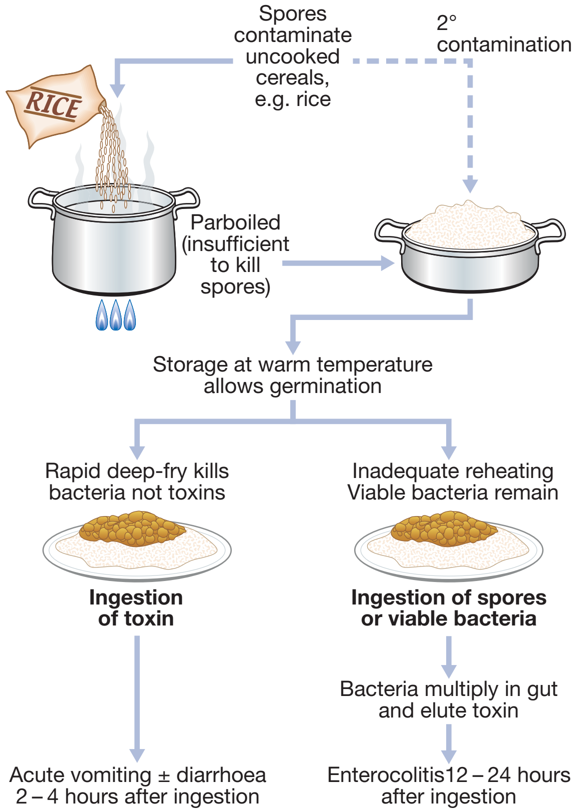

Fig. 11.25 ***Bacillus cereus* food poisoning.**

Campylobacter jejuni infection

This infection is essentially a zoonosis, although contaminated water may be implicated, as the organism can survive for many weeks in fresh water. The most common sources of the infection are chicken, beef and contaminated milk products. Pet puppies have also been sources. *Campylobacter* infection is now the most common cause of bacterial gastroenteritis in the UK, accounting for some 100 000 cases per annum, most of which are sporadic.

The incubation period is 2–5 days. Colicky abdominal pain may be severe and mimic acute appendicitis or other surgical pathology. Nausea, vomiting and significant diarrhoea, frequently containing blood, are common features. The majority of *Campylobacter* infections affect fit young adults and are self-limiting after 5–7 days. About 10–20% will have prolonged symptomatology, occasionally meriting treatment with a macrolide, most often azithromycin, as many organisms are resistant to ciprofloxacin.

Approximately 1% of cases will develop bacteraemia and possible distant foci of infection. *Campylobacter* spp. have been linked to Guillain–Barré syndrome and post-infectious reactive arthritis (pp. 1140 and 1031).

Salmonella spp. infection

Salmonella enterica serovars other than *Salmonella* Typhi and Paratyphi (p. 260), of which there are more than 2000, can cause gastroenteritis. They are widely distributed throughout the animal kingdom. Two serovars are most important worldwide: *Salmonella* Enteritidis phage type 4 and *Salmonella* Typhimurium dt.104. The

latter may be resistant to commonly used antibiotics such as ciprofloxacin. Some strains have a clear relationship to particular animal species, e.g. *Salmonella* Arizonae and pet reptiles. Transmission is by contaminated water or food, particularly poultry, egg products and minced beef, direct person-to-person spread or the handling of exotic pets such as salamanders, lizards or turtles. The incidence of *Salmonella* enteritis is falling in the UK due to an aggressive culling policy in broiler chicken stocks, coupled with vaccination.

The incubation period of *Salmonella* gastroenteritis is 12–72 hours and the predominant feature is diarrhoea, sometimes with passage of blood. Vomiting may be present at the outset. Approximately 5% of cases are bacteraemic and invasive non-typhoidal salmonellosis is a leading cause of bacteraemia in sub-Saharan Africa. Reactive (post-infective) arthritis occurs in approximately 2%.

Antibiotics are not indicated for uncomplicated *Salmonella* gastroenteritis but are prescribed for bacteraemia. Salmonellae are notorious for persistent infection and can seed endothelial surfaces such as an atherosclerotic aorta. Mortality, as with other forms of gastroenteritis, is higher in the elderly (see Box 11.12, p. 228).

Escherichia coli infection

Many serotypes of *E. coli* constitute part of the human gut microbiome. Clinical disease requires either colonisation with a new or previously unrecognised strain, or the acquisition by current colonising bacteria of a particular pathogenicity factor for mucosal attachment or toxin production. Travel to unfamiliar areas of the world allows contact with different strains of endemic *E. coli* and the development of travellers' diarrhoea. Enteropathogenic strains may be found in the gut of healthy individuals and, if these people move to a new environment, close contacts may develop symptoms.

At least five different clinico-pathological patterns of diarrhoea are associated with specific strains of *E. coli* with characteristic virulence factors.

Enterotoxigenic *E. coli*

Enterotoxigenic *E. coli* (ETEC) is the most common cause of travellers' diarrhoea, although there are other causes (see Box 11.20, p. 232). The organisms produce either a heat-labile or a heat-stable enterotoxin, causing marked secretory diarrhoea and vomiting after 1–2 days' incubation. The illness is usually mild and self-limiting after 3–4 days. Antibiotics are of questionable value (p. 232).

Entero-invasive *E. coli*

Illness caused by entero-invasive *E. coli* (EIEC) is very similar to *Shigella* dysentery (p. 265) and is caused by invasion and destruction of colonic mucosal cells. No enterotoxin is produced. Acute watery diarrhoea, abdominal cramps and some scanty blood-staining of the stool are common. The symptoms are rarely severe and are usually self-limiting.

Enteropathogenic *E. coli*

Enteropathogenic *E. coli* (EPEC) organisms are very important in infant diarrhoea. They are able to attach to the gut mucosa, inducing a specific 'attachment and effacement' lesion and causing destruction of microvilli and disruption of normal absorptive capacity. The symptoms vary from mild non-bloody diarrhoea to quite severe illness, but without bacteraemia.

Entero-aggregative *E. coli*

Entero-aggregative *E. coli* (EAEC) strains adhere to the mucosa but also produce a locally active enterotoxin and demonstrate a particular 'stacked brick' aggregation to tissue culture cells when viewed by microscopy. They have been associated with prolonged diarrhoea in children in South America, South-east Asia and India.

Enterohaemorrhagic *E. coli*

A number of distinct 'O' serotypes of *E. coli* possess both the genes necessary for adherence (see 'EPEC' above) and plasmids encoding two distinct enterotoxins (verotoxins), which are identical to the toxins produced by *Shigella* ('shiga toxins 1 and 2'). *E. coli* O157:H7 is perhaps the best known of these verotoxin-producing *E. coli* (VTEC) but others, including types O126 and O11, are also implicated. In 2011, an outbreak of food-borne illness linked to fenugreek seeds occurred in Germany and was due to *E. coli* O104:H4, an EAEC strain that had acquired genes encoding shiga toxin 2a. Although the incidence of enterohaemorrhagic *E. coli* (EHEC) is considerably lower than that of *Campylobacter* and *Salmonella* infection, it is increasing in the developing world.

The reservoir of infection is in the gut of herbivores. The organism has an extremely low infecting dose (10–100 organisms). Runoff water from pasture lands where cattle have grazed, which is used to irrigate vegetable crops, as well as contaminated milk, meat products (especially hamburgers that have been incompletely cooked), lettuce, radish shoots and apple juice have all been implicated as sources (Fig. 11.26).

The incubation period is between 1 and 7 days. Initial watery diarrhoea becomes uniformly blood-stained in 70% of cases and

11

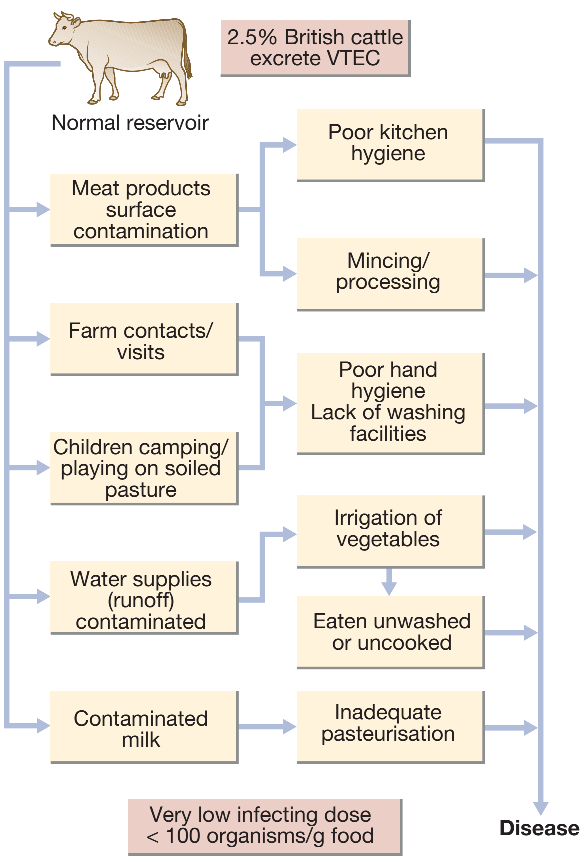

Fig. 11.26 Verocytotoxigenic *Escherichia coli* (VTEC) infections.

is associated with severe abdominal pain. There is little systemic upset, vomiting or fever.

Enterotoxins have both a local effect on the bowel and a distant effect on particular body tissues, such as glomerular apparatus, heart and brain. The potentially life-threatening haemolytic uraemic syndrome (HUS, p. 408) occurs in 10–15% of sufferers from this infection, arising 5–7 days after the onset of symptoms. It is most likely at the extremes of age, is heralded by a high peripheral leucocyte count, and may be induced, particularly in children, by antibiotic therapy.

HUS is treated by dialysis if necessary and may be averted by plasma exchange. Antibiotics should be avoided since they can stimulate toxin release.

Clostridium difficile infection

C. difficile is the most commonly diagnosed cause of antibiotic-associated diarrhoea (p. 230), and is an occasional constituent of the gut microbiome. *C. difficile* can produce two toxins (A and B). *C. difficile* infection (CDI) usually follows antimicrobial therapy, which alters the composition of the gastrointestinal flora and may result in colonisation with toxigenic *C. difficile*, if the patient is exposed to *C. difficile* spores. The combination of toxin production and the ability to produce environmentally stable spores accounts for the clinical features and transmissibility of CDI. A hypervirulent strain of *C. difficile*, ribotype 027, has emerged, which produces more toxin and more severe disease than other *C. difficile* strains.

Clinical features

Disease manifestations range from diarrhoea to life-threatening pseudomembranous colitis. Around 80% of cases occur in people over 65 years of age, many of whom are frail with comorbid diseases. Symptoms usually begin in the first week of antibiotic therapy but can occur at any time up to 6 weeks after treatment has finished. The onset is often insidious, with lower abdominal pain and diarrhoea that may become profuse and watery. The presentation may resemble acute ulcerative colitis with bloody diarrhoea, fever and even toxic dilatation and perforation. Ileus is also seen in pseudomembranous colitis.

Investigations

C. difficile can be isolated from stool culture in 30% of patients with antibiotic-associated diarrhoea and over 90% of those with pseudomembranous colitis, but also from 5% of healthy adults and up to 20% of elderly patients in residential care. The diagnosis of CDI therefore rests on detection of toxins A or B in the stool. Current practice in the UK is to screen stool from patients with a compatible clinical syndrome by detection either of glutamate dehydrogenase (GDH), an enzyme produced by *C. difficile*, or of *C. difficile* nucleic acid (e.g. by PCR); if screening is positive, a *C. difficile* toxin ELISA or a tissue culture cytotoxicity assay is performed.

The rectal appearances at sigmoidoscopy may be characteristic, with erythema, white plaques or an adherent pseudomembrane (Fig. 11.27), or may resemble ulcerative colitis. In some cases, the rectum is spared and abnormalities are observed in the proximal colon. Patients who are ill require abdominal and erect chest X-rays to exclude perforation or toxic dilatation. CT may be useful when the diagnosis is in doubt.

Management

The precipitating antibiotic should be stopped and the patient should be isolated. Supportive therapy includes intravenous fluids and bowel rest. First-line antimicrobial therapy involves metronidazole (500 mg orally 3 times daily for 10 days) or vancomycin (125 mg orally 4 times daily for 7–10 days). Although vancomycin is more effective than metronidazole against hypervirulent *C. difficile* strains (e.g. ribotype 027), it is more expensive and may drive the emergence of vancomycin resistance in other organisms (e.g. enterococci, *Staph. aureus*). For these reasons, some authorities reserve its use for relapse (15–30% of patients), failure of initial response or severe infection. Fidaxomicin is associated with a lower relapse rate than vancomycin but is more expensive. Intravenous immunoglobulin and/or glucocorticoids are sometimes given in the most severe or refractory cases, and faecal transplantation from a healthy donor is increasingly used to manage relapses by restoring a more advantageous gut microbiome profile. Surgical intervention needs to be considered early in severe cases.

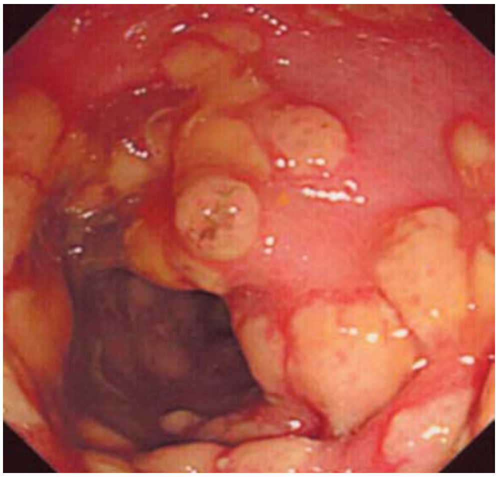

Fig. 11.27 Clostridium difficile infection. Colonoscopic view showing numerous adherent 'pseudomembranes' on the mucosa.

Yersinia enterocolitica infection

Yersinia enterocolitica, commonly found in pork, causes mild to moderate gastroenteritis and can produce significant mesenteric adenitis after an incubation period of 3–7 days. It predominantly causes disease in children but adults may also be affected. The illness resolves slowly. Complications include reactive arthritis (p. 1031; 10–13% of cases), which may be persistent, and anterior uveitis.

Cholera

Cholera, caused by *Vibrio cholerae* serotype O1, is the archetypal toxin-mediated bacterial cause of acute watery diarrhoea. The enterotoxin activates adenylate cyclase in the intestinal epithelium, inducing net secretion of chloride and water. *V. cholerae* O1 has two biotypes, classical and El Tor, and each of these has two distinct serotypes, Inaba and Ogawa. Following its origin in the Ganges valley, devastating epidemics have occurred, often in association with large religious festivals, and pandemics have spread worldwide. The seventh pandemic, due to the El Tor biotype, began in 1961 and spread via the Middle East to become endemic in Africa, subsequently spreading throughout South and Central America. Numbers of cases of cholera have been increasing, with outbreaks in Ghana in 2014 and Tanzania in 2015. El Tor is more resistant to commonly used antimicrobials than classical *Vibrio*, and causes prolonged carriage in 5% of

infections. An atypical serotype, O139, has been responsible for localised outbreaks in Bangladesh.

Infection spreads via the stools or vomit of symptomatic patients or of the much larger number of subclinical cases. Organisms survive for up to 2 weeks in fresh water and 8 weeks in salt water. Transmission is normally through infected drinking water, shellfish and food contaminated by flies, or on the hands of carriers.

Clinical features

Severe diarrhoea without pain or colic begins suddenly and is followed by vomiting. Following the evacuation of normal gut faecal contents, typical 'rice water' material is passed, consisting of clear fluid with flecks of mucus. Classical cholera produces enormous loss of fluid and electrolytes, leading to intense dehydration with muscular cramps. Shock and oliguria develop but mental clarity remains. Death from acute circulatory failure may occur rapidly unless fluid and electrolytes are replaced. Improvement is rapid with proper treatment.

The majority of infections, however, cause mild illness with slight diarrhoea. Occasionally, a very intense illness, 'cholera sicca', occurs, with loss of fluid into dilated bowel, killing the patient before typical gastrointestinal symptoms appear. The disease is more dangerous in children.

Diagnosis and management

Clinical diagnosis is easy during an epidemic. Otherwise, the diagnosis should be confirmed bacteriologically. Stool dark-field microscopy shows the typical 'shooting star' motility of *V. cholerae*. Rectal swab or stool cultures allow identification. Cholera is notifiable under international health regulations.

Maintenance of circulation by replacement of water and electrolytes is paramount (p. 229). Ringer-Lactate is the best fluid for intravenous replacement. Vomiting usually stops once the patient is rehydrated, and fluid should then be given orally up to 500 mL hourly. Early intervention with oral rehydration solutions that include resistant starch, based on either rice or cereal, shortens the duration of diarrhoea and improves prognosis. Severe dehydration, as indicated by altered consciousness, skin tenting, very dry tongue, decreased pulses, low blood pressure or minimal urine output, mandates intravenous replacement. Total fluid requirements may exceed 50 L over a period of 2–5 days. Accurate records are greatly facilitated by the use of a 'cholera cot', which has a reinforced hole under the patient's buttocks, beneath which a graded bucket is placed.

Three days' treatment with tetracycline 250 mg 4 times daily, a single dose of doxycycline 300 mg or ciprofloxacin 1 g in adults reduces the duration of excretion of *V. cholerae* and the total volume of fluid needed for replacement.

Prevention

Strict personal hygiene is vital and drinking water should come from a clean piped supply or be boiled. Flies must be denied access to food. Oral vaccines containing killed *V. cholerae* with or without the B subunit of cholera toxin are used in specific settings.

In epidemics, improvements in sanitation and access to clean water, public education and control of population movement are vital. Mass single-dose vaccination and treatment with tetracycline are valuable. Disinfection of discharges and soiled clothing, and scrupulous hand-washing by medical attendants reduce spread.

Vibrio parahaemolyticus infection

This marine organism produces a disease similar to enterotoxigenic *E. coli* (see above). It is very common where ingestion of raw seafood is widespread (e.g. Japan). After an incubation period of approximately 20 hours, explosive diarrhoea, abdominal cramps and vomiting occur. Systemic symptoms of headache and fever are frequent but the illness is self-limiting after 4–7 days. Rarely, a severe septic illness arises; in this case, *V. parahaemolyticus* can be isolated using specific halophilic culture.

Bacillary dysentery (shigellosis)

Shigellae are Gram-negative rods, closely related to *E. coli*, that invade the colonic mucosa. There are four main groups: *Sh. dysenteriae*, *flexneri*, *boydii* and *sonnei.* In the tropics, bacillary dysentery is usually caused by *Sh. flexneri*, while in the UK most cases are caused by *Sh. sonnei*. Shigellae are often resistant to multiple antibiotics, especially in tropical countries. The organism only infects humans and its spread is facilitated by its low infecting dose of around 10 organisms.

Spread may occur via contaminated food or flies, but person-to-person transmission by unwashed hands after defaecation is the most important factor. Outbreaks occur in psychiatric hospitals, residential schools and other closed institutions, and dysentery is a constant accompaniment of wars and natural catastrophes, which bring crowding and poor sanitation in their wake. *Shigella* infection may spread rapidly among men who have sex with men.

Clinical features

Disease severity varies from mild *Sh. sonnei* infections that may escape detection to more severe *Sh. flexneri* infections, while those due to *Sh. dysenteriae* may be fulminating and cause death within 48 hours.

In a moderately severe illness, the patient complains of diarrhoea, colicky abdominal pain and tenesmus. Stools are small, and after a few evacuations contain blood and purulent exudate with little faecal material. Fever, dehydration and weakness occur, with tenderness over the colon. Reactive arthritis or iritis may occasionally complicate bacillary dysentery (p. 1031).

Management and prevention

Oral rehydration therapy or, if diarrhoea is severe, intravenous replacement of water and electrolyte loss is necessary. Antibiotic therapy is with ciprofloxacin (500 mg twice daily for 3 days) Azithromycin and ceftriaxone are alternatives but resistance occurs to all agents, especially in Asia. The use of antidiarrhoeal medication should be avoided.

The prevention of faecal contamination of food and milk and the isolation of cases may be difficult, except in limited outbreaks. Hand-washing is very important.

Respiratory bacterial infections

Most of these infections are described in Chapter 17.

Diphtheria

Infection with *Corynebacterium diphtheriae* occurs most commonly in the upper respiratory tract and is usually spread by droplet infection. Infection may also complicate skin lesions, especially in alcoholics. The organisms remain localised at the site of infection but release of a soluble exotoxin damages the heart muscle and the nervous system.

Diphtheria has been eradicated from many parts of the world by mass vaccination using a modified exotoxin but remains

i 11.44 Clinical features of diphtheria

Acute infection
• Membranous tonsillitis • *or* Nasal infection • *or* Laryngeal infection • *or* Skin/wound/conjunctival infection (rare)
Complications
• Laryngeal obstruction or paralysis • Myocarditis • Peripheral neuropathy

important in areas where vaccination has been incomplete, e.g. in Russia and South-east Asia. The disease is notifiable in all countries of Europe and North America, and international guidelines have been issued by the WHO for the management of infection.

Clinical features

The average incubation period is 2–4 days. The disease begins insidiously with a sore throat (Box 11.44). Despite modest fever, there is usually marked tachycardia. The diagnostic feature is the 'wash-leather' elevated, greyish-green membrane on the tonsils. It has a well-defined edge, is firm and adherent, and is surrounded by a zone of inflammation. There may be swelling of the neck ('bull neck') and tender enlargement of the lymph nodes. In the mildest infections, especially where there is a high degree of immunity, a membrane may not appear and inflammation is minimal.

With anterior nasal infection there is nasal discharge, frequently blood-stained. In laryngeal diphtheria, a husky voice and high-pitched cough signal potential respiratory obstruction requiring urgent tracheostomy. If infection spreads to the uvula, fauces and nasopharynx, the patient is gravely ill.

Death from acute circulatory failure may occur within the first 10 days. Late complications arise as a result of toxin action on the heart or nervous system. About 25% of survivors of the early toxaemia may later develop myocarditis with arrhythmias or cardiac failure. These are usually reversible, with no permanent damage other than heart block in survivors.

Neurological involvement occurs in 75% of cases. After tonsillar or pharyngeal diphtheria, it usually starts after 10 days with palatal palsy. Paralysis of accommodation often follows, manifest by difficulty in reading small print. Generalised polyneuritis with weakness and paraesthesia may follow in the next 10–14 days. Recovery from such neuritis is always ultimately complete.

Management

A clinical diagnosis of diphtheria must be notified to the public health authorities and the patient sent urgently to a specialist infectious diseases unit. Empirical treatment should commence after collection of appropriate swabs.

Diphtheria antitoxin is produced from hyperimmune horse serum. It neutralises circulating toxin but has no effect on toxin already fixed to tissues, so it must be injected intramuscularly without awaiting the result of a throat swab. However, reactions to this foreign protein include a potentially lethal immediate anaphylactic reaction (p. 75) and a 'serum sickness' with fever, urticaria and joint pains, which occurs 7–12 days after injection. A careful history of previous horse serum injections or allergic reactions should be taken and a small test injection of serum should be given half an hour before the full dose in every patient. Adrenaline (epinephrine) solution must be available to deal with any immediate type of reaction (0.5–1.0 mL of 1/1000 solution IM). An antihistamine is also given. In a severely ill patient, the risk of anaphylactic shock is outweighed by the mortal danger of diphtheritic toxaemia. A dose of up to 100 000 IU of antitoxin is injected intravenously if the test dose is tolerated. For disease of moderate severity, 16 000–40 000 IU IM will suffice, and for mild cases 4000–8000 IU.

Penicillin (1200 mg 4 times daily IV) or amoxicillin (500 mg 3 times daily) should be administered for 2 weeks to eliminate *C. diphtheriae.* Patients allergic to penicillin can be given erythromycin. Due to poor immunogenicity of primary infection, all sufferers should be immunised with diphtheria toxoid following recovery.

Patients must be managed in strict isolation and attended by staff with a clearly documented immunisation history until three swabs 24 hours apart are culture-negative.

Prevention

Active immunisation should be given to all children. If diphtheria occurs in a closed community, contacts should be given erythromycin, which is more effective than penicillin in eradicating the organism in carriers.

All contacts should also be immunised or given a booster dose of toxoid. Booster doses are required every 10 years to maintain immunity.

Pneumococcal infection

Strep. pneumoniae (the pneumococcus) is the leading cause of community-acquired pneumonia globally (p. 582) and one of the leading causes of infection-related mortality. Otitis media, meningitis and sinusitis are also frequently caused by *Strep. pneumoniae*. Occasional patients present with bacteraemia without obvious focus. Asplenic individuals are at risk of fulminant pneumococcal disease with purpuric rash.

Increasing rates of penicillin resistance have been reported around the world for *Strep. pneumoniae*, although they remain low in the UK. Strains with cephalosporin resistance causing meningitis require treatment with a combination of cephalosporins, glycopeptides and rifampicin. Macrolide resistance is also increasing. Newer quinolones are also used (e.g. levofloxacin) but rates of resistance are rising.

Vaccination of infants with the protein conjugate pneumococcal vaccine decreases *Strep. pneumoniae* infection in infants and in their relatives. The polysaccharide pneumococcal vaccine is used in individuals predisposed to *Strep. pneumoniae* infection and the elderly, but only modestly reduces pneumococcal bacteraemia and does not prevent pneumonia. All asplenic individuals should receive vaccination against *Strep. pneumoniae*.

Anthrax

Anthrax is an endemic zoonosis in many countries; it causes human disease following inoculation of the spores of *Bacillus anthracis*. *B. anthracis* was the first bacterial pathogen described by Koch and the model pathogen for 'Koch's postulates' (see Box 6.1, p. 100). It is a Gram-positive organism with a central spore. The spores can survive for years in soil. Infection is commonly acquired from contact with animals, particularly herbivores. The ease of production of *B. anthracis* spores makes this infection a candidate for biological warfare or bioterrorism. *B. anthracis* produces a number of toxins that mediate the clinical features of disease.

Clinical features

These depend on the route of entry of the anthrax spores.

Cutaneous anthrax

This skin lesion is associated with occupational exposure to anthrax spores during processing of hides and bone products. It accounts for the vast majority of clinical cases. Animal infection is a serious problem in Africa, India, Pakistan and the Middle East.

Spores are inoculated into exposed skin. A single lesion develops as an irritable papule on an oedematous haemorrhagic base. This progresses to a depressed black eschar. Despite extensive oedema, pain is infrequent.

Gastrointestinal anthrax

This is associated with the ingestion of contaminated meat. The caecum becomes infected, which produces nausea, vomiting, anorexia and fever, followed in 2–3 days by severe abdominal pain and bloody diarrhoea. Toxaemia and death can develop rapidly thereafter.

Inhalational anthrax

This form of the disease is extremely rare but has been associated with bioterrorism. Without rapid and aggressive therapy at the onset of symptoms, the mortality is 50–90%. Fever, dyspnoea, cough, headache and sepsis develop 3–14 days following exposure. Typically, the chest X-ray shows only widening of the mediastinum and pleural effusions, which are haemorrhagic. Meningitis may occur.

Management

B. anthracis can be cultured from skin swabs from lesions. Skin lesions are readily curable with early antibiotic therapy. Treatment is with ciprofloxacin (500 mg twice daily) until penicillin susceptibility is confirmed; the regimen can then be changed to benzylpenicillin with doses up to 2.4 g IV given 6 times daily or phenoxymethylpenicillin 500–1000 mg 4 times daily administered for 10 days. The addition of an aminoglycoside may improve the outlook in severe disease. In view of concerns about concomitant inhalational exposure, particularly in the era of bioterrorism, a further 2-month course of ciprofloxacin 500 mg twice daily or doxycycline 100 mg twice daily orally is added to eradicate inhaled spores. Inhalational anthrax is treated with ciprofloxacin and clindamycin for at least 14 days, followed by therapy to eradicate spores. Monoclonal antibodies against *B. anthracis* protective antigen can be added for systemic infection. Prophylaxis with ciprofloxacin (500 mg twice daily for 2 months) is recommended for anyone at high risk of inhalational exposure to anthrax spores and should be combined with three doses of anthrax vaccine adsorbed (AVA).

Bacterial infections with neurological involvement

Infections affecting the CNS, including bacterial meningitis, botulism and tetanus, are described on page 1117.

Mycobacterial infections

Tuberculosis

Tuberculosis is predominantly, although by no means exclusively, a respiratory disease and is described on page 588.

Leprosy

Leprosy (Hansen's disease) is a chronic granulomatous disease affecting skin and nerves and caused by *Mycobacterium leprae*, a slow-growing mycobacterium that cannot be cultured in vitro. The clinical manifestations are determined by the degree of the patient's cell-mediated immunity (CMI; p. 69) towards *M. leprae* (Fig. 11.28). High levels of CMI with elimination of leprosy bacilli produces tuberculoid leprosy, whereas absent CMI results in lepromatous leprosy. Complications arise due to nerve damage, immunological reactions and bacillary infiltration. People with leprosy are frequently stigmatised and using the word 'leper' is inappropriate.

Epidemiology and transmission

Some 4 million people have leprosy and around 750 000 new cases are detected annually. About 70% of the world's leprosy patients live in India, with the disease endemic in Brazil, Indonesia, Mozambique, Madagascar, Tanzania and Nepal.

Untreated lepromatous patients discharge bacilli from the nose. Infection occurs through the nose, followed by haematogenous spread to skin and nerve. The incubation period is 2–5 years for tuberculoid cases and 8–12 years for lepromatous cases. Leprosy incidence peaks at 10–14 years, and is more common in males and in household contacts of leprosy cases.

Pathogenesis

M. leprae has tropism for Schwann cells and skin macrophages. In tuberculoid leprosy, effective CMI controls bacillary multiplication ('paucibacillary') and organised epithelioid granulomata form. In lepromatous leprosy, there is abundant bacillary multiplication ('multibacillary'), e.g. in Schwann cells and perineurium. Between these two extremes is a continuum, varying from patients with

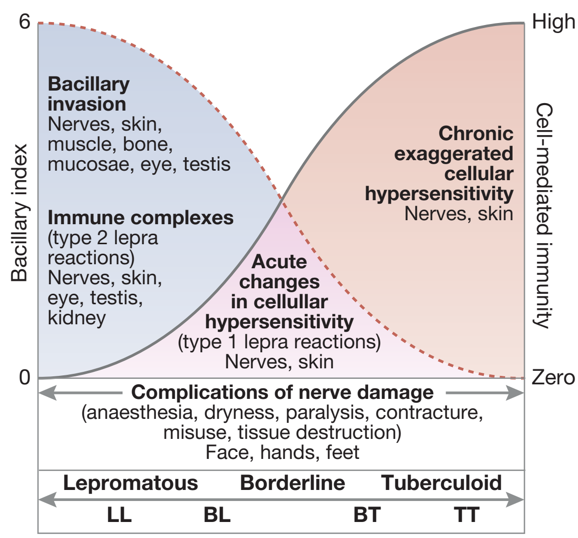

Fig. 11.28 Leprosy: mechanisms of damage and tissue affected. Mechanisms under the broken line are characteristic of disease near the lepromatous end of the spectrum, and those under the solid line are characteristic of the tuberculoid end. They overlap in the centre where, in addition, instability predisposes to type 1 lepra reactions. At the peak in the centre, neither bacillary growth nor cell-mediated immunity has the upper hand. (BL = borderline lepromatous; BT = borderline tuberculoid) *Adapted from Bryceson ADM, Pfaltzgraff RE. Leprosy, 3rd edn. Churchill Livingstone, Elsevier Ltd; 1990.*

moderate CMI (borderline tuberculoid) to patients with little cellular response (borderline lepromatous).

Immunological reactions evolve as the immune response develops and the bacillary antigenic stimulus varies, particularly in borderline patients. Delayed hypersensitivity reactions produce type 1 (reversal) reactions, while immune complexes contribute to type 2 (erythema nodosum leprosum) reactions.

HIV/leprosy co-infected patients have typical lepromatous and tuberculoid leprosy skin lesions and typical leprosy histology and granuloma formation. Surprisingly, even with low circulating CD4 counts, tuberculoid leprosy may be observed and there is not an obvious shift to lepromatous leprosy.

Clinical features

Box 11.45 gives the cardinal features of leprosy. Types of leprosy are compared in Box 11.46.

- *Skin.* The most common skin lesions are macules or plaques. Tuberculoid patients have few, hypopigmented lesions (Fig. 11.29A). In lepromatous leprosy, papules, nodules or diffuse infiltration of the skin occur. The earliest lesions are ill defined; gradually, the skin becomes infiltrated and thickened. Facial skin thickening leads to the characteristic leonine facies (Fig. 11.29B).
- *Anaesthesia.* In skin lesions, the small dermal sensory and autonomic nerve fibres are damaged, causing localised sensory loss and loss of sweating. Anaesthesia can occur in the distribution of a damaged large peripheral nerve. A 'glove and stocking' sensory neuropathy is also common in lepromatous leprosy.
- *Nerve damage.* Peripheral nerve trunks are affected at 'sites of predilection'. These are the ulnar (elbow), median (wrist), radial (humerus), radial cutaneous (wrist), common peroneal (knee), posterior tibial and sural nerves (ankle), facial nerve (zygomatic arch) and great auricular nerve (posterior triangle of the neck). Damage to peripheral nerve trunks produces characteristic signs with regional sensory loss and muscle dysfunction (Fig. 11.29C). All these nerves should be examined for enlargement and tenderness, and tested for motor and sensory function. The CNS is not affected.
- *Eye involvement.* Blindness is a devastating complication for a patient with anaesthetic hands and feet. Eyelid closure is impaired when the facial nerve is affected. Damage to the trigeminal nerve causes anaesthesia of the cornea and conjunctiva. The cornea is then susceptible to trauma and ulceration.
- *Other features.* Many organs can be affected. Nasal collapse occurs secondary to bacillary destruction of the nasal cartilage and bone. Diffuse infiltration of the testes causes testicular atrophy and the acute orchitis that occurs with type 2 reactions. This results in azoospermia and hypogonadism.

Leprosy reactions

Leprosy reactions (Box 11.47) are events superimposed on the cardinal features shown in Box 11.45.

- *Type 1 (reversal) reactions*. These occur in 30% of borderline patients (BT, BB or BL – see below) and are delayed hypersensitivity reactions. Skin lesions become

11.45 Cardinal features of leprosy

- Skin lesions, typically anaesthetic at tuberculoid end of spectrum
- Thickened peripheral nerves
- Acid-fast bacilli on skin smears or biopsy

11.46 Clinical characteristics of the polar forms of leprosy

Clinical and tissue-specific features	Lepromatous	Tuberculoid
Skin and nerves		
Number and distribution	Widely disseminated	One or a few sites, asymmetrical
Skin lesions		
Definition:		
Clarity of margin	Poor	Good
Elevation of margin	Never	Common
Colour:		
Dark skin	Slight hypopigmentation	Marked hypopigmentation
Light skin	Slight erythema	Coppery or red
Surface	Smooth, shiny	Dry, scaly
Central healing	None	Common
Sweat and hair growth	Impaired late	Impaired early
Loss of sensation	Late	Early and marked
Nerve enlargement and damage	Late	Early and marked
Bacilli (bacterial index)	Many (5 or 6+)	Absent (0)
Natural history	Progressive	Self-healing
Other tissues	Upper respiratory mucosa, eye, testes, bones, muscle	None
Reactions	Immune complexes (type 2)	Cell-mediated (type 1)

11.47 Reactions in leprosy

	Lepra reaction type 1 (reversal)	Lepra reaction type 2 (erythema nodosum leprosum)
Mechanism	Cell-mediated hypersensitivity	Immune complexes
Clinical features	Painful tender nerves, loss of function Swollen skin lesions New skin lesions	Tender papules and nodules; may ulcerate Painful tender nerves, loss of function Iritis, orchitis, myositis, lymphadenitis Fever, oedema
Management	Prednisolone 40 mg, reducing over 3–6 months[1]	Moderate: prednisolone 40 mg daily Severe: thalidomide[2] or prednisolone 40–80 mg daily, reducing over 1–6 months; local if eye involved[3]

[1]Indicated for any new impairment of nerve or eye function. [2]Contraindicated in women who may become pregnant. [3]1% hydrocortisone drops or ointment and 1% atropine drops.

Fig. 11.29 Clinical features of leprosy. A Tuberculoid leprosy. Single lesion with a well-defined active edge and anaesthesia within the lesion. B Lepromatous leprosy. Widespread nodules and infiltration, with loss of the eyebrows. This man also has early collapse of the nose. C Borderline tuberculoid leprosy with severe nerve damage. This boy has several well-defined, hypopigmented, macular, anaesthetic lesions. He has severe nerve damage affecting both ulnar and median nerves bilaterally and has sustained severe burns to his hands. D Reversal (type 1) reactions. Erythematous, oedematous lesions.

erythematous (Fig. 11.29D). Peripheral nerves become tender and painful, with sudden loss of nerve function. These reactions may occur spontaneously, after starting treatment and also after completion of multidrug therapy (MDT).

- *Type 2 (erythema nodosum leprosum, ENL) reactions*. These are partly due to immune complex deposition and occur in BL and LL patients who produce antibodies and have a high antigen load. They manifest with malaise, fever and crops of small pink nodules on the face and limbs. Iritis and episcleritis are common. Other signs are acute neuritis, lymphadenitis, orchitis, bone pain, dactylitis, arthritis and proteinuria. ENL may continue intermittently for several years.

Borderline cases

In borderline tuberculoid (BT) cases, skin lesions are more numerous than in tuberculoid (TT) cases, and there is more severe nerve damage and a risk of type 1 reactions. In borderline leprosy (BB) cases, skin lesions are numerous and vary in size, shape and distribution; annular lesions are characteristic and nerve damage is variable. In borderline lepromatous (BL) cases, there are widespread small macules in the skin and widespread nerve involvement; both type 1 and type 2 reactions occur.

Pure neural leprosy (i.e. without skin lesions) occurs principally in India and accounts for 10% of patients. There is asymmetrical involvement of peripheral nerve trunks and no visible skin lesions. On nerve biopsy, all types of leprosy have been found.

Investigations

The diagnosis is clinical, made by finding a cardinal sign of leprosy and supported by detecting acid-fast bacilli in slit-skin smears or typical histology in a skin biopsy. Slit-skin smears are obtained by scraping dermal material on to a glass slide. The smears are then stained for acid-fast bacilli, the number counted per high-power field and a score derived on a logarithmic scale (0–6): the bacterial index (BI). Smears are useful for confirming the diagnosis and monitoring response to treatment. Neither serology nor PCR is sensitive or specific enough for diagnosis.

i 11.48 Principles of leprosy treatment

- Stop the infection with chemotherapy
- Treat reactions
- Educate the patient about leprosy
- Prevent disability
- Support the patient socially and psychologically

Management

The principles of treatment are outlined in Box 11.48. All leprosy patients require MDT with an approved first-line regimen (Box 11.49).

Rifampicin is a potent bactericidal for *M. leprae* but should always be given in combination with other antileprotics, since a single-step mutation can confer resistance. Dapsone is bacteriostatic. It commonly causes mild haemolysis and rarely anaemia. Clofazimine is a red, fat-soluble crystalline dye, weakly bactericidal for *M. leprae*. Skin discoloration (red to purple–black) and ichthyosis are troublesome side-effects, particularly on pale skins. New bactericidal drugs against *M. leprae* have been identified, notably fluoroquinolones (pefloxacin and ofloxacin). Minocycline and clarithromycin may also be used. These agents are now established second-line drugs. Minocycline causes a grey pigmentation of skin lesions.

11.49 Modified WHO-recommended multidrug therapy (MDT) regimens in leprosy

Type of leprosy[1]	Monthly supervised treatment	Daily self-administered treatment	Duration of treatment[2]
Paucibacillary	Rifampicin 600 mg	Dapsone 100 mg	6 months
Multibacillary	Rifampicin 600 mg Clofazimine 300 mg	Clofazimine 50 mg Dapsone 100 mg	12 months
Paucibacillary single-lesion	Ofloxacin 400 mg Rifampicin 600 mg Minocycline 100 mg		Single dose

[1]Classification uses the bacillary index (BI) in slit-skin smears or, if BI is not available, the number of skin lesions:
- paucibacillary single-lesion leprosy (1 skin lesion)
- paucibacillary (2–5 skin lesions)
- multibacillary (>5 skin lesions).

[2]Studies from India have shown that multibacillary patients with an initial BI of >4 need longer treatment, for at least 24 months.

Although single-dose treatment is less effective than the conventional 6-month treatment for paucibacillary leprosy, it is an operationally attractive field regimen recommended by the WHO.

Lepra reactions are treated as shown in Box 11.47. Chloroquine can also be used.

Patient education

This is essential and should patients should be informed that, after 3 days of chemotherapy, they are not infectious and can lead a normal social life. It should emphasise that gross deformities are not inevitable.

Patients with anaesthetic hands or feet need to avoid and treat burns or other minor injuries. Good footwear is important. Physiotherapy helps maintain range of movement of affected muscles and neighbouring joints.

Prognosis

Untreated, tuberculoid leprosy has a good prognosis; it may self-heal and peripheral nerve damage is limited. Lepromatous leprosy (LL) is a progressive condition with high morbidity if untreated.

After treatment, the majority of patients, especially those who have no nerve damage at the time of diagnosis, do well, with resolution of skin lesions. Borderline patients are at risk of developing type 1 reactions, which may result in devastating nerve damage.

Prevention and control

The previous strategy of centralised leprosy control campaigns has been superseded by integrated programmes, with primary health-care workers in many countries now responsible for case detection and provision of MDT. It is not yet clear how successful this will be, especially in the time-consuming area of disability prevention.

BCG vaccination has been shown to give good but variable protection against leprosy; adding killed *M. leprae* to BCG does not enhance protection.

Rickettsial and related intracellular bacterial infections

Rickettsial fevers

The rickettsial fevers are the most common tick-borne infections. It is important to ask potentially infected patients about contact with ticks, lice or fleas. There are two main groups of rickettsial fevers: spotted fevers and typhus (Box 11.50).

Pathogenesis

The rickettsiae are intracellular Gram-negative organisms that parasitise the intestinal canal of arthropods. Infection of humans through the skin occurs from the excreta of arthropods, but the saliva of some biting vectors is infected. The organisms multiply in capillary endothelial cells, producing lesions in the skin, CNS, heart, lungs, liver, kidneys and skeletal muscles. Endothelial proliferation, associated with a perivascular reaction, may cause thrombosis and purpura. In epidemic typhus, the brain is the target organ; in scrub typhus, the cardiovascular system and lungs in particular are attacked. An eschar, a black necrotic crusted sore, is often found in tick- and mite-borne typhus (see Fig. 11.7C, p. 235). This is due to vasculitis following immunological recognition of the inoculated organism. Regional lymph nodes often enlarge.

Spotted fever group

Rocky Mountain spotted fever

Rickettsia rickettsii is transmitted by tick bites. It is widely distributed and increasing in western and south-eastern states of the USA and also in Central and South America. The incubation period is about 7 days. The rash appears on about the third or fourth day of illness, looking at first like measles, but in a few hours a typical maculopapular eruption develops. The rash spreads in 24–48 hours from wrists, forearms and ankles to the back, limbs and chest, and then to the abdomen, where it is least pronounced. Larger cutaneous and subcutaneous haemorrhages may appear in severe cases. The liver and spleen become palpable. At the extremes of life, the mortality is 2–12%.

Other spotted fevers

R. conorii (boutonneuse fever) and *R. africae* (African tick bite fever) cause Mediterranean and African tick typhus, which also occurs on the Indian subcontinent. The incubation period is approximately 7 days. Infected ticks may be picked up by walking on grasslands, or dogs may bring ticks into the house. Careful examination might reveal a diagnostic eschar, and the maculopapular rash on the trunk, limbs, palms and soles. There may be delirium and meningeal signs in severe infections but recovery is usual. *R. africae* can be associated with multiple eschars. Some cases, particularly those with *R. africae*, present without rash ('spotless spotted fever'). Other spotted fevers are shown in Box 11.50.

Typhus group

Scrub typhus fever

Scrub typhus is caused by *Orientia tsutsugamushi* (formerly *Rickettsia tsutsugamushi*), transmitted by mites. It occurs in the Far East, Myanmar, Pakistan, Bangladesh, India, Indonesia, the South Pacific islands and Queensland, particularly where patches of forest cleared for plantations have attracted rats and mites.

In many patients, one eschar or more develops, surrounded by an area of cellulitis (see Fig. 11.7C, p. 235) and

11.50 Features of rickettsial infections

Disease	Organism	Reservoir	Vector	Geographical area	Rash	Gangrene	Target organs	Mortality
Spotted fever group								
Rocky Mountain spotted fever	*R. rickettsii*	Rodents, dogs, ticks	*Ixodes* tick	North, Central and South America	Morbilliform Haemorrhagic	Often	Bronchi, myocardium, brain, skin	2–12%[2]
Boutonneuse fever	*R. conorii*	Rodents, dogs, ticks	*Ixodes* tick	Mediterranean, Africa, South-west Asia, India	Maculopapular	–	Skin, meninges	2.5%[3]
Siberian tick typhus	*R. sibirica*	Rodents, birds, domestic animals, ticks	Various ticks	Siberia, Mongolia, northern China	Maculopapular	–	Skin, meninges	Rare[3]
Australian tick typhus	*R. australis*	Rodents, ticks	Ticks	Australia	Maculopapular	–	Skin, meninges	Rare[3]
Oriental spotted fever	*R. japonica*	Rodents, dogs, ticks	Ticks	Japan	Maculopapular	–	Skin, meninges	Rare[3]
African tick bite fever[1]	*R. africae*	Cattle, game, ticks	*Ixodes* tick	South Africa	Can be spotless	–	Skin, meninges	Rare[3]
Typhus group								
Scrub typhus	*Orientia tsutsugamushi*	Rodents	*Trombicula* mite	South-east Asia	Maculopapular	Unusual	Bronchi, myocardium, brain, skin	Rare[3]
Epidemic typhus	*R. prowazekii*	Humans	Louse	Worldwide	Morbilliform Haemorrhagic	Often	Brain, skin, bronchi, myocardium	Up to 40%
Endemic typhus	*R. typhi*	Rats	Flea	Worldwide	Slight	–	–	Rare[3]

[1]Eschar at bite site and local lymphadenopathy. [2]Highest in adult males. [3]Except in infants, older people and the debilitated.

enlargement of regional lymph nodes. The incubation period is about 9 days.

Mild or subclinical cases are common. The onset of symptoms is usually sudden, with headache (often retro-orbital), fever, malaise, weakness and cough. In severe illness, the general symptoms increase, with apathy and prostration. An erythematous maculopapular rash often appears on about the 5th–7th day and spreads to the trunk, face and limbs, including the palms and soles, with generalised painless lymphadenopathy. The rash fades by the 14th day. The temperature rises rapidly and continues as a remittent fever (i.e. the difference between maximum and minimum temperature exceeds 1°C), remaining above normal with sweating until it falls on the 12th–18th day. In severe infection, the patient is prostrate with cough, pneumonia, delirium and deafness. Cardiac failure, renal failure and haemorrhage may develop. Convalescence is often slow and tachycardia may persist for some weeks.

Epidemic (louse-borne) typhus

Epidemic typhus is caused by *R. prowazekii* and is transmitted by infected faeces of the human body louse, usually through scratching the skin. Patients suffering from epidemic typhus infect lice, which leave when the patient is febrile. In conditions of overcrowding, the disease spreads rapidly. It is prevalent in parts of Africa, especially Ethiopia and Rwanda, and in the South American Andes and Afghanistan. Large epidemics have occurred in Europe, usually as a sequel to war. The incubation period is usually 12–14 days.

There may be a few days of malaise but the onset is more often sudden, with rigors, fever, frontal headaches, pains in the back and limbs, constipation and bronchitis. The face is flushed and cyanotic, the eyes are congested and the patient becomes confused. The rash appears on the 4th–6th day. In its early stages, it disappears on pressure but soon becomes petechial with subcutaneous mottling. It appears first on the anterior folds of the axillae, sides of the abdomen or backs of hands, then on the trunk and forearms. The neck and face are seldom affected. During the second week, symptoms increase in severity. Sores develop on the lips. The tongue becomes dry, brown, shrunken and tremulous. The spleen is palpable, the pulse feeble and the patient stuporous and delirious. The temperature falls rapidly at the end of the second week and the patient recovers gradually. In fatal cases, the patient usually dies in the second week from toxaemia, cardiac or renal failure, or pneumonia.

Endemic (flea-borne) typhus

Flea-borne or 'endemic' typhus caused by *R. typhi* is endemic worldwide. Humans are infected when the faeces or contents of a crushed flea, which has fed on an infected rat, are introduced into the skin. The incubation period is 8–14 days. The symptoms resemble those of a mild louse-borne typhus. The rash may be scanty and transient.

Investigation of rickettsial infection

Routine blood investigations are not diagnostic. There is usually hepatitis and thrombocytopenia. Diagnosis is made on clinical grounds and response to treatment, and may be confirmed by antibody detection or PCR in specialised laboratories. Differential diagnoses include malaria, which should be excluded, typhoid, meningococcal sepsis and leptospirosis.

Management of rickettsial fevers

The different rickettsial fevers vary in severity but all respond to tetracycline 500 mg 4 times daily, doxycycline 200 mg daily

or chloramphenicol 500 mg 4 times daily for 7 days. Louse-borne typhus and scrub typhus can be treated with a single dose of 200 mg doxycycline, repeated for 2–3 days to prevent relapse. Chloramphenicol- and doxycycline-resistant strains of *O. tsutsugamushi* have been reported from Thailand and patients here may need treatment with rifampicin.

Nursing care is important, especially in epidemic typhus. Sedation may be required for delirium and blood transfusion for haemorrhage. Relapsing fever and typhoid are common intercurrent infections in epidemic typhus, and pneumonia in scrub typhus, which require diagnosis and treatment. Convalescence is usually protracted, especially in older people.

To prevent rickettsial infection, lice, fleas, ticks and mites need to be controlled with insecticides.

Q fever

Q fever occurs worldwide and is caused by the rickettsia-like organism *Coxiella burnetii*, an obligate intracellular organism that survives in the extracellular environment. Cattle, sheep and goats are important reservoirs and the organism is transmitted by inhalation of aerosolised particles. An important characteristic of *C. burnetii* is its antigenic variation, called phase variation, due to a change of lipopolysaccharide (LPS). When isolated from animals or humans, *C. burnetii* expresses phase I antigen and is very infectious (a single bacterium is sufficient to infect a human). In culture, there is an antigenic shift to the phase II form, which is not infectious. Measurement of antigenic shift helps differentiate acute and chronic Q fever.

Clinical features

The incubation period is 3–4 weeks. The initial symptoms are non-specific with fever, headache and chills; in 20% of cases, a maculopapular rash occurs. Other presentations include pneumonia and hepatitis. Chronic Q fever may present with osteomyelitis, encephalitis and endocarditis.

Investigations and management

Diagnosis is usually serological and the stage of the infection can be distinguished by isotype tests and phase-specific antigens. Phase I and II IgM titres peak at 4–6 weeks. In chronic infections, IgG titres to phase I and II antigens may be raised.

Prompt treatment of acute Q fever with doxycycline reduces fever duration. Treatment of Q fever endocarditis is problematic, requiring prolonged therapy with doxycycline and rifampicin or ciprofloxacin with hydroxychloroquine; even then, organisms are not always eradicated. Valve surgery is often required (p. 526).

Bartonellosis

This group of diseases is caused by intracellular Gram-negative bacilli closely related to the rickettsiae, which have been discovered to be important causes of 'culture-negative' endocarditis. They are found in many domestic pets, such as cats, although for several the host is undefined (Box 11.51). The principal human pathogens are *Bartonella quintana*, *B. henselae* and *B. bacilliformis*. *Bartonella* infections are associated with the following:

- *Trench fever*. This is a relapsing fever with severe leg pain and is caused by *B. quintana.* The disease is not fatal but is very debilitating.
- *Bacteraemia and endocarditis in the homeless*. Endocarditis due to *B. quintana* or *B. henselae* is associated with severe damage to the heart valves.

11.51 Clinical diseases caused by *Bartonella* spp.

Reservoir	Vector	Organism	Disease
Cats	Flea	*B. henselae*	**Cat scratch disease, bacillary angiomatosis, endocarditis**
Undefined	Lice	*B. quintana*	**Trench fever, bacillary angiomatosis, endocarditis**
Undefined	Sandfly	*B. bacilliformis*	**Carrion's disease: Oroya fever and verruga peruana**
Undefined	Flea	*B. rochalimae*	**Fever, rash, anaemia, splenomegaly**

- *Cat scratch disease*. *B. henselae* causes this common benign lymphadenopathy in children and young adults. A vesicle or papule develops on the head, neck or arms after a cat scratch. The lesion resolves spontaneously but there may be regional lymphadenopathy that persists for up to 4 months before also resolving spontaneously. Rare complications include retinitis and encephalopathy.
- *Bacillary angiomatosis*. This is an HIV-associated disease caused by *B. quintana* or *B. henselae* (p. 316).
- *Oroya fever and verruga peruana* (*Carrion's disease*). This is endemic in areas of Peru. It is a biphasic disease caused by *B. bacilliformis*, transmitted by sandflies of the genus *Phlebotomus.* Fever, haemolytic anaemia and microvascular thrombosis with end-organ ischaemia are features. It is frequently fatal if untreated.

Investigations and management

Bartonellae can be cultured in specialised laboratories but PCR is often used to diagnose infection. Serum antibody detection is possible but cross-reactions occur with *Chlamydia* and *Coxiella* spp.

Bartonella spp. are typically treated with macrolides or tetracyclines. Antibiotic use is guided by clinical need. Cat scratch disease usually resolves spontaneously but *Bartonella* endocarditis requires valve replacement and combination antibiotic therapy with doxycycline and gentamicin.

Chlamydial infections

These are listed in Box 11.52 and are also described on pages 340 and 582.

11.52 Chlamydial infections

Organism	Disease caused
Chlamydia trachomatis	Trachoma Lymphogranuloma venereum (see Box 13.12, p. 341) Cervicitis, urethritis, proctitis (p. 334)
Chlamydia psittaci	Psittacosis (see Box 17.36, p. 582)
Chlamydophila (Chlamydia) pneumoniae	Atypical pneumonia (see Box 17.36, p. 582) Acute/chronic sinusitis

Trachoma

Trachoma is a chronic keratoconjunctivitis caused by *Chlamydia trachomatis* and is the most common cause of avoidable blindness. The classic trachoma environment is dry and dirty, causing children to have eye and nose discharges. Transmission occurs through flies, on fingers and within families. In endemic areas, the disease is most common in children.

Pathology and clinical features

The onset is usually insidious. Infection may be asymptomatic, lasts for years, may be latent over long periods and may recrudesce. The conjunctiva of the upper lid is first affected with vascularisation and cellular infiltration. Early symptoms include conjunctival irritation and blepharospasm. The early follicles are characteristic (Fig. 11.30) but clinical differentiation from conjunctivitis due to other causes may be difficult. Scarring causes inversion of the lids (entropion) so that the lashes rub against the cornea (trichiasis). The cornea becomes vascularised and opaque. The problem may not be detected until vision begins to fail.

Investigations and management

Intracellular inclusions may be demonstrated in conjunctival scrapings by staining with iodine or immunofluorescence. Although chlamydiae may, in theory, be isolated in chick embryo or cell culture or detected by nucleic acid amplification tests, these methods are rarely available in the areas where trachoma is encountered, and in any case their sensitivity and specificity are poorly established. Diagnosis of trachoma is therefore based on clinical and epidemiological features.

A single dose of azithromycin (20 mg/kg) has been shown to be superior to 6 weeks of tetracycline eye ointment twice daily for individuals in mass treatment programmes. Deformity and scarring of the lids, and corneal opacities, ulceration and scarring require surgical treatment after control of local infection.

Prevention

Personal and family hygiene should be improved. Proper care of the eyes of newborn and young children is essential. Family contacts should be examined. The WHO is promoting the SAFE strategy for trachoma control (surgery, antibiotics, facial cleanliness and environmental improvement).

Fig. 11.30 Trachoma. Trachoma is characterised by hyperaemia and numerous pale follicles. *Courtesy of Institute of Ophthalmology, Moorfields Eye Hospital, London.*

Protozoal infections

Protozoa are responsible for many important infectious diseases. They can be categorised according to whether they cause systemic or local infection. Trichomoniasis is described on page 335.

Systemic protozoal infections

Malaria

Malaria in humans is caused by *Plasmodium falciparum*, *P. vivax*, *P. ovale* (subspecies *curtisi* and *wallikeri*), *P. malariae* and the predominantly simian parasite *P. knowlesi.* It is transmitted by the bite of female anopheline mosquitoes and occurs throughout the tropics and subtropics at altitudes below 1500 metres (Fig. 11.31). The WHO estimates that 214 million cases of clinical malaria occurred in 2015, 88% of these in Africa, especially among children and pregnant women. WHO prevention and treatment campaigns reduced the incidence of malaria between 1950 and 1960, but since 1970 there has been resurgence. Furthermore, *P. falciparum* has now become resistant to chloroquine and sulfadoxine-pyrimethamine, initially in South-east Asia and now throughout Africa. The WHO's Millennium Development Goal malaria target aimed to halt the spread of the disease by 2015 and this has been achieved. The 'Roll Back Malaria' campaign was designed to halve mortality by 2010 by utilising the 'best evidence' vector and disease control methods, such as artemisinin combination therapy (ACT).

Travellers are susceptible to malaria (p. 230). Most cases are due to *P. falciparum*, usually from Africa, and of these 1% die because of late diagnosis. Migrants from endemic countries who spend long periods of time in non-endemic countries are particularly at risk if they visit friends and family in their country of origin. They have lost their partial immunity and frequently do not take malaria prophylaxis. A few people living near airports in Europe have acquired malaria from accidentally imported mosquitoes.

Pathogenesis

Life cycle of the malarial parasite

The female anopheline mosquito becomes infected when it feeds on human blood containing gametocytes, the sexual forms of the malarial parasite (Figs 11.32 and 11.33). Development in the mosquito takes 7–20 days, and results in sporozoites accumulating in the salivary glands and being inoculated into the human blood stream. Sporozoites disappear from human blood within half an hour and enter the liver. After some days, merozoites leave the liver and invade red blood cells, where further asexual cycles of multiplication take place, producing schizonts.

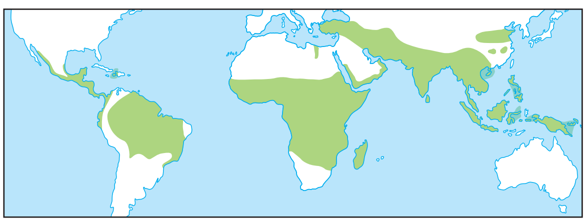

Fig. 11.31 Distribution of malaria. (For up-to-date information see the Malaria Atlas Project (MAP): map.ox.ac.uk.)

Rupture of the schizont releases more merozoites into the blood and causes fever, the periodicity of which depends on the species of parasite.

P. vivax and *P. ovale* may persist in liver cells as dormant forms, hypnozoites, capable of developing into merozoites months or years later. Thus the first attack of clinical malaria may occur long after the patient has left the endemic area, and the disease may relapse after treatment with drugs that only kill the erythrocytic stage of the parasite.

P. falciparum, *P. knowlesi* and *P. malariae* have no persistent exo-erythrocytic phase but recrudescence of fever may result from multiplication of parasites in red cells that have not been eliminated by treatment and immune processes (Box 11.53).

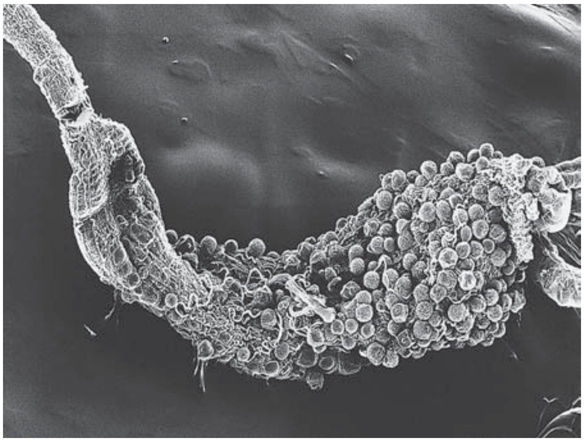

Fig. 11.32 Scanning electron micrograph of *Plasmodium falciparum* oöcysts lining an anopheline mosquito's stomach.

Pathology

Red cells infected with malaria are prone to haemolysis. This is most severe with *P. falciparum*, which invades red cells of all ages but especially young cells; *P. vivax* and *P. ovale* invade reticulocytes, and *P. malariae* normoblasts, so that infections

11.53 Relationships between life cycle of parasite and clinical features of malaria

Cycle/feature	*Plasmodium vivax, P. ovale*	*P. malariae*	*P. falciparum*
Pre-patent period (minimum incubation)	8–25 days	15–30 days	8–25 days
Exo-erythrocytic cycle	Persistent as hypnozoites	Pre-erythrocytic only	Pre-erythrocytic only
Asexual cycle	48 hrs synchronous	72 hrs synchronous	<48 hrs asynchronous
Fever periodicity	Alternate days	Every third day	None
Delayed onset	Common	Rare	Rare
Relapses	Common up to 2 years	Recrudescence many years later	Recrudescence up to 1 year

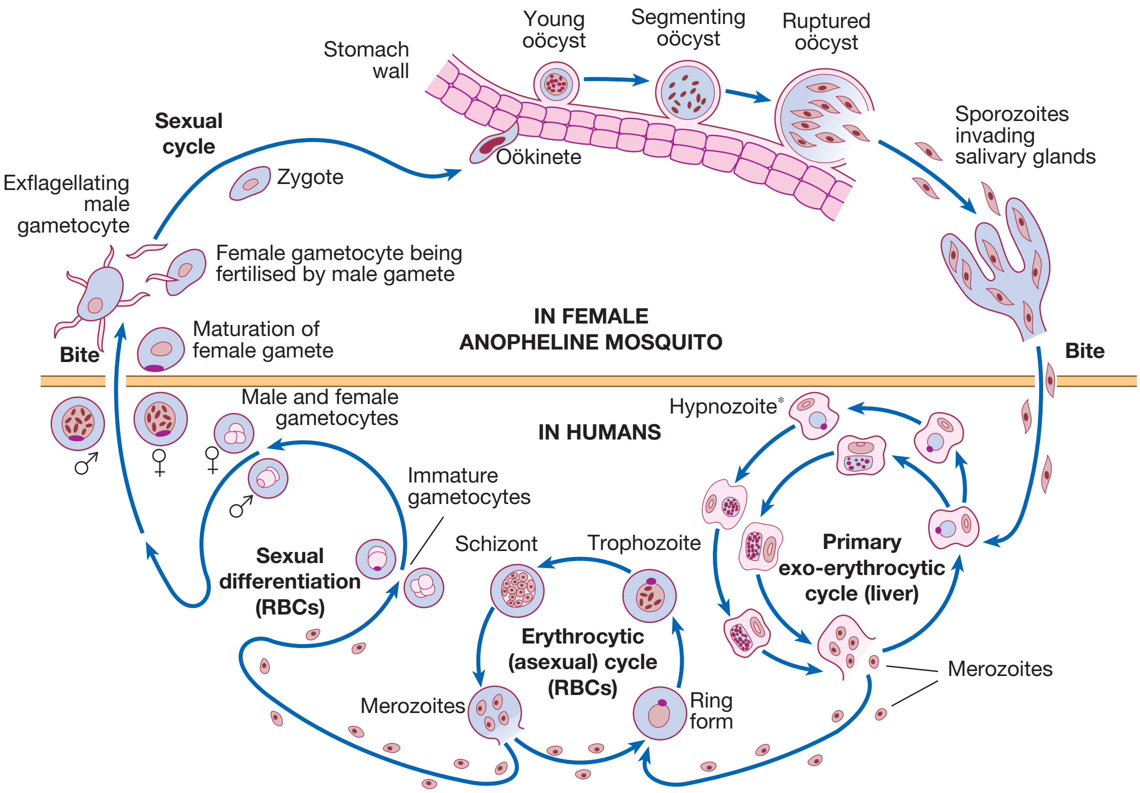

Fig. 11.33 Malarial parasites: life cycle. Hypnozoites(*) are present only in *Plasmodium vivax* and *P. ovale* infections. (RBC = red blood cell)

remain lighter. Anaemia may be profound and is worsened by dyserythropoiesis, splenomegaly and depletion of folate stores.

In *P. falciparum* malaria, red cells containing trophozoites adhere to vascular endothelium in post-capillary venules in brain, kidney, liver, lungs and gut by the formation of 'knob' proteins. They also form 'rosettes' and rouleaux with uninfected red cells. Vessel congestion results in organ damage, which is exacerbated by rupture of schizonts, liberating toxic and antigenic substances (Fig. 11.33).

P. falciparum has influenced human evolution, with the appearance of protective mutations such as sickle-cell (HbS; p. 951), thalassaemia (p. 953), glucose-6-phosphate dehydrogenase (G6PD) deficiency (p. 948) and HLA-B53. *P. falciparum* does not grow well in red cells that contain haemoglobin F, C or especially S. Haemoglobin S heterozygotes (AS) are protected against the lethal complications of malaria. *P. vivax* cannot enter red cells that lack the Duffy blood group; therefore many West Africans and African Americans are protected.

Clinical features

The clinical features of malaria are non-specific and the diagnosis must be suspected in anyone returning from an endemic area who has features of infection.

P. falciparum infection

This is the most dangerous of the malarias. The onset is often insidious, with malaise, headache and vomiting. Cough and mild diarrhoea are also common. The fever has no particular pattern. Jaundice is common due to haemolysis and hepatic dysfunction. The liver and spleen enlarge and may become tender. Anaemia develops rapidly, as does thrombocytopenia.

A patient with *falciparum* malaria, apparently not seriously ill, may rapidly develop dangerous complications (Fig. 11.34 and Box 11.54). Cerebral malaria is manifested by delirium, seizures or coma, usually without localising signs. Children die rapidly without any specific symptoms other than fever. Immunity is impaired in pregnancy and the parasite can preferentially bind to the placental protein chondroitin sulphate A. Abortion and intrauterine growth retardation from parasitisation of the maternal side of the placenta are frequent. Previous splenectomy increases the risk of severe malaria.

P. vivax and *P. ovale* infection

In many cases, the illness starts with several days of continued fever before the development of classical bouts of fever on alternate days. Fever starts with a rigor. The patient feels cold and the temperature rises to about 40°C. After half an hour to

(RBC = red blood cell) *Insets (malaria retinopathy) Courtesy of Dr Nicholas Beare, Royal Liverpool University Hospital; (blood films of* P. vivax *and* P. falciparum*) Courtesy of Dr Kamolrat Silamut, Mahidol Oxford Research Unit, Bangkok, Thailand.*

11.54 Severe manifestations/complications of *falciparum* malaria and their immediate management

Coma (cerebral malaria)	**Spontaneous bleeding and coagulopathy**
• Maintain airway • Nurse on side • Exclude other treatable causes of coma (e.g. hypoglycaemia, bacterial meningitis) • Avoid harmful ancillary treatments such as glucocorticoids, heparin and adrenaline (epinephrine) • Intubate if necessary	• Transfuse screened fresh whole blood (cryoprecipitate/fresh frozen plasma and platelets if available) • Vitamin K injection
Hyperpyrexia	**Metabolic acidosis**
• Tepid sponging, fanning, cooling blanket • Antipyretic drug (paracetamol)	• Exclude or treat hypoglycaemia, hypovolaemia and Gram-negative sepsis • Fluid resuscitation • Give oxygen
Convulsions	**Shock ('algid malaria')**
• Maintain airway • Treat promptly with diazepam or paraldehyde injection	• Suspect Gram-negative sepsis • Take blood cultures • Give parenteral antimicrobials • Correct haemodynamic disturbances
Hypoglycaemia	**Aspiration pneumonia**
• Measure blood glucose • Give 50% dextrose injection followed by 10% dextrose infusion (glucagon may be ineffective)	• Give parenteral antimicrobial drugs • Change position • Physiotherapy • Give oxygen
Severe anaemia (packed cell volume <15%)	**Hyperparasitaemia**
• Transfuse fresh whole blood or packed cells if pathogen screening of donor blood is available	• Consider exchange transfusion (e.g. >10% of circulating erythrocytes parasitised in non-immune patient with severe disease)
Acute pulmonary oedema	**Specific therapy**
• Nurse at 45°, give oxygen, venesect 250 mL of blood, give diuretic, stop intravenous fluids • Intubate and add PEEP/CPAP (p. 202) in life-threatening hypoxaemia • Haemofilter	• Intravenous artesunate • Mefloquine should be avoided due to increased risk of post-malaria neurological syndrome
Acute kidney injury	
• Exclude pre-renal causes • Fluid resuscitation if appropriate • Peritoneal dialysis (haemofiltration or haemodialysis if available)	

(CPAP = continuous positive airway pressure; PEEP = positive end-expiratory pressure)
From WHO. Severe falciparum malaria. In: Severe and complicated malaria, 3rd edn. Trans Roy Soc Trop Med Hyg 2000; 94 (suppl. 1):S1–41.

an hour, the hot or flush phase begins. It lasts several hours and gives way to profuse perspiration and a gradual fall in temperature. The cycle is repeated 48 hours later. Gradually, the spleen and liver enlarge and may become tender. Anaemia develops slowly. Relapses are frequent in the first 2 years after leaving the malarious area and infection may be acquired from blood transfusion.

P. malariae and *P. knowlesi* infection

This is usually associated with mild symptoms and bouts of fever every third day. Parasitaemia may persist for many years, with the occasional recrudescence of fever or without producing any symptoms. Chronic *P. malariae* infection causes glomerulonephritis and long-term nephrotic syndrome in children. *P. knowlesi* is usually mild but can deteriorate rapidly.

Investigations

Giemsa-stained thick and thin blood films should be examined whenever malaria is suspected. In the thick film, erythrocytes are lysed, releasing all blood stages of the parasite. This, as well as the fact that more blood is used in thick films, facilitates the diagnosis of low-level parasitaemia. A thin film is essential to confirm the diagnosis, species and, in *P. falciparum* infections, to quantify the parasite load (by counting the percentage of infected erythrocytes). *P. falciparum* parasites may be very scanty, especially in patients who have been partially treated. With *P. falciparum*, only ring forms are normally seen in the early stages (Fig. 11.34); with the other species, all stages of the erythrocytic cycle may be found. Gametocytes appear after about 2 weeks, persist after treatment and are harmless, except that they are the source by which more mosquitoes become infected.

Immunochromatographic rapid diagnostic tests (RDTs) for malaria antigens, such as OptiMAL (which detects the *Plasmodium* LDH of *P. falciparum* and *vivax*) and Parasight-F (which detects the *P. falciparum* histidine-rich protein 2), are extremely sensitive and specific for *falciparum* malaria but less so for other species. They should be used in parallel with blood film examination but are especially useful where the microscopist is less experienced in examining blood films (e.g. in the UK). They are less sensitive for low-level parasitaemia and positivity may persist for a month or more in some individuals. The QBC Malaria Test is a fluorescence microscopy-based malaria diagnostic test that is also widely used.

DNA detection (PCR) is used mainly in research and is useful for determining whether a patient has a recrudescence of the same malaria parasite or a reinfection with a new parasite.

Management

Mild *P. falciparum* malaria

Since *P. falciparum* is now resistant to chloroquine and sulfadoxine-pyrimethamine (Fansidar) almost worldwide, an artemisinin-based treatment is recommended (Box 11.55) and WHO policy in Africa recommends always using ACT, e.g. co-artemether or artesunate–amodiaquine. Unfortunately, artemisinin resistance has now been reported in South-east Asia.

i 11.55 Malaria treatment

Mild malaria

Preferred therapy

- Co-artemether (CoArtem or Riamet); contains artemether and lumefantrine (4 tablets orally at 0, 8, 24, 36, 48 and 60 hrs)

Alternative therapy

- Quinine (600 mg of quinine salt 3 times daily orally for 5–7 days), together with or followed by doxycycline (200 mg once daily orally for 7 days)
  Use clindamycin not doxycycline if the patient is a pregnant woman or young child

or

- Atovaquone–proguanil (Malarone, 4 tablets orally once daily for 3 days)

Pregnancy

- Co-artemether but avoid in early pregnancy.
- If not using co-artemether, use quinine plus clindamycin (450 mg 3 times daily orally for 7 days)

Other regimens

- Artesunate (200 mg orally daily for 3 days) and mefloquine (1 g orally on day 2 and 500 mg orally on day 3)

Severe malaria

Preferred therapy

- Artesunate 2.4 mg/kg IV at 0, 12 and 24 hrs and then once daily for 7 days. Once the patient is able to recommence oral intake, switch to 2 mg/kg orally once daily, to complete a total cumulative dose of 17–18 mg/kg

Alternative therapy

- Quinine, loading dose 20 mg/kg IV over 4 hrs, up to a maximum of 1.4 g, then maintenance doses of 10 mg/kg quinine salt given as 4-hr infusions 3 times daily for the first 48 hrs then twice a day, up to a maximum of 700 mg per dose or until the patient can take drugs orally. Combine with doxycycline (or clindamycin if there are contraindications to doxycycline)
- Note the loading dose should not be given if quinine, quinidine or mefloquine has been administered in the previous 24 hrs
- Patients should be monitored by ECG while receiving quinine, with special attention to QRS duration and QT interval

Non-*falciparum* malaria

Preferred therapy

- Chloroquine: 600 mg chloroquine base orally, followed by 300 mg base in 6 hrs, then 150 mg base twice daily for 2 more days plus primaquine (30 mg orally daily (for *P. vivax*) or 15 mg orally daily (for *P. ovale*) for 14 days) after confirming G6PD-negative

Patients with mild to moderate G6PD deficiency and *P. vivax* or *P. ovale*

- Chloroquine plus primaquine 0.75 mg/kg weekly orally for 8 weeks

Chloroquine-resistant *P. vivax*

- Co-artemether as for *P. falciparum*

(G6PD = glucose-6-phosphate dehydrogenase)

Complicated *P. falciparum* malaria

Severe malaria should be considered in any non-immune patient with a parasite count greater than 2% or with complications, and is a medical emergency (see Box 11.54). Management includes early and appropriate antimalarial chemotherapy, active treatment of complications, correction of fluid, electrolyte and acid–base balance, and avoidance of harmful ancillary treatments.

The treatment of choice is intravenous artesunate. Late haemolysis is a treatment side-effect in some patients. Rectal administration of artesunate is also being developed to allow administration in remote rural areas. Quinine salt is the alternative.

Exchange transfusion has not been tested in randomised controlled trials but may be beneficial for non-immune patients with persisting high parasitaemias (>10% circulating erythrocytes).

Non-*falciparum* malaria

P. vivax, *P. ovale*, *P. knowlesi* and *P. malariae* infections should be treated with oral chloroquine but some chloroquine resistance has been reported from Indonesia. 'Radical cure' is achieved in patients with *P. vivax* or *P. ovale* malaria using a course of primaquine, which destroys the hypnozoite phase in the liver. Haemolysis may develop in those who are G6PD-deficient. Cyanosis due to the formation of methaemoglobin in the red cells is more common but not dangerous (see Fig. 7.1, p. 135). All are sensitive to ACTs.

Prevention

Clinical attacks of malaria may be preventable with chemoprophylaxis using chloroquine, atovaquone plus proguanil (Malarone), doxycycline or mefloquine. Box 11.56 gives the recommended doses for protection of the non-immune. The risk of malaria in the area to be visited and the degree of chloroquine resistance guide the recommendations for prophylaxis. Updated recommendations are summarised at fitfortravel.nhs.uk. Fansidar should not be used for chemoprophylaxis, as deaths have occurred from agranulocytosis or Stevens–Johnson syndrome (pp. 1224 and 1254). Mefloquine is useful in areas of multiple drug resistance, such as East and Central Africa and Papua New Guinea. Experience shows it to be safe for at least 2 years but there are several contraindications to its use (Box 11.56).

Expert advice is required for individuals unable to tolerate the first-line agents listed or in whom they are contraindicated. Mefloquine should be started 2–3 weeks before travel to give time for assessment of side-effects. Chloroquine should not be taken continuously as a prophylactic for more than 5 years without regular ophthalmic examination, as it may cause irreversible retinopathy. Pregnant and lactating women may take proguanil or chloroquine safely.

Prevention also involves advice about the use of high-percentage diethyltoluamide (DEET), covering up extremities when out after dark, and sleeping under permethrin-impregnated mosquito nets.

Malaria control in endemic areas

There are major initiatives to reduce and eliminate malaria in endemic areas. Successful programmes combine vector control, including indoor residual spraying, use of long-lasting insecticide-treated bed nets (ITNs) and intermittent preventative therapy (IPT; repeated dose of prophylactic drugs in high-risk groups, such as children and pregnant women, which reduces malaria and anaemia).

Research to produce a fully protective malaria vaccine is ongoing.

11.56 Chemoprophylaxis of malaria[1]

Antimalarial tablets	Adult prophylactic dose	Regimen
Chloroquine resistance high		
Mefloquine[2]	250 mg weekly	Started 2–3 weeks before travel and continued until 4 weeks after
or Doxycycline[3,4]	100 mg daily	Started 1 week before and continued until 4 weeks after travel
or Malarone[4]	1 tablet daily	From 1–2 days before travel until 1 week after return
Chloroquine resistance absent		
Chloroquine[5] *and* proguanil	300 mg base weekly } 100–200 mg daily }	Started 1 week before and continued until 4 weeks after travel

[1]Choice of regimen is determined by area to be visited, length of stay, level of malaria transmission, level of drug resistance, presence of underlying disease in the traveller and concomitant medication taken. [2]Contraindicated in the first trimester of pregnancy, lactation, cardiac conduction disorders, epilepsy, psychiatric disorders; may cause neuropsychiatric disorders. [3]Causes photosensitisation and sunburn if high-protection sunblock is not used. [4]Avoid in pregnancy. [5]British preparations of chloroquine usually contain 150 mg base, French preparations 100 mg base and American preparations 300 mg base.

Babesiosis

Babesiosis is a tick-borne intra-erythrocytic protozoon parasite. There are more than 100 species of *Babesia*, all of which have an animal reservoir, typically either rodents or cattle, and are transmitted to humans via the tick vector *Ixodes scapularis*. Most American cases of babesiosis are due to *B. microti* and most European cases to *B. divergens.* Patients present with fever and malaise 1–4 weeks after a tick bite. Illness may be complicated by haemolytic anaemia. Severe illness is seen in splenectomised patients. The diagnosis is made by blood-film examination. Treatment is with quinine and clindamycin.

African trypanosomiasis (sleeping sickness)

African sleeping sickness is caused by trypanosomes (Fig. 11.35) conveyed to humans by the bites of infected tsetse flies, and is unique to sub-Saharan Africa (Fig. 11.36). The incidence of sleeping sickness across Africa has declined by over 60% since 1990 due to better control measures. *Trypanosoma brucei gambiense* trypanosomiasis has a wide distribution in West and Central Africa and accounts for 90% of human African trypanosomiasis (HAT). *T. brucei rhodesiense* trypanosomiasis is found in parts of East and Central Africa. In West Africa, transmission is mainly at the riverside, where the fly rests in the shade of trees; no animal reservoir has been identified for *T. gambiense*. *T. rhodesiense* has a large reservoir in numerous wild animals and transmission takes place in the shade of woods bordering grasslands. Rural populations employed in agriculture, fishing and animal husbandry are susceptible. Local people and tourists visiting forests infested with tsetse flies and animal reservoirs may become infected.

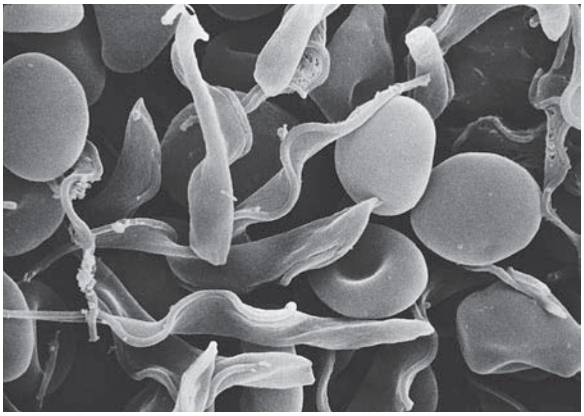

Fig. 11.35 Trypanosomiasis. Scanning electron micrograph showing trypanosomes swimming among erythrocytes.

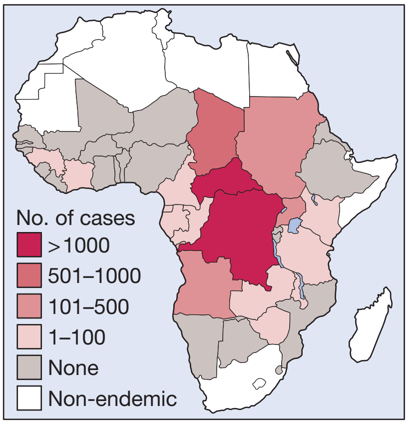

Fig. 11.36 Distribution of human African trypanosomiasis. Data are from 2009. *From Simarro PP, Diarra A, Ruiz Postigo JA, et al. The human African trypanosomiasis control and surveillance programme of the World Health Organization 2000–2009: the way forward. PLoS Negl Trop Dis 2011; 5(2):e1007.*

Clinical features

A bite by a tsetse fly is painful and commonly becomes inflamed; if trypanosomes are introduced, the site may again become painful and swollen about 10 days later ('trypanosomal chancre'), associated with regional lymphadenopathy. Within 2–3 weeks of infection, the trypanosomes invade the blood stream. The disease is characterised by an early haematolymphatic (stage 1) and a late encephalitic phase (stage 2), in which the parasite crosses the blood–brain barrier and chronic encephalopathy develops.

Rhodesiense infections

In these infections, the disease is more acute and severe than in *gambiense* infections, so that, within days or a few weeks, the patient is usually severely ill and may have developed pleural effusions and signs of myocarditis or hepatitis. There may be a petechial rash. The patient may die before there are signs of involvement of the CNS. If the illness is less acute, drowsiness, tremors and coma develop.

Gambiense infections

The distinction between early and late stages may not be apparent in *gambiense* infections. The disease usually runs a slow course over months or years, with irregular bouts of fever and enlargement of lymph nodes. These are characteristically firm, discrete, rubbery and painless, and are particularly prominent in the posterior triangle of the neck ('Winterbottom's sign'). The spleen and liver may become palpable. After some months without treatment, the CNS is invaded. Patients develop headache, altered behaviour, blunting of higher mental functions, insomnia by night and sleepiness by day, delirium and eventually tremors, pareses, wasting, coma and death.

Investigations

Trypanosomiasis should be considered in any febrile patient from an endemic area. In *rhodesiense* infections, thick and thin malaria blood films will reveal trypanosomes. The trypanosomes may be seen in the blood or from puncture of the primary lesion in the earliest stages of *gambiense* infections, but it is usually easier to demonstrate them by aspiration of a lymph node. Concentration methods include buffy coat microscopy and miniature anion exchange chromatography.

Due to the cyclical nature of parasitaemia, the diagnosis is often made by demonstration of antibodies using a simple, rapid screening card agglutination trypanosomiasis test (CATT) for *gambiense* HAT, followed by parasitological confirmation. No reliable serological test is available for *rhodesiense* HAT. PCR diagnosis is available, although technical requirements limit its availability in endemic regions. If the CNS is affected, the cell count ($>20\times10^9$ leucocytes/L) and protein content of the CSF are increased and the glucose is diminished. A very high level of serum IgM or the presence of IgM in the CSF is suggestive of trypanosomiasis. Recognition of CNS involvement is critical, as failure to treat it might be fatal.

Management

Therapeutic options for African trypanosomiasis are limited and most antitrypanosomal drugs are toxic and expensive. The prognosis is good if treatment is begun early, before the brain has been invaded. At this stage, intravenous suramin, after a test dose of 100–200 mg, should be given for *rhodesiense* infections, followed by five injections of 20 mg/kg every 7 days. For *gambiense* infections, deep intramuscular or intravenous pentamidine 4 mg/kg for 7 days is given.

For the treatment of stage 2 (nervous system) infection caused by *gambiense* HAT, patients were previously treated with melarsoprol (an arsenical). Treatment-related mortality with melarsoprol is 4–12% due to reactive encephalopathy. Now eflornithine (DFMO), an irreversible inhibitor of ornithine decarboxylase (100 and 150 mg/kg IV 4 times daily for 14 days for adults and children, respectively), is a safer and cost-effective option. Combinations of eflornithine (400 mg daily for 7 days) with oral nifurtimox (15 mg/kg daily for 15 days) have been shown to decrease relapses, deaths and drug toxicity. Stage 2 *rhodesiense* infection is treated with melarsoprol 2.2 mg/kg IV for 10 days.

Prevention

In endemic *gambiense* areas, various measures are taken against tsetse flies, and field teams help detect and treat early HAT. In *rhodesiense* endemic areas, control is difficult.

American trypanosomiasis (Chagas' disease)

Chagas' disease occurs widely in South and Central America. The cause is *Trypanosoma cruzi*, transmitted to humans from the faeces of a reduviid (triatomine) bug, in which the trypanosomes develop before infecting humans. These bugs live in wild forests in crevices, burrows and palm trees. The *Triatoma infestans* bug has become domesticated in the Southern Cone countries (Argentina, Brazil, Chile, Paraguay and Uruguay). It lives in the mud and wattle walls and thatched roofs of simple rural houses and emerges at night to feed and defaecate on the sleeping occupants. Infected faeces are rubbed in through the conjunctiva, mucosa of mouth or nose, or abrasions of the skin. Over 100 species of mammal – domestic, peridomestic and wild – may serve as reservoirs of infection. In some areas, blood transfusion accounts for about 5% of cases. Congenital transmission occasionally occurs.

Pathology

The trypanosomes migrate via the blood stream, develop into amastigote forms in the tissues and multiply intracellularly by binary fission. In the acute phase (primarily cell-mediated), inflammation of parasitised, as well as non-parasitised, cardiac muscles and capillaries occurs, resulting in acute myocarditis. In the chronic phase, focal myocardial atrophy, signs of chronic passive congestion and thromboembolic phenomena, cardiomegaly and apical cardiac aneurysm are salient findings. In the digestive form of disease, focal myositis and discontinuous lesions of the intramural myenteric plexus are seen, predominantly in the oesophagus and colon.

Clinical features

Acute phase

Clinical manifestations of the acute phase are seen in only 1–2% of individuals infected before the age of 15 years. Young children (1–5 years) are most commonly affected. The entrance of *T. cruzi* through an abrasion produces a dusky-red, firm swelling and enlargement of regional lymph nodes. A conjunctival lesion, although less common, is characteristic; the unilateral firm, reddish swelling of the lids may close the eye and constitutes 'Romaña's sign'. In a few patients, an acute generalised infection soon appears, with a transient morbilliform or urticarial rash, fever, lymphadenopathy and enlargement of the spleen and liver. In a small minority of patients, acute myocarditis and heart failure or neurological features, including personality changes and signs of meningoencephalitis, may be seen. The acute infection may be fatal to infants.

Chronic phase

About 50–70% of infected patients become seropositive and develop an indeterminate form when no parasitaemia is detectable. They have a normal lifespan with no symptoms but are a natural reservoir for the disease and maintain the life cycle of parasites. After a latent period of several years, 10–30% of chronic cases develop low-grade myocarditis and damage to conducting fibres, which causes cardiomyopathy characterised by cardiac dilatation, arrhythmias, partial or complete heart block and sudden death. In nearly 10% of patients, damage to Auerbach's plexus results in dilatation of various parts of the alimentary canal, especially the colon and oesophagus, so-called 'mega' disease. Dilatation of the bile ducts and bronchi are also recognised sequelae. Autoimmune processes may be responsible for much of the damage. There are geographical variations of the basic pattern

of disease. Reactivation of Chagas' disease can occur in patients with HIV if the CD4 count falls lower than 200 cells/mm^3; this can cause space-occupying lesions with a presentation similar to *Toxoplasma gondii*, encephalitis, encephalitis, meningoencephalitis or myocarditis.

Investigations

T. cruzi is easily detectable in a blood film in the acute illness. In chronic disease, it may be recovered in up to 50% of cases by xenodiagnosis, in which infection-free, laboratory-bred reduviid bugs feed on the patient; subsequently, the hindgut or faeces of the bug are examined for parasites. Parasite DNA detection by PCR in the patient's blood is a highly sensitive method for documentation of infection and, in addition, can be employed in faeces of bugs used in xenodiagnosis tests to improve sensitivity. Antibody detection is also highly sensitive.

Management and prevention

Parasiticidal agents are used to treat the acute phase, congenital disease and early chronic phase (within 10 years of infection). Nifurtimox is given orally. The dose, which has to be carefully supervised to minimise toxicity while preserving parasiticidal activity, is 10 mg/kg daily orally, divided into three equal doses for 90 days. The paediatric dose is 15 mg/kg daily. Cure rates of 80% in acute disease are obtained. Benznidazole is an alternative, given at a dose of 5 mg/kg daily orally, in two divided doses for 60 days; children receive 10 mg/kg daily. Both nifurtimox and benznidazole are toxic, with adverse reaction rates of 30–55%. Parasiticidal treatment of the chronic phase is usually performed but, in the cardiac or digestive 'mega' diseases, does not reverse tissue damage. Surgery may be needed.

Preventative measures include improvement of housing and destruction of reduviid bugs by spraying of houses with insecticides. Blood and organ donors should be screened.

Toxoplasmosis

Toxoplasma gondii is an intracellular parasite. The sexual phase of the parasite's life cycle (Fig. 11.37) occurs in the small intestinal epithelium of the domestic cat. Oöcysts are shed in cat faeces and are spread to intermediate hosts (pigs, sheep and also humans) through widespread contamination of soil. Oöcysts may survive in moist conditions for weeks or months. Once they are ingested, the parasite transforms into rapidly dividing tachyzoites through cycles of asexual multiplication. Microscopic tissue cysts develop containing bradyzoites, which persist for the lifetime of the host. Cats become infected or reinfected by ingesting tissue cysts in prey such as rodents and birds.

Human infection occurs via oöcyst-contaminated soil, salads and vegetables, or by ingestion of raw or under-cooked meats containing tissue cysts. Sheep, pigs and rabbits are the most common meat sources. Outbreaks of toxoplasmosis have been linked to the consumption of unfiltered water. In developed countries, toxoplasmosis is the most common protozoal infection; around 22% of adults in the UK are seropositive. Most primary infections are subclinical; however, toxoplasmosis is thought to account for about 15% of heterophile antibody-negative infectious mononucleosis (p. 241). In India or Brazil, approximately 40–60% of pregnant females are seropositive for *T. gondii*. In HIV-1 infection (p. 320), toxoplasmosis is an important opportunistic infection with considerable morbidity and mortality. Generalised toxoplasmosis has been described after accidental laboratory infection with highly virulent strains.

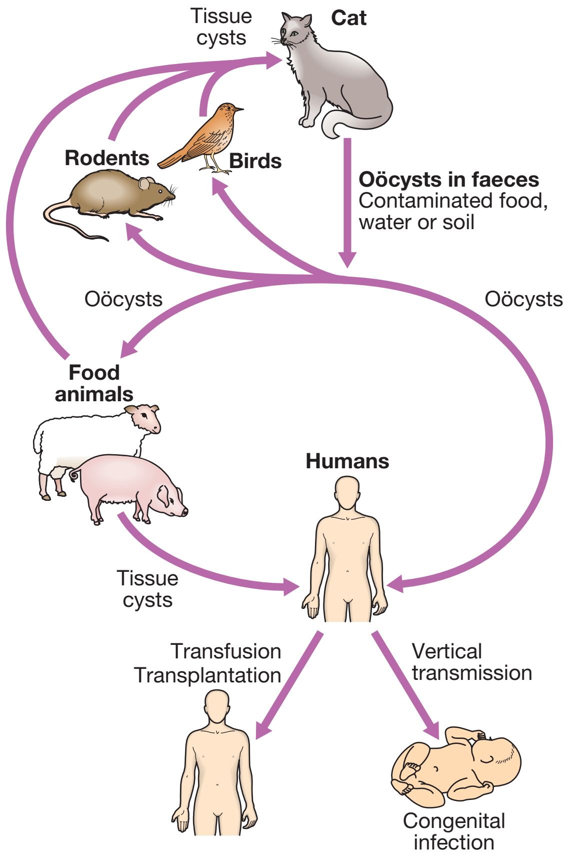

Fig. 11.37 Life cycle of *Toxoplasma gondii*.

Clinical features

In most immunocompetent individuals, including children and pregnant women, the infection goes unnoticed. In approximately 10% of patients, it causes a self-limiting illness, most common in adults aged 25–35 years. The presenting feature is usually localised or generalised painless lymphadenopathy. The cervical nodes are primarily involved but mediastinal, mesenteric or retroperitoneal groups may be affected. The spleen is seldom palpable. Most patients have no systemic symptoms but some complain of malaise, fever, fatigue, muscle pain, sore throat and headache. Complete resolution usually occurs within a few months, although symptoms and lymphadenopathy tend to fluctuate unpredictably and some patients do not recover completely for a year or more. Encephalitis, myocarditis, polymyositis, pneumonitis or hepatitis occasionally occur in immunocompetent patients but are more frequent in immunocompromised hosts. Retinochoroiditis (Fig. 11.38) is usually the result of congenital infection but has also been reported in acquired disease.

Congenital toxoplasmosis

Acute toxoplasmosis, mostly subclinical, affects 0.3–1% of pregnant women, with an approximately 60% transmission rate to the fetus, which rises with increasing gestation. Seropositive females infected 6 months before conception have no risk of fetal transmission. Congenital disease affects approximately 40% of infected fetuses, and is more likely and more severe with infection early in gestation (see Box 11.26, p. 235). Many fetal infections are subclinical at birth but long-term sequelae include retinochoroiditis, microcephaly and hydrocephalus.

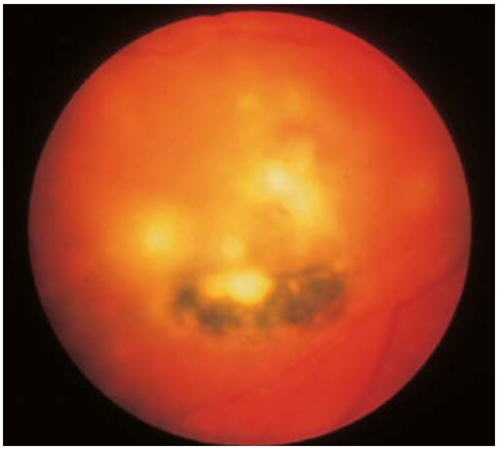

Fig. 11.38 Retinochoroiditis due to toxoplasmosis.

Investigations

In contrast to immunocompromised patients, in whom the diagnosis often requires direct detection of parasites, serology is often used in immunocompetent individuals. The Sabin–Feldman dye test (indirect fluorescent antibody test), which detects IgG antibody, is most commonly used. Recent infection induces a fourfold or greater increase in titre when paired sera are tested in parallel. Peak titres of 1/1000 or more are reached within 1–2 months of the onset of infection, and serology then becomes an unreliable indicator of recent infection. The detection of significant levels of *Toxoplasma*-specific IgM antibody may be useful in confirming acute infection. A false-positive result or persistence of IgM antibodies for years after infection makes interpretation difficult; however, negative IgM antibodies virtually rule out acute infection.

During pregnancy, it is critical to differentiate recent from past infection; the presence of high-avidity IgG antibodies excludes infection acquired in the preceding 3–4 months.

If necessary, the presence of *Toxoplasma* organisms in a lymph node biopsy or other tissue can be detected histochemically with *T. gondii* antiserum, or by the use of PCR to detect *Toxoplasma*-specific DNA.

Management

In immunocompetent subjects, uncomplicated toxoplasmosis is self-limiting and responds poorly to antimicrobial therapy. Treatment with sulfadiazine, pyrimethamine and folinic acid is usually reserved for severe or progressive disease, and for infection in immunocompromised patients.

In pregnant women with established recent infection, spiramycin (3 g daily in divided doses) is given until term. Once fetal infection is established, treatment with sulfadiazine and pyrimethamine plus calcium folinate is recommended (spiramycin does not cross the placental barrier). The cost/benefit of routine *Toxoplasma* screening and treatment in pregnancy is being debated in many countries. There is insufficient evidence to determine the effects on mother or baby of current antiparasitic treatment for women who seroconvert in pregnancy.

Leishmaniasis

Leishmaniasis is caused by unicellular, flagellate, intracellular protozoa belonging to the genus *Leishmania* (order Kinetoplastidae). There are 21 leishmanial species that cause diverse clinical syndromes, which can be placed into three broad groups:

- visceral leishmaniasis (VL, kala-azar)
- cutaneous leishmaniasis (CL)
- mucosal leishmaniasis (ML).

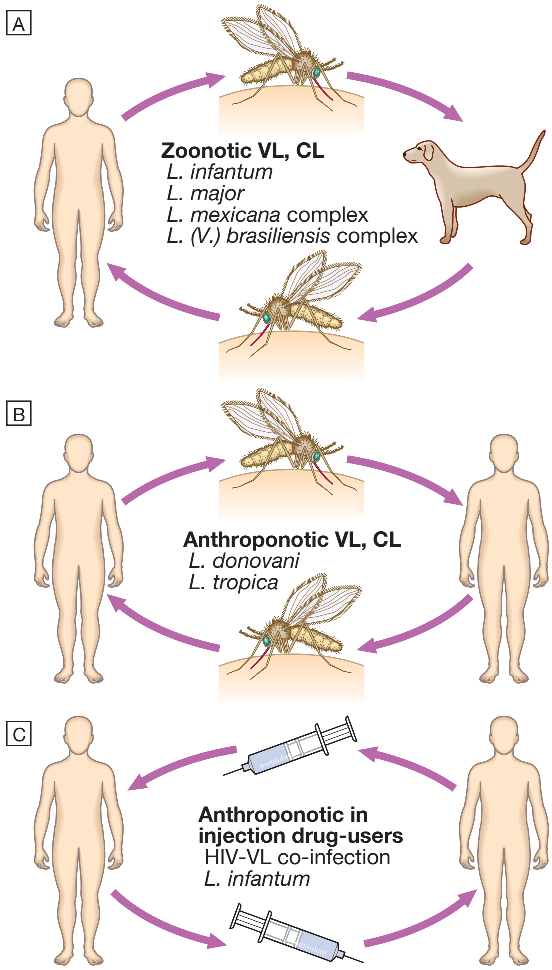

Fig. 11.39 Transmission of leishmaniasis. A Zoonotic transmission. B Anthroponotic transmission. C Anthroponotic transmission in the injection drug-user. (CL = cutaneous leishmaniasis; VL = visceral leishmaniasis)

Epidemiology and transmission

Although most clinical syndromes are caused by zoonotic transmission of parasites from animals (chiefly canine and rodent reservoirs) to humans through phlebotomine sandfly vectors (Fig. 11.39A), humans are the only known reservoir (anthroponotic person-to-person transmission) in major VL foci in the Indian subcontinent and in injection drug-users (Fig. 11.39B and C). Leishmaniasis occurs in approximately 100 countries around the world, with an estimated annual incidence of 0.9–1.3 million new cases (25% VL).

The life cycle of *Leishmania* is shown in Figure 11.40. Flagellar promastigotes (10–20 μm) are introduced by the feeding female sandfly. The promastigotes are taken up by neutrophils, which undergo apoptosis and are then engulfed by macrophages, in which the parasites transform into amastigotes (2–4 μm; Leishman–Donovan body). These multiply, causing macrophage

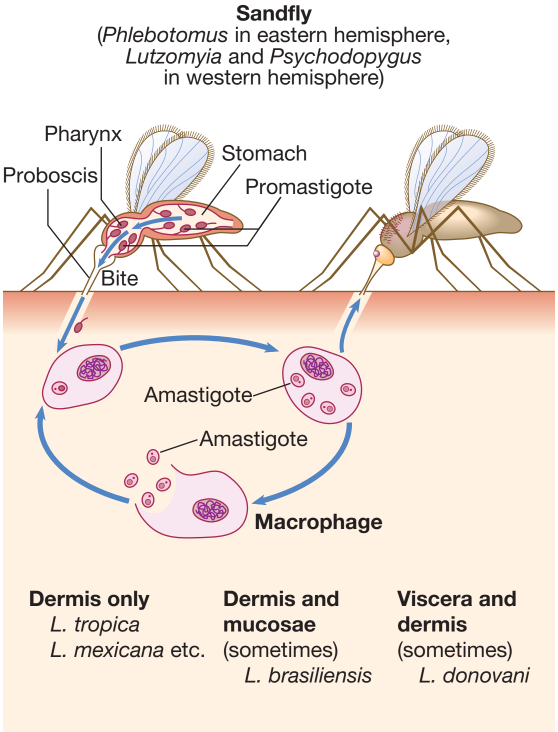

Fig. 11.40 Life cycle of *Leishmania.* *From Knight R. Parasitic disease in man. Churchill Livingstone, Elsevier Ltd; 1982.*

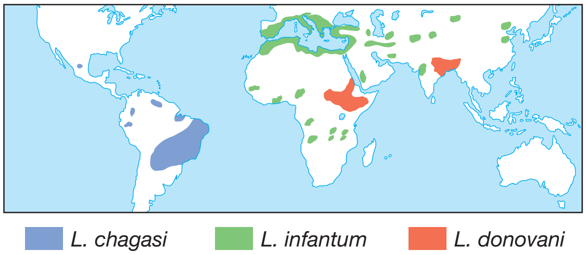

Fig. 11.41 World distribution of visceral leishmaniasis.

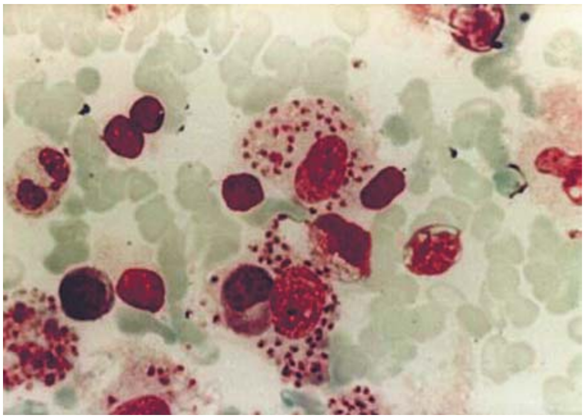

Fig. 11.42 Splenic smear showing numerous intracellular, and a few extracellular, amastigotes. *Courtesy of Dr S. Sundar and Dr H.W. Murray.*

lysis and infection of other cells. Sandflies pick up amastigotes when feeding on infected patients or animal reservoirs. In the sandfly, the parasite transforms into a flagellar promastigote, which multiplies by binary fission in the gut of the vector and migrates to the proboscis to infect a new host.

Sandflies live in hot and humid climates in the cracks and crevices of mud or straw houses and lay eggs in organic matter. People living in such conditions are more prone to leishmaniasis. Female sandflies bite during the night and preferentially feed on animals; humans are incidental hosts.

Visceral leishmaniasis (kala-azar)

VL is caused by the protozoon *Leishmania donovani* complex (comprising *L. donovani*, *L. infantum* and *L. chagasi*). India, Sudan, Bangladesh and Brazil account for 90% of cases of VL. Other affected regions include the Mediterranean, East Africa, China, Arabia, Israel and other South American countries (Fig. 11.41). In addition to sandfly transmission, VL has also been reported to follow blood transfusion, and disease can present unexpectedly in immunosuppressed patients – for example, after renal transplantation and in HIV infection.

The majority of people infected remain asymptomatic. In visceral disease, the spleen, liver, bone marrow and lymph nodes are primarily involved.

Clinical features

In the Indian subcontinent, adults and children are equally affected; elsewhere, VL is mainly a disease of small children and infants, except in adults with HIV co-infection. The incubation period ranges from weeks to months (occasionally, several years).

The first sign of infection is high fever, usually accompanied by rigor and chills. Fever intensity decreases over time and patients may become afebrile for intervening periods ranging from weeks to months. This is followed by a relapse of fever, often of lesser intensity. Splenomegaly develops quickly in the first few weeks and becomes massive as the disease progresses. Moderate hepatomegaly occurs later. Lymphadenopathy is common in Africa, the Mediterranean and South America but is rare in the Indian subcontinent. Blackish discoloration of the skin, from which the disease derived its name, kala-azar (the Hindi word for 'black fever'), is a feature of advanced illness but is now rarely seen. Pancytopenia is common. Moderate to severe anaemia develops rapidly and can cause cardiac failure. Thrombocytopenia, often compounded by hepatic dysfunction, may result in bleeding from the retina, gastrointestinal tract and nose. In advanced illness, hypoalbuminaemia may manifest as pedal oedema, ascites and anasarca (gross generalised oedema and swelling).

As disease progresses, there is profound immunosuppression and secondary infections are very common. These include tuberculosis, pneumonia, gastroenteritis, severe amoebic or bacillary dysentery, boils, cellulitis, chickenpox, shingles and scabies. Without adequate treatment, most patients with clinical VL die.

Investigations

Pancytopenia is the dominant feature, with granulocytopenia and monocytosis. Polyclonal hypergammaglobulinaemia, chiefly IgG followed by IgM, and hypoalbuminaemia are seen later.

Demonstration of amastigotes (Leishman–Donovan bodies) in splenic smears is the most efficient means of diagnosis, with 98% sensitivity (Fig. 11.42); however, it carries a risk of serious haemorrhage in inexperienced hands. Safer methods, such as bone marrow or lymph node smears, are not as sensitive but

are frequently employed. Parasites may be demonstrated in buffy coat smears, especially in immunosuppressed patients. Sensitivity is improved by culturing the aspirate material or by using PCR for DNA detection and species identification, but these tests can only be performed in specialised laboratories.

Serodiagnosis, by ELISA or immunofluorescence antibody test, is employed in developed countries. In endemic regions, a highly sensitive direct agglutination test using stained promastigotes and an equally efficient rapid immunochromatographic k39 strip test have become popular. These tests remain positive for several months after cure has been achieved, so do not predict response to treatment or relapse. The vast majority of people exposed to the parasite do not develop clinical illness but may have positive serological tests thereafter. Formal gel (aldehyde) or other similar tests based on the detection of raised globulin have limited value and should not be employed for the diagnosis of VL.

Differential diagnosis

This includes malaria, typhoid, tuberculosis, schistosomiasis and many other infectious and neoplastic conditions, some of which may coexist with VL. Fever, splenomegaly, pancytopenia and non-response to antimalarial therapy may provide clues before specific laboratory diagnosis is made.

Management

Pentavalent antimonials

Antimony (Sb) compounds were the first drugs to be used for the treatment of leishmaniasis and remain the mainstay of treatment in most parts of the world. The exception is the Indian subcontinent, especially Bihar state, where almost two-thirds of cases are refractory to Sb treatment. Traditionally, pentavalent antimony is available as sodium stibogluconate (100 mg/mL) in English-speaking countries and meglumine antimoniate (85 mg/mL) in French-speaking ones. The daily dose is 20 mg/kg body weight, intravenously or intramuscularly, for 28–30 days. Side-effects are common and include arthralgia, myalgia, raised hepatic transaminases, pancreatitis (especially in patients co-infected with HIV) and ECG changes (T-wave inversion and reduced amplitude). Severe cardiotoxicity, manifest by concave ST segment elevation, prolongation of QT_c greater than 0.5 msec and ventricular dysrhythmias, is not uncommon. The incidence of cardiotoxicity and death is particularly high with improperly manufactured Sb.

Amphotericin B

Amphotericin B deoxycholate, given once daily or on alternate days at a dose of 0.75–1.00 mg/kg for 15–20 doses, is used as the first-line drug in many regions where there is a significant level of Sb unresponsiveness. It has a cure rate of nearly 100%. Infusion-related side-effects, such as high fever with rigor, thrombophlebitis, diarrhoea and vomiting, are extremely common. Serious side-effects, including renal or hepatic toxicity, hypokalaemia and thrombocytopenia, are observed frequently.

Lipid formulations of amphotericin B (p. 126) are less toxic. AmBisome is first-line therapy in Europe for VL. Dosing recommendations vary according to geographical region. In the Indian subcontinent, a total dose of 10 or 15 mg/kg, administered in a single dose or as multiple doses over several days, respectively, is considered adequate, whereas in Africa 14–18 mg/kg, and in South America and Europe 21–24 mg/kg, in divided doses, typically spread over 10 days, is recommended for immunocompetent patients. High daily doses of the lipid formulations are well tolerated, and in one study a single dose of 10 mg/kg of AmBisome cured 96% of Indian patients. The manufacturer of AmBisome has donated a large quantity of the drug for use in the Kala-azar Elimination Programme in India, Nepal and Bangladesh, leading to its adoption as the first-line drug in treatment.

Other drugs

The oral drug miltefosine, an alkyl phospholipid, has been approved in several countries for the treatment of VL. A daily dose of 50 mg (patient's body weight <25 kg) to 100 mg (≥25 kg), or 2.5 mg/kg for children, for 28 days cures over 90% of patients. Side-effects include mild to moderate vomiting and diarrhoea, and rarely skin allergy or renal or liver toxicity. Since it is a teratogenic drug, it cannot be used in pregnancy; female patients are advised not to become pregnant for the duration of treatment and 3 months thereafter because of its half-life of nearly 1 week.

Paromomycin is an aminoglycoside that has undergone trials in India and Africa, and is highly effective if given intramuscularly at 11 mg/kg of paromomycin base, daily for 3 weeks. No significant auditory or renal toxicity is seen. The drug is approved in India for VL treatment.

11

Pentamidine isethionate was used to treat Sb-refractory patients with VL. However, declining efficacy and serious side-effects, such as type 1 diabetes mellitus, hypoglycaemia and hypotension, have led to it being abandoned.

Multidrug therapy of VL is likely to be used increasingly to prevent emergence of drug resistance, and in India short-course combinations (a single dose of AmBisome 5 mg/kg with either 7 days of miltefosine or 10 days of paromomycin, or 10 days each of miltefosine and paromomycin) were as effective as standard therapy. In India, in treatment centres where the cold chain (a temperature-controlled supply chain) is not maintained, 10 days of paromomycin combined with miltefosine is an alternative treatment regimen.

Response to treatment

A good response results in fever resolution, improved well-being, reduction in splenomegaly, weight gain and recovery of blood counts. Patients should be followed regularly for 6–12 months, as some may experience relapse irrespective of the treatment regimen.

HIV–visceral leishmaniasis co-infection

HIV-induced immunosuppression (Ch. 12) increases the risk of contracting VL 100–1000 times. Most cases of HIV–VL co-infection have been reported from Spain, France, Italy and Portugal. Antiretroviral therapy (ART) has led to a remarkable decline in the incidence of VL co-infection in Europe. However, numbers are increasing in Africa (mainly Ethiopia), Brazil and the Indian subcontinent.

Although the clinical triad of fever, splenomegaly and hepatomegaly is found in the majority of co-infected patients, those with low CD4 count may have atypical clinical presentations. VL may present with gastrointestinal involvement (stomach, duodenum or colon), ascites, pleural or pericardial effusion, or involvement of lungs, tonsil, oral mucosa or skin. Diagnostic principles remain the same as those in non-HIV patients. Parasites are numerous and easily demonstrable, even in buffy coat preparations. Sometimes amastigotes are found in unusual sites, such as bronchoalveolar lavage fluid, pleural fluid or biopsies of the gastrointestinal tract. Serological tests have low sensitivity. DNA detection by PCR of the blood or its buffy coat is at least 95% sensitive and accurately tracks recovery and relapse.

Treatment of VL with HIV co-infection is essentially the same as in immunocompetent patients but there are some differences in outcome. Conventional amphotericin B (0.7 mg/kg/day for 28 days) may be more effective in achieving initial cure than Sb (20 mg/kg/day for 28 days). Using high-dose liposomal amphotericin B (4 mg/kg on days 1–5, 10, 17, 24, 31 and 38), a high cure rate is possible. However, co-infected patients have a tendency to relapse within 1 year and maintenance chemotherapy with monthly liposomal amphotericin B is useful.

Post-kala-azar dermal leishmaniasis

After treatment and apparent recovery from VL in India and Sudan, some patients develop dermatological manifestations due to local parasitic infection.

Clinical features

In India, dermatological changes occur in a small minority of patients 6 months to at least 3 years after the initial infection. They are seen as macules, papules, nodules (most frequently) and plaques, which have a predilection for the face, especially the area around the chin. The face often appears erythematous (Fig. 11.43A). Hypopigmented macules can occur over all parts of the body and are highly variable in extent. There are no systemic symptoms and little spontaneous healing occurs.

In Sudan, approximately 50% of patients with VL develop post-kala-azar dermal leishmaniasis (PKDL), experiencing skin manifestations concurrently with VL or within the following 6 months. In addition to the dermatological features, a measles-like micropapular rash (Fig. 11.43B) may be seen all over the body. In Sudan, children are more frequently affected than in India. Spontaneous healing occurs in about three-quarters of cases within 1 year.

Investigations and management

The diagnosis is clinical, supported by demonstration of scanty parasites in lesions by slit-skin smear and culture. Immunofluorescence and immunohistochemistry may demonstrate the parasite in skin tissues. In the majority of patients, serological tests (direct agglutination test or k39 strip tests) are positive.

Treatment of PKDL is difficult. In India, Sb for 120 days, several courses of amphotericin B infusions, or miltefosine for 12 weeks is required. In Sudan, Sb for 2 months is considered adequate. In the absence of a physical handicap, most patients are reluctant to complete the treatment. PKDL patients are a human reservoir, and focal outbreaks have been linked to patients with PKDL in areas previously free of VL.

Prevention and control

Sandfly control through insecticide spray is very important. Mosquito nets or curtains treated with insecticides will keep out the tiny sandflies. In endemic areas with zoonotic transmission, infected or stray dogs should be destroyed.

In areas with anthroponotic transmission, early diagnosis and treatment of human infections, to reduce the reservoir and control epidemics of VL, is extremely important. Serology is useful in diagnosis of suspected cases in the field. No vaccine is currently available.

Cutaneous and mucosal leishmaniasis

Cutaneous leishmaniasis

CL (oriental sore) occurs in both the Old World (Asia, Africa and Europe) and the New World (the Americas). Transmission is described on page 281.

In the Old World, CL is mild. It is found around the Mediterranean basin, throughout the Middle East and Central Asia as far as Pakistan, and in sub-Saharan West Africa and Sudan (Fig. 11.44). The causative organisms for Old World zoonotic CL are *L. major*, *L. tropica* and *L. aethiopica* (Box 11.57). Anthroponotic CL is caused by *L. tropica*, and is confined to urban or suburban areas of the Old World. Afghanistan is currently the biggest focus but infection is endemic in Pakistan, the western deserts of India, Iran, Iraq, Syria and other areas of the Middle East. In recent years, there has been an increase in the incidence of zoonotic CL in both the Old and the New Worlds due to urbanisation and deforestation, which led to peridomestic transmission (in and around human dwellings).

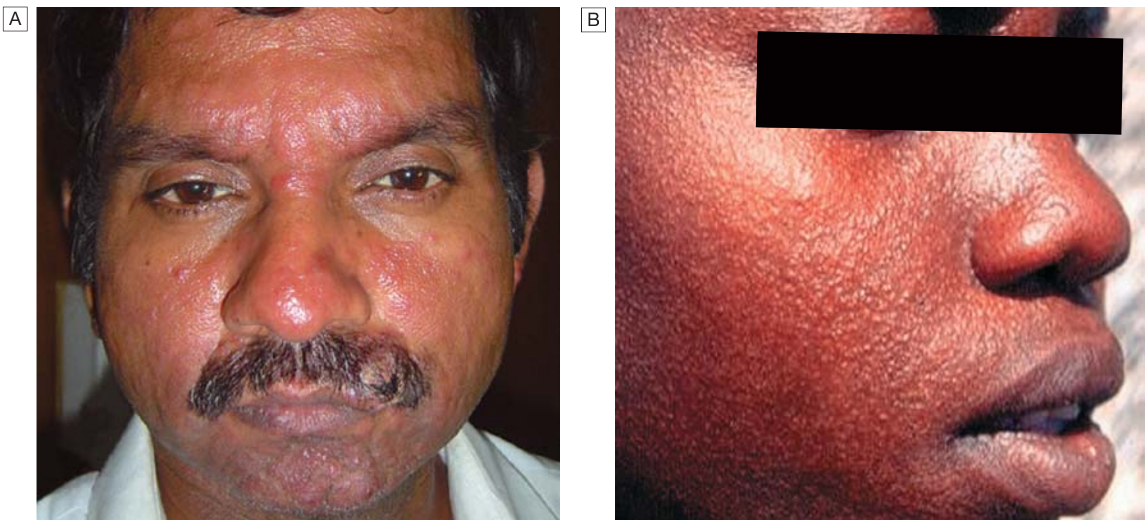

Fig. 11.43 Post-kala-azar dermal leishmaniasis. **A** In India, with macules, papules, nodules and plaques. **B** In Sudan, with micronodular rash.
A, From Sundar S, Kumar K, Chakravarty J, et al. Cure of antimony-unresponsive Indian post-kala-azar dermal leishmaniasis with oral miltefosine. Trans R Soc Trop Med Hyg 2006; 100(7):698–700. B, Courtesy of Dr E.E. Zijlstra.

New World CL is a more significant disease, which may disfigure the nose, ears and mouth, and is caused by the *L. mexicana* complex (comprising *L. mexicana*, *L. amazonensis* and *L. venezuelensis*) and by the *Viannia* subgenus *L. (V.) brasiliensis* complex (comprising *L. (V.) guyanensis*, *L. (V.) panamensis*, *L. (V.) brasiliensis* and *L. (V.) peruviana*).

CL is commonly imported and should be considered in the differential diagnosis of an ulcerating skin lesion, especially in travellers who have visited endemic areas of the Old World or forests in Central and South America.

Pathogenesis

Inoculated parasites are taken up by dermal macrophages, in which they multiply and form a focus for lymphocytes, epithelioid cells and plasma cells. Self-healing may occur with necrosis of infected macrophages, or the lesion may become chronic with ulceration of the overlying epidermis, depending on the aetiological pathogen.

Clinical features

The incubation period is typically 2–3 months (range 2 weeks to 5 years). In all types of CL a papule develops at the site of the vector bite. The small, red papules may be single or multiple and increase gradually in size, reaching 2–10 cm in diameter. A crust forms, overlying an ulcer with a granular base and with raised borders (Fig. 11.45). These ulcers develop a few weeks or months after the bite. There can be satellite lesions, especially in *L. major* and occasionally in *L. tropica* infections. Regional lymphadenopathy, pain, pruritus and secondary bacterial infections may occur.

Lesions of *L. mexicana* and *L. peruviana* closely resemble those seen in the Old World, but lesions on the pinna of the ear are common and are chronic and destructive. *L. mexicana* is responsible for chiclero ulcers, the self-healing sores of Mexico.

If immunity is effective, there is usually spontaneous healing in *L. tropica*, *L. major* and *L. mexicana* lesions. In some patients with anergy to *Leishmania*, the skin lesions of *L. aethiopica*, *L. mexicana* and *L. amazonensis* infections progress to the development of diffuse CL; this is characterised by spread of the infection from the initial ulcer, usually on the face, to involve the whole body in the form of non-ulcerative nodules. Occasionally, in *L. tropica* infections, sores that have apparently healed relapse persistently (recidivans or lupoid leishmaniasis).

11.57 Types of Old World cutaneous leishmaniasis

Leishmania spp.	Host	Clinical features
L. tropica	Dogs	Slow evolution, less severe
L. major	Gerbils, desert rodents	Rapid necrosis, wet sores
L. aethiopica	Hyraxes	Solitary facial lesions with satellites

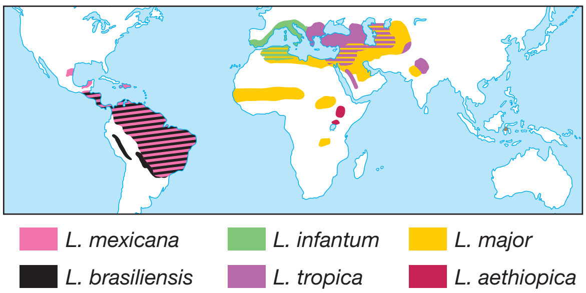

Fig. 11.44 **World distribution of cutaneous leishmaniasis.**

Mucosal leishmaniasis

The *Viannia* subgenus extends widely from the Amazon basin as far as Paraguay and Costa Rica, and is responsible for deep sores and ML. In *L. (V.) brasiliensis* complex infections, cutaneous lesions may be followed by mucosal spread of the disease simultaneously or even years later. Young men with chronic lesions are particularly at risk, and 2–40% of infected persons develop 'espundia', metastatic lesions in the mucosa of the nose or mouth. This is characterised by thickening and erythema of the nasal mucosa, typically starting at the junction of the nose and upper lip. Later, ulceration develops. The lips, soft palate, fauces and larynx may also be invaded and destroyed, leading to considerable suffering and deformity. There is no spontaneous healing, and death may result from severe respiratory tract infections due to massive destruction of the pharynx.

Investigations in CL and ML

CL is often diagnosed on the basis of the lesions' clinical characteristics. Parasitological confirmation is important, however, because clinical manifestations may be mimicked by other infections. Amastigotes can be demonstrated on a slit-skin smear with Giemsa staining; alternatively, they can be cultured from the sores early during the infection. Parasites seem to be particularly

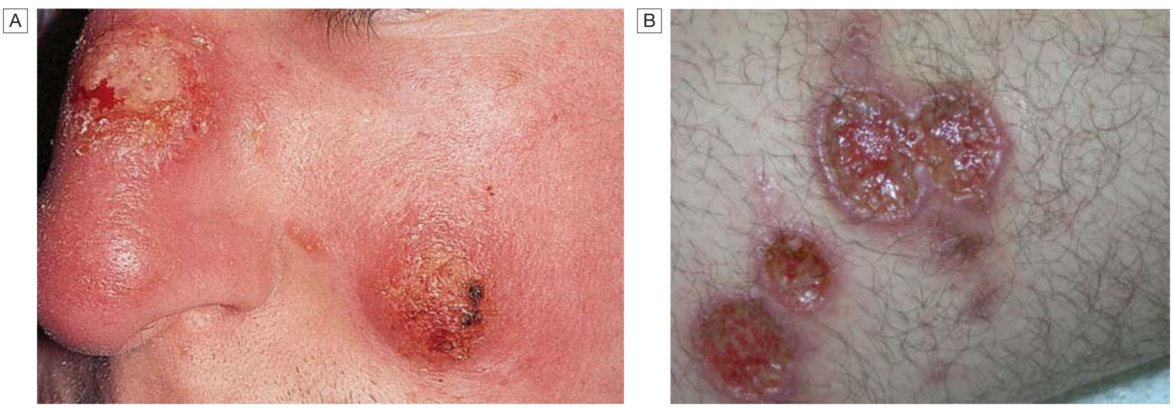

Fig. 11.45 **Cutaneous leishmaniasis.** A Papule. B Ulcer. *B, Courtesy of Dr Ravi Gowda, Royal Hallamshire Hospital, Sheffield.*

difficult to isolate from sores caused by *L. brasiliensis*, responsible for the vast majority of cases in Brazil. Touch preparations from biopsies and histopathology usually have a low sensitivity. Culture of fine needle aspiration material has been reported to be the most sensitive method.

ML is more difficult to diagnose parasitologically. The leishmanin skin test measures delayed-type hypersensitivity to killed *Leishmania* organisms. A positive test is defined as induration of more than 5 mm, 48 hours after intradermal injection. The test is positive, except in diffuse CL and during active VL. PCR is used increasingly for diagnosis and speciation, which is useful in selecting therapy.

Management of CL and ML

Small lesions may self-heal or are treated by freezing with liquid nitrogen or curettage. There is no ideal antimicrobial therapy. Treatment should be individualised on the basis of the causative organism, severity of the lesions, availability of drugs, tolerance of the patient for toxicity, and local resistance patterns.

In CL, topical application of paromomycin 15% plus methylbenzethonium chloride 12% is beneficial. Intralesional antimony (Sb 0.2–0.8 mL/lesion) up to 2 g seems to be rapidly effective in suitable cases; it is well tolerated and economic, and is safe in patients with cardiac, liver or renal diseases.

In ML, and in CL when the lesions are multiple or in a disfiguring site, it is better to treat with parenteral Sb in a dose of 20 mg/kg/day (usually given for 20 days for CL and 28 days for ML), or with conventional or liposomal amphotericin B (see treatment of VL above). Sb is also indicated to prevent the development of mucosal disease, if there is any chance that a lesion acquired in South America is due to an *L. brasiliensis* strain. Refractory CL or ML should be treated with an amphotericin B preparation.

Other regimens may be effective. Two to four doses of pentamidine (2–4 mg/kg), administered on alternate days, are effective in New World CL caused by *L. guyanensis*. In ML, 8 injections of pentamidine (4 mg/kg on alternate days) cure the majority of patients. Ketoconazole (600 mg daily for 4 weeks) has shown some potential against *L. mexicana* infection. In Saudi Arabia, fluconazole (200 mg daily for 6 weeks) reduced healing times and cured 79% of patients with CL caused by *L. major*. In India, itraconazole (200 mg daily for 6 weeks) produced good results in CL.

Prevention of CL and ML

Personal protection against sandfly bites is important. No effective vaccine is yet available.

Gastrointestinal protozoal infections

Amoebiasis

Amoebiasis is caused by *Entamoeba histolytica*, which is spread between humans by its cysts. It is one of the leading parasitic causes of morbidity and mortality in the tropics and is occasionally acquired in non-tropical countries. Two non-pathogenic *Entamoeba* species (*E. dispar* and *E. moshkovskii*) are morphologically identical to *E. histolytica*, and are distinguishable only by molecular techniques, isoenzyme studies or monoclonal antibody typing. However, only *E. histolytica* causes amoebic dysentery or liver abscess. The life cycle of the amoeba is shown in Figure 11.46A.

Pathology

Cysts of *E. histolytica* are ingested in water or uncooked foods contaminated by human faeces. Infection may also be acquired through anal/oral sexual practices. In the colon, trophozoite forms emerge from the cysts. The parasite invades the mucous membrane of the large bowel, producing lesions that are maximal

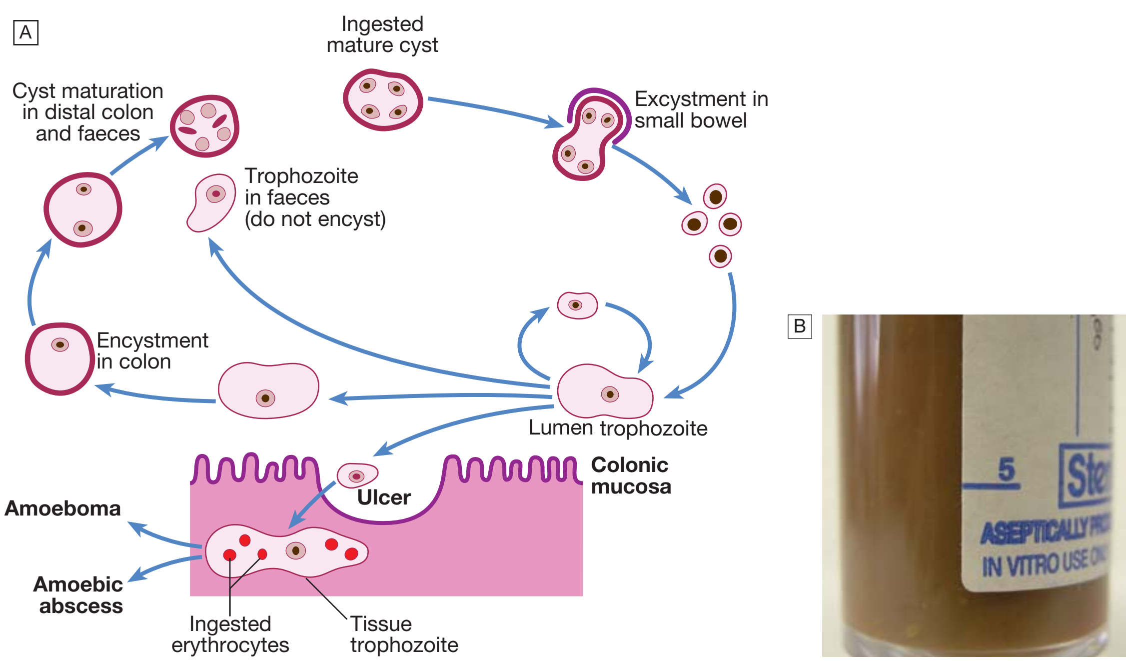

Fig. 11.46 Amoebiasis. A The life cycle of *Entamoeba histolytica*. B The chocolate-brown appearance of aspirated material from an amoebic liver abscess. *A, From Knight R. Parasitic disease in man. Churchill Livingstone, Elsevier Ltd; 1982. B, Courtesy of Dr Ravi Gowda, Royal Hallamshire Hospital, Sheffield.*

in the caecum but extend to the anal canal. These are flask-shaped ulcers, varying greatly in size and surrounded by healthy mucosa. A localised granuloma (amoeboma), presenting as a palpable mass in the rectum or a filling defect in the colon on radiography, is a rare complication that should be differentiated from carcinoma. Amoebic ulcers may cause severe haemorrhage but rarely perforate the bowel wall.

Amoebic trophozoites can emerge from the vegetative cyst from the bowel and be carried to the liver in a portal venule. They can multiply rapidly and destroy the liver parenchyma, causing an abscess (see also p. 879). The liquid contents at first have a characteristic pinkish colour, which may later change to chocolate-brown (said to resemble anchovy sauce).

Cutaneous amoebiasis, though rare, causes progressive genital, perianal or peri-abdominal surgical wound ulceration.

Clinical features

Intestinal amoebiasis – amoebic dysentery

Most amoebic infections are asymptomatic. The incubation period of amoebiasis ranges from 2 weeks to many years, followed by a chronic course with abdominal pains and two or more unformed stools a day. Offensive diarrhoea, alternating with constipation, and blood or mucus in the stool are common. There may be abdominal pain, especially in the right lower quadrant (which may mimic acute appendicitis). A dysenteric presentation with passage of blood, simulating bacillary dysentery or ulcerative colitis, occurs particularly in older people, in the puerperium and with super-added pyogenic infection of the ulcers.

Amoebic liver abscess

The abscess is usually found in the right hepatic lobe. There may not be associated diarrhoea. Early symptoms may be only local discomfort and malaise; later, a swinging temperature and sweating may develop, usually without marked systemic symptoms or signs. An enlarged, tender liver, cough and pain in the right shoulder are characteristic but symptoms may remain vague and signs minimal. A large abscess may penetrate the diaphragm, rupturing into the lung, and may be coughed up through a hepatobronchial fistula. Rupture into the pleural or peritoneal cavity, or rupture of a left lobe abscess in the pericardial sac, is less common but more serious.

Investigations

The stool and any exudate should undergo prompt microscopic examination for motile trophozoites containing red blood cells. Movements cease rapidly as the stool preparation cools. Several stools may need to be examined in chronic amoebiasis before cysts are found. Sigmoidoscopy may reveal typical flask-shaped ulcers, which should be scraped and examined immediately for *E. histolytica*. In endemic areas, one-third of the population are symptomless passers of amoebic cysts.

An amoebic abscess of the liver is suspected on clinical grounds; there is often a neutrophil leucocytosis and a raised right hemidiaphragm on chest X-ray. Confirmation is by ultrasonic scanning. Aspirated pus from an amoebic abscess has the characteristic chocolate-brown appearance but only rarely contains free amoebae (Fig. 11.46B).

Serum antibodies are detectable by immunofluorescence in over 95% of patients with hepatic amoebiasis and intestinal amoeboma, but in only about 60% of dysenteric amoebiasis. DNA detection by PCR has been shown to be useful in diagnosis of *E. histolytica* infections but is not generally available.

Management

Intestinal and early hepatic amoebiasis responds quickly to oral metronidazole (800 mg 3 times daily for 5–10 days) or other long-acting nitroimidazoles like tinidazole or ornidazole (both in doses of 2 g daily for 3 days). Nitazoxanide (500 mg twice daily for 3 days) is an alternative drug. Either diloxanide furoate or paromomycin, in doses of 500 mg orally 3 times daily for 10 days after treatment, should be given to eliminate luminal cysts.

If a liver abscess is large or threatens to burst, or if the response to chemotherapy is not prompt, aspiration is required and is repeated if necessary. Rupture of an abscess into the pleural cavity, pericardial sac or peritoneal cavity necessitates immediate aspiration or surgical drainage. Small serous effusions resolve without drainage.

Prevention

Personal precautions against contracting amoebiasis include not eating fresh, uncooked vegetables or drinking unclean water.

Giardiasis

Infection with *Giardia lamblia* is found worldwide and is common in the tropics. It particularly affects children, tourists and immunosuppressed individuals, and is the parasite most commonly imported into the UK. In cystic form, it remains viable in water for up to 3 months and infection usually occurs by ingesting contaminated water. Its flagellar trophozoite form attaches to the duodenal and jejunal mucosa, causing inflammation.

Clinical features and investigations

After an incubation period of 1–3 weeks, there is diarrhoea, abdominal pain, weakness, anorexia, nausea and vomiting. On examination, there may be abdominal distension and tenderness. Chronic diarrhoea and malabsorption may occur, with bulky stools that float.

Stools obtained at 2–3-day intervals should be examined for cysts. Duodenal or jejunal aspiration by endoscopy gives a higher diagnostic yield. The 'string test' may be used, in which one end of a piece of string is passed into the duodenum by swallowing and retrieved after an overnight fast; expressed fluid is then examined for the presence of *G. lamblia* trophozoites. A number of stool antigen detection tests are available. Jejunal biopsy specimens may show *G. lamblia* on the epithelial surface.

Management

Treatment is with a single dose of tinidazole 2 g, metronidazole 400 mg 3 times daily for 10 days, or nitazoxanide 500 mg orally twice daily for 3 days.

Cryptosporidiosis

Cryptosporidium spp. are coccidian protozoal parasites of humans and domestic animals. Infection is acquired by the faecal–oral route through contaminated water supplies. The incubation period is approximately 7–10 days and is followed by watery diarrhoea and abdominal cramps. The illness is usually self-limiting but in immunocompromised patients, especially those with HIV, the illness can be devastating, with persistent severe diarrhoea and substantial weight loss (p. 317).

Cyclosporiasis

Cyclospora cayetanensis is a globally distributed coccidian protozoal parasite of humans. Infection is acquired by ingestion

of contaminated water and recent food-borne outbreaks have been associated with raspberries and coriander (cilantro). The incubation period of approximately 2–11 days is followed by diarrhoea with abdominal cramps, which may remit and relapse. Although usually self-limiting, the illness may last as long as 6 weeks, with significant weight loss and malabsorption, and is more severe in immunocompromised individuals. Diagnosis is by detection of oöcysts on faecal microscopy or PCR of stool. Treatment may be necessary in a few cases, using co-trimoxazole 960 mg twice daily for 7 days.

Infections caused by helminths

Helminths (from the Greek *helmins*, meaning worm) include three groups of parasitic worm (Box 11.58), large multicellular organisms with complex tissues and organs.

Intestinal human nematodes

Adult nematodes living in the human gut can cause disease. There are two types:

- the hookworms, which have a soil stage in which they develop into larvae that then penetrate the host
- a group of nematodes that survive in the soil merely as eggs, which have to be ingested for their life cycle to continue.

The geographical distribution of hookworms is limited by the larval requirement for warmth and humidity. Soil-transmitted nematode infections can be prevented by avoidance of faecal soil contamination (adequate sewerage disposal) or skin contact (wearing shoes), and by strict personal hygiene.

Ancylostomiasis (hookworm)

Ancylostomiasis is caused by *Ancylostoma duodenale* or *Necator americanus.* The complex life cycle is shown in Figure 11.47. The adult hookworm is 1 cm long and lives in the duodenum and upper jejunum. Eggs are passed in the faeces. In warm, moist, shady soil, the larvae develop into rhabditiform and then the infective filariform stages; they then penetrate human skin and are carried to the lungs. After entering the alveoli, they ascend the bronchi, are swallowed and mature in the small intestine, reaching maturity 4–7 weeks after infection. The worms attach to the mucosa of the small intestine by their buccal capsule (Fig. 11.48) and withdraw blood. The mean daily blood loss from one *A. duodenale* is 0.15 mL and that from *N. americanus* 0.03 mL.

Hookworm infection is a leading cause of anaemia in the tropics and subtropics. *A. duodenale* is endemic in the Far East and Mediterranean coastal regions, and is also present in Africa, while *N. americanus* is endemic in West, East and Central Africa, and Central and South America, as well as in the Far East.

i 11.58 Classes of helminth that parasitise humans

Nematodes or roundworms

- Intestinal human nematodes: *Ancylostoma duodenale*, *Necator americanus*, *Strongyloides stercoralis*, *Ascaris lumbricoides*, *Enterobius vermicularis*, *Trichuris trichiura*
- Tissue-dwelling human nematodes: *Wuchereria bancrofti*, *Brugia malayi*, *Loa loa*, *Onchocerca volvulus*, *Dracunculus medinensis*, *Mansonella perstans*, *Dirofilaria immitis*
- Zoonotic nematodes: *Trichinella spiralis*

Trematodes or flukes

- Blood flukes: *Schistosoma haematobium*, *S. mansoni*, *S. japonicum*, *S. mekongi*, *S. intercalatum*
- Lung flukes: *Paragonimus* spp.
- Hepatobiliary flukes: *Clonorchis sinensis*, *Fasciola hepatica*, *Opisthorchis felineus*
- Intestinal flukes: *Fasciolopsis buski*

Cestodes or tapeworms

- Intestinal tapeworms: *Taenia saginata*, *T. solium*, *Diphyllobothrium latum*, *Hymenolepis nana*
- Tissue-dwelling cysts or worms: *Taenia solium*, *Echinococcus granulosus*

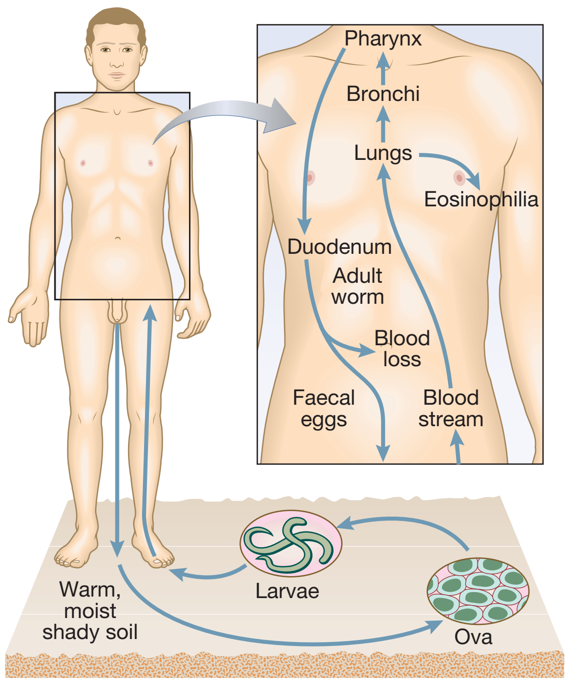

Fig. 11.47 Ancylostomiasis. Life cycle of *Ancylostoma.*

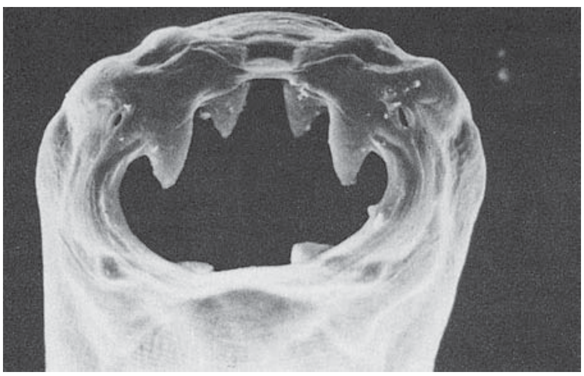

Fig. 11.48 *Ancylostoma duodenale.* Electron micrograph showing the ventral teeth. *From Gibbons LM. SEM guide to the morphology of nematode parasites of vertebrates. Farnham Royal, Slough: Commonwealth Agricultural Bureau International; 1986.*

Clinical features

An allergic dermatitis, usually on the feet (ground itch), may be experienced at the time of infection. The passage of the larvae through the lungs in a heavy infection causes a paroxysmal cough with blood-stained sputum, associated with patchy pulmonary consolidation and eosinophilia. When the worms reach the small intestine, vomiting and epigastric pain resembling peptic ulcer disease may occur. Sometimes, frequent loose stools are passed. The degree of iron and protein deficiency depends not only on the worm burden but also on patient nutrition and iron stores. Anaemia with high-output cardiac failure may result. The mental and physical development of children may be delayed in severe infection.

Investigations

There is eosinophilia. The characteristic ovum can be recognised in the stool. If hookworms are present in numbers sufficient to cause anaemia, faecal occult blood testing will be positive.

Management

A single dose of albendazole (400 mg) is the treatment of choice. Alternatively, mebendazole 100 mg twice daily for 3 days may be used. Anaemia and heart failure associated with hookworm infection respond well to oral iron, even when severe; blood transfusion is rarely required.

Strongyloidiasis (threadworm)

Strongyloides stercoralis is a small nematode (2 mm×0.4 mm) that parasitises the mucosa of the upper part of the small intestine, often in large numbers, causing persistent eosinophilia. The eggs hatch in the bowel but only larvae are passed in the faeces. In moist soil, they moult and become the infective filariform larvae. After penetrating human skin, they undergo a development cycle similar to that of hookworms, except that the female worms burrow into the intestinal mucosa and submucosa. Some larvae in the intestine may develop into filariform larvae, which may then penetrate the mucosa or the perianal skin and lead to autoinfection and persistent infection. Patients with *Strongyloides* infection persisting for more than 35 years have been described. Strongyloidiasis occurs in the tropics and subtropics, and is especially prevalent in the Far East.

Clinical features

These are shown in Box 11.59. The classic triad of symptoms consists of abdominal pain, diarrhoea and urticaria. Cutaneous manifestations, either urticaria or larva currens (a highly characteristic pruritic, elevated, erythematous lesion, rapidly advancing along the course of larval migration), are characteristic and occur in 66% of patients.

Systemic strongyloidiasis (the *Strongyloides* hyperinfection syndrome), with dissemination of larvae throughout the body, occurs with immune suppression (HIV or HTLV-1 infection, immunosuppressant treatment). Patients present with severe, generalised abdominal pain, abdominal distension and shock. Massive larval invasion of the lungs causes cough, wheeze and dyspnoea; cerebral involvement has manifestations ranging from subtle neurological signs to coma. Gram-negative sepsis frequently complicates the picture.

i 11.59 Clinical features of strongyloidiasis

Penetration of skin by infective larvae
• Itchy rash
Presence of worms in gut
• Abdominal pain, diarrhoea, steatorrhoea, weight loss
Allergic phenomena
• Urticarial plaques and papules, wheezing, arthralgia
Autoinfection
• Transient itchy, linear, urticarial weals across abdomen and buttocks (larva currens)
Systemic (super-)infection
• Diarrhoea, pneumonia, meningoencephalitis, death

Investigations

There is eosinophilia. Serology (ELISA) is helpful but definitive diagnosis depends on finding the larvae. The faeces should be examined microscopically for motile larvae; excretion is intermittent and so repeated examinations are necessary. Larvae may be found in jejunal aspirates or detected using the string test (p. 287). Larvae may also be cultured from faeces.

Management

A course of two doses of ivermectin (200 μg/kg), administered on successive days, is effective. Alternatively, albendazole is given orally (15 mg/kg twice daily for 3 days). A second course may be required. For the *Strongyloides* hyperinfection syndrome, ivermectin is given at 200 μg/kg for 5–7 days.

Ascaris lumbricoides (roundworm)

This pale yellow nematode is 20–35 cm long. Humans are infected by eating food contaminated with mature ova. *Ascaris* larvae hatch in the duodenum, migrate through the lungs, ascend the bronchial tree, are swallowed and mature in the small intestine. This tissue migration can provoke both local and general hypersensitivity reactions, with pneumonitis, eosinophilic granulomas, wheezing and urticaria.

Clinical features

Intestinal ascariasis causes symptoms ranging from vague abdominal pain to malnutrition. The large size of the adult worm and its tendency to aggregate and migrate cause obstructive complications. Tropical and subtropical areas are endemic for ascariasis, and here it causes up to 35% of all intestinal obstructions, most commonly in the terminal ileum. Obstruction can be complicated further by intussusception, volvulus, haemorrhagic infarction and perforation. Other complications include blockage of the bile or pancreatic duct and obstruction of the appendix by adult worms. Ascariasis in non-endemic areas has been associated with pig husbandry and may be caused by *Ascaris suum*, which is indistinguishable from (and possibly the same species as) *Ascaris lumbricoides*.

Investigations

The diagnosis is made microscopically by finding ova in the faeces. Adult worms are frequently expelled rectally or orally. Occasionally, the worms are demonstrated radiographically by a barium examination. There is eosinophilia.

Management

A single dose of albendazole (400 mg), pyrantel pamoate (11 mg/kg; maximum 1 g), or ivermectin (150–200 μg/kg), or alternatively mebendazole (100 mg twice daily for 3 days)

11

treats intestinal ascariasis. Patients should be warned that they might expel numerous whole, large worms. Obstruction due to ascariasis should be treated with nasogastric suction, piperazine and intravenous fluids. Complete intestinal obstruction and its complications require urgent surgical intervention.

Prevention

Community chemotherapy programmes reduce *Ascaris* infection. The whole community can be treated every 3 months for several years. Alternatively, schoolchildren are targeted; treating them lowers the prevalence of ascariasis in the community.

Enterobius vermicularis (threadworm)

This helminth is common worldwide and affects mainly children. After the ova are swallowed, development takes place in the small intestine but the adult worms are found chiefly in the colon.

Clinical features

The female lays ova around the anus, causing intense itching, especially at night. The ova are often carried to the mouth on the fingers and so reinfection or human-to-human infection occurs (Fig. 11.49). In females, the genitalia may be involved. The adult worms may be seen moving on the buttocks or in the stool.

Investigations

Ova are detected in stool samples or by applying the adhesive surface of cellophane tape to the perianal skin in the morning. This is then examined on a glass slide under the microscope. A perianal swab, moistened with saline, also allows diagnosis.

Management

A single dose of mebendazole (100 mg), albendazole (400 mg), pyrantel pamoate (11 mg/kg) or piperazine (4 g) treats infection and is repeated after 2 weeks to control auto-reinfection. If infection recurs in a family, each member should be treated. All nightclothes and bed linen are laundered during treatment. Fingernails must be kept short and hands washed carefully before meals. Subsequent therapy is reserved for family members with recurrent infection.

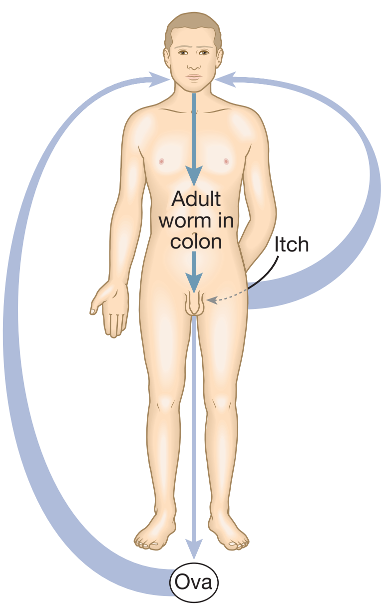

Fig. 11.49 Threadworm. Life cycle of *Enterobius vermicularis.*

Trichuris trichiura (whipworm)

Whipworm infections are common worldwide with poor hygiene. Infection follows ingestion of earth or food contaminated with ova, which have become infective after lying for 3 weeks or more in moist soil. The adult worm is 3–5 cm long and has a coiled anterior end resembling a whip. Whipworms inhabit the caecum, lower ileum, appendix, colon and anal canal. There are usually no symptoms, but intense infections in children may cause persistent diarrhoea or rectal prolapse, and growth retardation. The diagnosis is readily made by identifying ova in faeces. Treatment is with mebendazole in doses of 100 mg twice daily or albendazole 400 mg daily for 3 days for patients with light infections, and for 5–7 days for those with heavy infections.

Tissue-dwelling human nematodes

Filarial worms are tissue-dwelling nematodes. The larval stages are inoculated by biting mosquitoes or flies, each specific to a particular filarial species. The larvae develop into adult worms (2–50 cm long), which, after mating, produce millions of microfilariae (170–320 μm long) that migrate in blood or skin. The life cycle is completed when the vector takes up microfilariae by biting humans. In the insect, ingested microfilariae develop into infective larvae for inoculation in humans, normally the only host.

Disease is due to the host's immune response to the worms (both adult and microfilariae), particularly dying worms, and its pattern and severity vary with the site and stage of each species (Box 11.60). The worms are long-lived: microfilariae survive 2–3 years and adult worms 10–15 years. The infections are chronic and worst in individuals constantly reinfected.

Lymphatic filariasis

The filarial worms *Wuchereria bancrofti* and *Brugia malayi* infect approximately 120 million people globally and cause clinical outcomes ranging from subclinical infection to hydrocele and elephantiasis.

W. bancrofti is usually transmitted by night-biting culicine or anopheline mosquitoes (Fig. 11.50). The adult worms, 4–10 cm in length, live in the lymphatics, and the females produce microfilariae that circulate in large numbers in the peripheral blood, usually at night. The infection is widespread in tropical Africa, on the North African coast, in coastal areas of Asia, Indonesia and northern Australia, the South Pacific islands, the West Indies and also in North and South America.

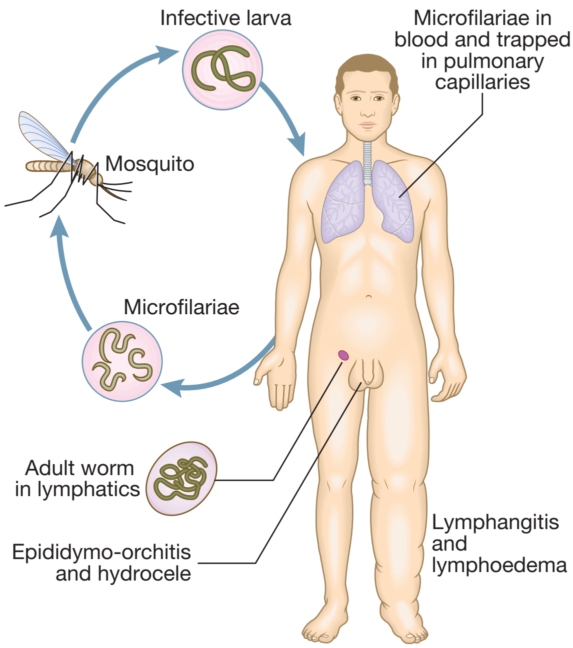

Fig. 11.50 ***Wuchereria bancrofti* and *Brugia malayi*.** Life cycle of organisms and pathogenesis of lymphatic filariasis.

B. malayi usually causes less severe disease than *W. bancrofti* and is transmitted by *Mansonia* or *Anopheles* mosquitoes in Indonesia, Borneo, Malaysia, Vietnam, South China, South India and Sri Lanka.

Pathology

Several factors contribute to the pathogenesis of lymphatic filariasis. Toxins released by adult worms cause lymphangiectasia; this dilatation of the lymphatic vessels leads to lymphatic dysfunction and the chronic clinical manifestations of lymphatic filariasis, lymphoedema and hydrocele. Death of the adult worm results in acute filarial lymphangitis. The filariae are symbiotically infected with rickettsia-like bacteria (*Wolbachia* spp.), and lipopolysaccharide released from *Wolbachia* triggers inflammation. Lymphatic obstruction persists after death of the adult worm. Secondary bacterial infections cause tissue destruction. The host response to microfilariae is central to the pathogenesis of tropical pulmonary eosinophilia.

Clinical features

Acute filarial lymphangitis presents with fever, pain, tenderness and erythema along the course of inflamed lymphatic vessels. Inflammation of the spermatic cord, epididymis and testis is common. Episodes last a few days but may recur several times a year. Temporary oedema becomes more persistent and regional lymph nodes enlarge. Progressive enlargement, coarsening, corrugation, fissuring and bacterial infection of the skin and subcutaneous tissue develop gradually, causing irreversible 'elephantiasis'. The scrotum may reach an enormous size. Chyluria and chylous effusions are milky and opalescent; on standing, fat globules rise to the top.

Acute lymphatic manifestations of filariasis must be differentiated from thrombophlebitis and infection. Oedema and lymphatic obstructive changes must be distinguished from congestive cardiac failure, malignancy, trauma and idiopathic abnormalities of the lymphatic system. Silicates absorbed from volcanic soil can also cause non-filarial elephantiasis.

Tropical pulmonary eosinophilia is a complication, seen mainly in India, due to microfilariae trapped in the pulmonary capillaries that are destroyed by allergic inflammation. Patients present with paroxysmal cough, wheeze and fever. If untreated, this may progress to debilitating chronic interstitial lung disease.

Investigations

In the earliest stages of lymphangitis, the diagnosis is made on clinical grounds, supported by eosinophilia and sometimes by positive filarial serology. Filarial infections cause the highest eosinophil counts of all helminthic infections.

Microfilariae can be found in the peripheral blood at night, and either are seen moving in a wet blood film or are detected by microfiltration of a sample of lysed blood. They are usually present in hydrocele fluid, which may occasionally yield an adult filaria. By the time elephantiasis develops, microfilariae become difficult to find. Calcified filariae may sometimes be demonstrable by radiography. Movement of adult worms can be seen on scrotal ultrasound. PCR-based tests for detection of *W. bancrofti* and *B. malayi* DNA from blood have been developed.

Indirect fluorescence and ELISA detect antibodies in over 95% of active cases and 70% of established elephantiasis. The test becomes negative 1–2 years after cure. Serological tests cannot distinguish the different filarial infections. Highly sensitive and specific, commercially available, immunochromatographic card tests detect circulating *W. bancrofti* antigen using fingerprick blood samples taken at any time of the day.

In tropical pulmonary eosinophilia, serology is strongly positive and IgE levels are massively elevated but circulating microfilariae are not found. The chest X-ray shows miliary changes or mottled opacities. Pulmonary function tests show a restrictive picture.

Management

Treatment is aimed at halting and reversing disease progression. Diethylcarbamazine (DEC, 2 mg/kg orally 3 times daily for 12 days, or 6 mg/kg as a single dose) kills microfilariae and adult worms. Most adverse effects seen with DEC treatment are due to the host response to dying microfilariae, which is directly proportional to the microfilarial load. The main symptoms are fever, headache, nausea, vomiting, arthralgia and prostration. These usually occur within 24–36 hours of the first dose of DEC. Antihistamines or glucocorticoids treat these allergic phenomena. Combining albendazole (400 mg) with ivermectin (200 μg/kg) in a single dose, with or without DEC (300 mg), is also highly effective in clearing the parasites. Treatment of *Wolbachia* with doxycycline (200 mg/day) for 4–8 weeks provides additional benefit by eliminating the bacteria; this leads to interruption of parasite embryogenesis. For tropical pulmonary eosinophilia, DEC for 14 days is the treatment of choice.

Chronic lymphatic pathology

Experience in India and Brazil shows that active management of chronic lymphatic pathology can alleviate symptoms. Patients should be taught meticulous skin care of their lymphoedematous limbs to prevent secondary bacterial and fungal infections. Tight bandaging, massage and bed rest with elevation of the affected limb help to control the lymphoedema. Prompt diagnosis and antibiotic therapy of bacterial cellulitis prevent further lymphatic damage and worsening of existing elephantiasis. Plastic surgery may be indicated in established elephantiasis. Relief can be obtained by removal of excess tissue but recurrences are probable

unless new lymphatic drainage is established. Hydroceles and chyluria can be repaired surgically.

Prevention

Treatment of the whole population in endemic areas with annual single-dose DEC (6 mg/kg), either alone or in combination with albendazole or ivermectin, can reduce filarial transmission. Mass treatment should be combined with mosquito control programmes.

Loiasis

Loiasis is caused by infection with the filaria *Loa loa.* The disease is endemic in forested and swampy parts of Western and Central Africa. The adult worms, 3–7 cm×4 mm, chiefly parasitise the subcutaneous tissue of humans, releasing larval microfilariae into the peripheral blood in the daytime. The vector is *Chrysops*, a forest-dwelling, day-biting fly.

The host response to *Loa loa* is usually absent or mild, so that the infection may be harmless. From time to time a short-lived, inflammatory, oedematous swelling (a Calabar swelling) is produced around an adult worm. Heavy infections, especially when treated, may cause encephalitis.

Clinical features

The infection is often symptomless. The incubation period is commonly over a year but may be just 3 months. The first sign is usually a Calabar swelling: an irritating, tense, localised swelling that may be painful, especially if it is near a joint. The swelling is generally on a limb; it measures a few centimetres in diameter but may be diffuse and extensive. It usually disappears after a few days but may persist for 2–3 weeks. Several swellings may appear at irregular intervals, often in adjacent sites. Sometimes, there is urticaria and pruritus elsewhere. Occasionally, a worm may be seen wriggling under the skin, especially that of an eyelid, and may cross the eye under the conjunctiva, taking many minutes to do so.

Investigations

Diagnosis is by demonstrating microfilariae in blood taken during the day, but they may not always be found in patients with Calabar swellings. Antifilarial antibodies are positive in 95% of patients and there is massive eosinophilia. Occasionally, a calcified worm may be seen on X-ray.

Management

DEC (see above) is curative, in a dose of 9–12 mg/kg daily, continued for 21 days. Treatment may precipitate a severe reaction in patients with a heavy microfilaraemia, characterised by fever, joint and muscle pain, and encephalitis; microfilaraemic patients should be given glucocorticoid cover.

Prevention

Building houses away from trees and having dwellings wire-screened reduce infections. Protective clothing and insect repellents are also useful. DEC in a dose of 5 mg/kg daily for 3 days each month is partially protective.

Onchocerciasis (river blindness)

Onchocerciasis results from infection by the filarial *Onchocerca volvulus*. The infection is conveyed by flies of the genus *Simulium*, which breed in rapidly flowing, well-aerated water. Adult flies inflict painful bites during the day, both inside and outside houses. While feeding, they pick up the microfilariae, which mature into the infective larva and are transmitted to a new host in subsequent bites. Humans are the only known hosts (Fig. 11.51).

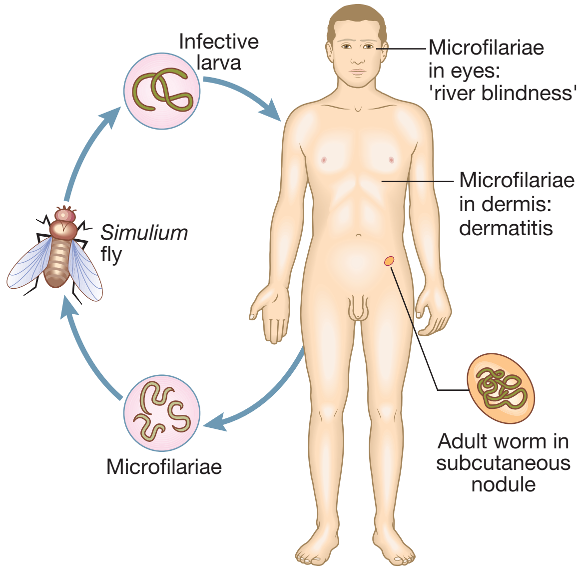

Fig. 11.51 ***Onchocerca volvulus.*** Life cycle of organism and pathogenesis of onchocerciasis.

Onchocerciasis is endemic in sub-Saharan Africa, Yemen and a few foci in Central and South America. It is estimated that 26 million people are infected, of whom 500 000 are visually impaired and 270 000 blind. Due to onchocerciasis, huge tracts of fertile land lie virtually untilled and individuals and communities are impoverished.

Pathology

After inoculation of larvae by a bite, the worms mature in 2–4 months and live for up to 17 years in subcutaneous and connective tissues. At sites of trauma, over bony prominences and around joints, fibrosis may form nodules around adult worms, which otherwise cause no direct damage. Innumerable microfilariae, discharged by the female *O. volvulus*, move actively in these nodules and in the adjacent tissues. The microfilariae are widely distributed in the skin and may invade the eye. Live microfilariae elicit little tissue reaction but dead ones may cause severe allergic inflammation, leading to hyaline necrosis and loss of collagen and elastin. Death of microfilariae in the eye causes inflammation and may lead to blindness.

Clinical features

The infection may remain symptomless for months or years. The first symptom is usually itching, localised to one quadrant of the body and later becoming generalised and involving the eyes. Transient oedema of part or all of a limb is an early sign, followed by papular urticaria spreading gradually from the site of infection. This is difficult to see on dark skins, in which the most common signs are papules excoriated by scratching, spotty hyperpigmentation from resolving inflammation, and chronic changes of a rough, thickened or inelastic, wrinkled skin. Both infected and uninfected superficial lymph nodes enlarge and may hang down in folds of loose skin in the groin. Hydrocele, femoral hernias and scrotal elephantiasis can occur. Firm subcutaneous nodules of more than 1 cm in diameter (onchocercomas) occur in chronic infection.

Eye disease is most common in highly endemic areas and is associated with chronic heavy infections and nodules on the head. Early manifestations include itching, lacrimation and conjunctival injection. These cause conjunctivitis; sclerosing keratitis with pannus formation; uveitis, which may lead to glaucoma and cataract; and, less commonly, choroiditis and optic neuritis. Classically, 'snowflake' deposits are seen in the edges of the cornea.

Investigations

The finding of nodules or characteristic lesions of the skin or eyes in a patient from an endemic area, associated with eosinophilia, is suggestive. Skin snips or shavings, taken with a corneoscleral punch or scalpel blade from calf, buttock and shoulder, are placed in saline under a cover slip on a microscope slide and examined after 4 hours. Microfilariae are seen wriggling free in all but the lightest infections. Slit-lamp examination may reveal microfilariae moving in the anterior chamber of the eye or trapped in the cornea. A nodule may be removed and incised, showing the coiled, thread-like adult worm.

Filarial antibodies are positive in up to 95% of patients. Rapid strip tests to detect antibody or antigen are under clinical evaluation. When there is a strong suspicion of onchocerciasis but tests are negative, a provocative Mazzotti test, in which administration of 0.5–1.0 mg/kg of DEC exacerbates pruritus or dermatitis, strongly suggests onchocerciasis.

Management

Ivermectin is recommended, in a single dose of 100–200 μg/kg, repeated several times at 3-monthly intervals to prevent relapses. It kills microfilariae and has minimal toxicity. In the rare event of a severe reaction causing oedema or postural hypotension, prednisolone 20–30 mg may be given daily for 2 or 3 days. Ivermectin has little macrofilaricidal effect so that, 1 year after ivermectin treatment, skin microfilarial densities regain at least 20% of pre-treatment levels; repeated treatments are required for the lifespan of the adult worm. Eradication of *Wolbachia* with doxycycline (100 mg daily for 6 weeks) prevents worm reproduction.

Prevention

Mass treatment with ivermectin reduces community morbidity and slows the progression of eye disease but it does not clear worm infection. *Simulium* can be destroyed in its larval stage by the application of insecticide to streams. Long trousers, skirts and sleeves discourage the fly from biting.

Dracunculiasis (Guinea worm)

Infestation with the Guinea worm *Dracunculus medinensis* manifests when the female worm, over a metre long, emerges from the skin. Humans are infected by ingesting a small crustacean, *Cyclops*, which inhabits wells and ponds, and contains the infective larval stage of the worm. The worm was widely distributed across Africa and the Middle East but successful global eradication programmes have limited the infection to a few countries in sub-Saharan Africa. However, recent findings of dog dracunculiasis in Chad and Ethiopia pose a new threat to eradication efforts.

Management and prevention

Traditionally, the protruding worm is extracted by winding it out gently over several days on a matchstick. The worm must never be broken. Antibiotics for secondary infection and prophylaxis of tetanus are also required.

A global eradication campaign aims to provide clean drinking water and eradicate water fleas from drinking water by simple filtration of water through a plastic mesh filter and chemical treatment of water supplies.

Other filariases

Mansonella perstans

This filarial worm is transmitted by the midges *Culicoides austeni* and *C. grahami*. It is common throughout equatorial Africa, as far south as Zambia, and also in Trinidad and parts of northern and eastern South America.

M. perstans has never been proven to cause disease but it may be responsible for a persistent eosinophilia and occasional allergic manifestations. *M. perstans* is resistant to ivermectin and DEC, and the infection may persist for many years.

Dirofilaria immitis

This dog heartworm infects humans, causing skin and lung lesions. It is not uncommon in the USA, Japan and Australia.

11

Zoonotic nematodes

Trichinosis (trichinellosis)

Trichinella spiralis is a nematode that parasitises rats and pigs, and is transmitted to humans by ingestion of partially cooked infected pork, particularly sausage or ham, or occasionally by bear meat. Symptoms result from invasion of intestinal submucosa by ingested larvae, which develop into adult worms, and the secondary invasion of striated muscle by fresh larvae produced by these adult worms. Outbreaks have occurred in countries where pork is eaten.

Clinical features

The clinical features of trichinosis are determined by the larval numbers. A light infection with a few worms may be asymptomatic; a heavy infection causes nausea and diarrhoea 24–48 hours after the infected meal. A few days later, the symptoms associated with larval invasion predominate: there is fever and oedema of the face, eyelids and conjunctivae; invasion of the diaphragm may cause pain, cough and dyspnoea; and involvement of the muscles of the limbs, chest and mouth causes stiffness, pain and tenderness in affected muscles. Larval migration may cause acute myocarditis and encephalitis. Eosinophilia is observed after the second week. An intense infection may prove fatal but those who survive recover completely.

Investigations

Frequently, people who have eaten infected pork from a common source develop symptoms at about the same time. Biopsy from the deltoid or gastrocnemius muscle after the third week of symptoms may reveal encysted larvae. Serological tests are also helpful.

Management

Treatment is with albendazole (400 mg twice daily for 8–14 days) or mebendazole (200–400 mg three times daily for 3 days, followed by 400–500 mg three times daily for 10 days). Treatment commenced early in infection kills newly formed adult worms in the submucosa and reduces the number of larvae reaching the

muscles. Glucocorticoids are necessary to control the serious effects of acute inflammation.

Anisakiasis (herring worm)

This infection is caused by the larvae of a fish nematode (*Anisakis simplex* or *Pseudoterranova decipiens*) and is associated with consumption of under-cooked fish or squid. The parasite cannot complete its life cycle in humans but larval ingestion is associated with pharyngeal tingling, abdominal pain, diarrhoea and vomiting. Diagnosis is made by identification of the larva by patients or endoscopists, and albendazole (400 mg twice a day for 5 days) can be used in treatment if larvae are not removed.

Cutaneous larva migrans

Cutaneous larva migrans (CLM) is the most common linear lesion seen in travellers (Fig. 11.52). Intensely pruritic, linear, serpiginous lesions result from the larval migration of the dog hookworm (*Ancylostoma caninum*). The track moves across the skin at a rate of 2–3 cm/day. This contrasts with the fast-moving transient rash of *Strongyloides* (p. 289). Although the larvae of dog hookworms frequently infect humans, they do not usually develop into the adult form. The most common site for CLM is the foot but elbows, breasts and buttocks may be affected. Most patients with CLM have recently visited a beach where the affected part was exposed. The diagnosis is clinical. Treatment may be local with 12-hourly application of 15% thiabendazole cream, or systemic with a single dose of albendazole (400 mg) or ivermectin (150–200 μg/kg).

Angiostrongylus cantonensis

The rat lungworm infects humans in Asia and the Pacific basin, via infected snails or contaminated water. It causes eosinophilic meningitis. The role of combination therapy with glucocorticoids and albendazole remains controversial.

Fig. 11.52 Cutaneous larva migrans. *Courtesy of Dr Ravi Gowda, Royal Hallamshire Hospital, Sheffield.*

Gnathostomiasis

Gnathostomiasis is a nematode infection that occurs predominantly in South-east Asia and is due to *Gnathostoma spinigerum.* It also occurs in other parts of Asia, Central and South America, and Africa. Humans are infected by the larvae from intermediate hosts (raw or under-cooked freshwater fish, shrimps and frogs) and are not definitive hosts, so the life cycle is incomplete. Pruritic, painful, migratory nodules appear 3–4 weeks after ingestion due to larval migration. Complications include cough, visual disturbance, eosinophilic meningitis or encephalitis. Serology confirms diagnosis and the preferred treatment is albendazole (400 mg twice daily) for 21 days, but its role in visual or neurological disease is uncertain as it may increase larval migration.

Trematodes (flukes)

These leaf-shaped worms are parasitic to humans and animals. Their complex life cycles may involve one or more intermediate hosts, often freshwater molluscs.

Schistosomiasis

Schistosomiasis is a major cause of morbidity in the tropics. The species commonly causing disease in humans are: *Schistosoma haematobium*, *S. mansoni*, *S. japonicum*, *S. mekongi* and *S. intercalatum. S. haematobium* is sometimes called bilharzia or bilharziasis. Schistosome eggs have been found in Egyptian mummies.

The life cycle is shown in Figure 11.53A. The ovum is passed in the urine or faeces of infected individuals and gains access to fresh water, where the ciliated miracidium inside it is liberated; it enters its intermediate host, a species of freshwater snail, and multiplies. Large numbers of fork-tailed cercariae are then liberated into the water, where they may survive for 2–3 days. Cercariae can penetrate the skin or the mucous membrane of the mouth of humans. They transform into schistosomulae and moult as they pass through the lungs; then they are carried by the blood stream to the liver, and so to the portal vein, where they mature. The male worm is up to 20 mm in length and the more slender cylindrical female, usually enfolded longitudinally by the male, is longer (Fig. 11.53B). Within 4–6 weeks of infection, they migrate to the venules draining the pelvic viscera, where the females deposit ova.

Pathology

Disease is usually due to passage of eggs through mucosa and to the granulomatous reaction to eggs deposited in tissues. The eggs of *S. haematobium* pass mainly through the bladder wall but may also involve the rectum, seminal vesicles, vagina, cervix and uterine tubes. *S. mansoni* and *S. japonicum* eggs pass mainly through the wall of the lower bowel or are carried to the liver. The most serious, although rare, site of ectopic egg deposition is the CNS. Granulomas are composed of macrophages, eosinophils, and epithelioid and giant cells around an ovum. Later, there is fibrosis and eggs calcify, which is often visible radiologically. Eggs of *S. haematobium* may leave the vesical plexus and be carried directly to the lung. Those of *S. mansoni* and *S. japonicum* may also reach the lungs after the development of portal hypertension and consequent portasystemic collateral circulation. Egg deposition in the pulmonary vasculature, and the resultant host response, can lead to pulmonary hypertension.

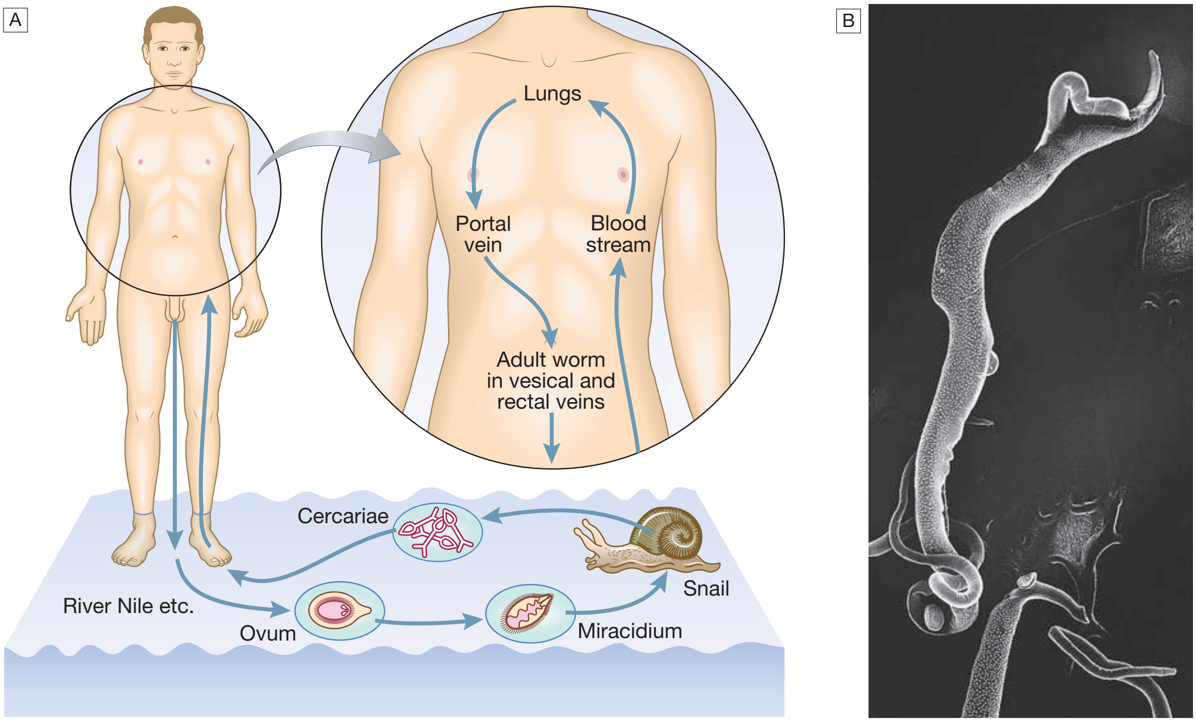

Fig. 11.53 ***Schistosoma.*** **A** Life cycle. **B** Scanning electron micrograph of adult schistosome worms, showing the larger male worm embracing the thinner female.

11

Clinical features

Recent travellers, especially those overlanding through Africa, may present with allergic manifestations and eosinophilia; residents of schistosomiasis-endemic areas are more likely to present with chronic urinary tract pathology or portal hypertension.

During the early stages of infection, there may be itching lasting 1–2 days at the site of cercarial penetration ('swimmer's itch'). After a symptom-free period of 3–5 weeks, acute schistosomiasis (Katayama syndrome) may present with allergic manifestations, such as urticaria, fever, muscle aches, abdominal pain, headaches, cough and sweating. On examination, hepatomegaly, splenomegaly, lymphadenopathy and pneumonia may be present. These allergic phenomena may be severe in infections with *S. mansoni* and *S. japonicum*, but are rare with *S. haematobium*. The features subside after 1–2 weeks.

Chronic schistosomiasis is due to egg deposition and occurs months to years after infection. The symptoms and signs depend on the intensity of infection and the species of infecting schistosome (Box 11.61).

Schistosoma haematobium

Humans are the only natural hosts of *S. haematobium*, which is highly endemic in Egypt and East Africa, and occurs throughout Africa and the Middle East (Fig. 11.54). Infection can be acquired after a brief exposure, such as swimming in freshwater lakes in Africa.

Painless terminal haematuria is usually the first and most common symptom. Frequency of micturition follows, due to bladder neck obstruction. Later, frequent urinary tract infections, bladder or ureteric stones, hydronephrosis, and ultimately renal failure with a contracted calcified bladder may occur. Pain is often felt in the iliac fossa or in the loin, and radiates to the groin. In several endemic areas, there is a strong epidemiological association of *S. haematobium* infection with squamous cell carcinoma of the bladder. Disease of the seminal vesicles may lead to haematospermia. Females may develop schistosomal papillomas of the vulva, and schistosomal lesions of the cervix may be mistaken for cancer. Intestinal symptoms may follow

involvement of the bowel wall. Ectopic worms cause skin or spinal cord lesions.

The severity of *S. haematobium* infection varies greatly and many with a light infection are asymptomatic. However, as adult worms can live for 20 years or more and lesions may progress, these patients should always be treated.

Schistosoma mansoni

S. mansoni is endemic throughout Africa, the Middle East, Venezuela, Brazil and the Caribbean (Fig. 11.54).

Characteristic symptoms begin 2 months or more after infection. They may be slight – no more than malaise – or consist of abdominal pain and frequent stools that contain blood-stained mucus. With severe advanced disease, increased discomfort from rectal polyps may be experienced. The early hepatomegaly is reversible but portal hypertension may cause massive splenomegaly, fatal haematemesis from oesophageal varices, or progressive ascites (p. 868). Liver function is initially preserved because the pathology is fibrotic rather than cirrhotic. *S. mansoni* and other schistosome infections predispose to the carriage of *Salmonella*, in part because *Salmonella* may attach to the schistosomes and in part because shared antigens on schistosomes may induce immunological tolerance to *Salmonella*.

Schistosoma japonicum, *S. mekongi* and *S. intercalatum*

In addition to humans, the adult worm of *S. japonicum* infects the dog, rat, field mouse, water buffalo, ox, cat, pig, horse and sheep. Although other *Schistosoma* spp. can infect species other than humans, the non-human reservoir seems to be particularly important only in transmission for *S. japonicum*. *S. japonicum* is prevalent in the Yellow River and Yangtze–Jiang basins in China, where the infection is a major public health problem. It also has a focal distribution in the Philippines, Indonesia and Thailand (Fig. 11.54). The related *S. mekongi* occurs in Laos, Thailand and Myanmar, and *S. intercalatum* in West and Central Africa.

The pathology of *S. japonicum* is similar to that of *S. mansoni*, but as this worm produces more eggs, the lesions tend to be more extensive and widespread. The clinical features resemble those of severe infection with *S. mansoni*, with added neurological features. The small and large bowel may be affected, and hepatic fibrosis with splenic enlargement is usual. Deposition of eggs or worms in the CNS, especially in the brain or spinal cord, causes symptoms in about 5% of infections, notably epilepsy, blindness, hemiplegia or paraplegia.

Investigations

There is marked eosinophilia. Serological tests (ELISA) are useful as screening tests but remain positive after treatment.

In *S. haematobium* infection, dipstick urine testing shows blood and albumin. The eggs can be found by microscopic examination of the centrifuged deposit of terminal stream urine (Fig. 11.55). Ultrasound assesses the urinary tract; bladder wall thickening, hydronephrosis and bladder calcification can be detected. Cystoscopy reveals 'sandy' patches, bleeding mucosa and later distortion.

In a heavy infection with *S. mansoni* or *S. japonicum*, the characteristic egg with its lateral spine can usually be found in the stool. When the infection is light or of long duration, a rectal biopsy can be examined. Sigmoidoscopy may show inflammation or bleeding. Biopsies should be examined for ova.

Management

The object of therapy is to kill the adult schistosomes and stop egg-laying. Praziquantel (20 mg/kg orally twice daily for 1 day) is the drug of choice for all forms of schistosomiasis except *S. japonicum* and *S. mekongi*, for which 60 mg/kg (20 mg for 3 doses) is recommended. The drug produces parasitological cure in 80% of treated individuals and over 90% reduction in egg counts in the remainder. Side-effects are uncommon but include nausea and abdominal pain. Praziquantel therapy in early infection reverses hepatomegaly, bladder wall thickening and granulomas.

Surgery may be required to deal with residual lesions such as ureteric stricture, small fibrotic urinary bladders, or granulomatous masses in the brain or spinal cord. Removal of rectal papillomas by diathermy or by other means may provide symptomatic relief.

Prevention

No single means of controlling schistosomiasis has been established to date. The life cycle is terminated if fresh water containing the snail host is not contaminated by ova-containing urine or faeces. The provision of latrines and of a safe water supply, however, remains a major problem in rural areas throughout the

Geographical distribution	Far East, especially South China	Far East, especially North-east Thailand	Cosmopolitan, including UK
Pathology	*Escherichia coli* cholangitis, abscesses, biliary carcinoma	As for *C. sinensis*	Toxaemia, cholangitis, eosinophilia
Symptoms	Often symptom-free, recurrent jaundice	As for *C. sinensis*	Unexplained fever, tender liver, may be ectopic, e.g. subcutaneous fluke
Diagnosis	Ova in stool or duodenal aspirate	As for *C. sinensis*	As for *C. sinensis*, also serology
Prevention	Cook fish	Cook fish	Avoid contaminated watercress
Treatment	Praziquantel 25 mg/kg 3 times daily for 2 days	As for *C. sinensis* but for 1 day only	Triclabendazole 10 mg/kg single dose; repeat treatment may be required*

*In the UK, available from the Hospital for Tropical Diseases, London.

tropics. Furthermore, *S. japonicum* has so many hosts besides humans that latrines would have little impact. Population mass treatment annually helps prevent *S. haematobium* and *S. mansoni* infection but so far has had little success with *S. japonicum*. Targeting the intermediate host, the snail, is problematic and has not, on its own, proved successful. For personal protection, contact with infected water must be avoided.

Liver flukes

Liver flukes infect at least 20 million people and remain an important public health problem in endemic areas. They are associated with abdominal pain, hepatomegaly and relapsing cholangitis. *Clonorchis sinensis* and *Opisthorchis felineus* are major aetiological agents of bile duct cancer. The three major liver flukes have similar life cycles and pathologies, as outlined in Box 11.62.

Other flukes of medical importance include lung and intestinal flukes (see Box 11.58).

Cestodes (tapeworms)

Cestodes are ribbon-shaped worms that inhabit the intestinal tract. They have no alimentary system and absorb nutrients through the tegumental surface. The anterior end, or scolex, has suckers for attaching to the host. From the scolex, a series of progressively developing segments arise, the proglottides, which may continue to show active movements when shed. Cross-fertilisation takes place between segments. Ova, present in large numbers in mature proglottides, remain viable for weeks, and during this period they may be consumed by the intermediate host. Larvae liberated from the ingested ova pass into the tissues of the intermediate host, forming larval cysticerci.

Tapeworms cause two distinct patterns of disease: either intestinal infection or systemic cysticercosis (Fig. 11.56). *Taenia saginata* (beef tapeworm), *Taenia asiatica* and *Diphyllobothrium latum* (fish tapeworm) cause only intestinal infection in humans, following ingestion of intermediate hosts. *Taenia solium* causes intestinal infection if a cysticerci-containing intermediate host

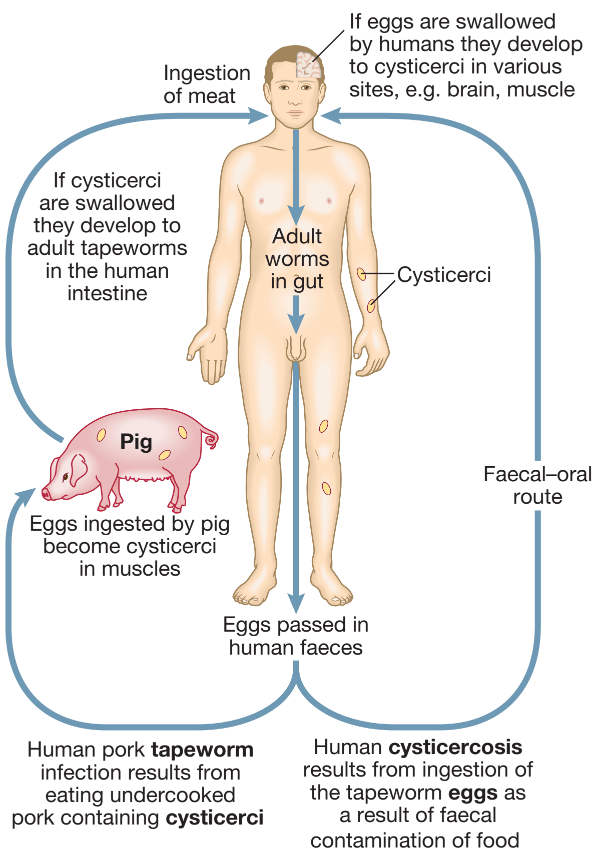

Fig. 11.56 Cysticercosis. Life cycle of *Taenia solium*.

is ingested, and cysticercosis (systemic infection from larval migration) if ova are ingested. *Echinococcus granulosus* (dog tapeworm) does not cause human intestinal infection, but causes hydatid disease (which is analogous to cysticercosis) following ingestion of ova and subsequent larval migration.

Intestinal tapeworm

Humans acquire tapeworm by eating under-cooked beef infected with the larval stage of *T. saginata*, under-cooked pork containing the larval stage of *T. solium* or *T. asiatica*, or under-cooked freshwater fish containing larvae of *D. latum*. Usually, only one adult tapeworm is present in the gut but up to 10 have been reported. The ova of all the three *Taenia* are indistinguishable microscopically. However, examination of scolex and proglottides can differentiate them: *T. solium* has a rostellum and two rows of hooklets on the scolex, and discharges multiple proglottides (3–5) attached together with lower degrees of uterine branching (approximately 10); *T. saginata* has only four suckers in its scolex, and discharges single proglottids with greater uterine branching (up to 30); *T. asiatica* has a rostellum without hooks on its scolex and is difficult to differentiate from *T. saginata*, except that there are fewer uterine branches (16–21).

Taenia solium

T. solium, the pork tapeworm, is common in central Europe, South Africa, South America and parts of Asia. It is not as large as *T. saginata*. The adult worm is found only in humans following the ingestion of pork containing cysticerci. Intestinal infection is treated with praziquantel (5–10 mg/kg) or niclosamide (2 g), both as a single dose, or alternatively with nitazoxanide (500 mg twice daily for 3 days). These are followed by a mild laxative (after 1–2 hours) to prevent retrograde intestinal autoinfection. Cooking pork well prevents intestinal infection. Great care must be taken while attending a patient harbouring an adult worm to avoid ingestion of ova or segments.

Taenia saginata

Infection with *T. saginata* occurs in all parts of the world. The adult worm may be several metres long and produces little or no intestinal upset in human beings, but identification of segments in the faeces or on underclothing may distress the patient. Ova may be found in the stool. Praziquantel is the drug of choice; niclosamide or nitazoxanide is an alternative. Prevention depends on efficient meat inspection and the thorough cooking of beef.

Taenia asiatica

T. asiatica is a newly recognised species of *Taenia*, restricted to Asia. It is acquired by eating uncooked meat or viscera of pigs. Clinical features and treatment are similar to those of *T. saginata*.

Cysticercosis

Human cysticercosis is acquired by ingesting *T. solium* tapeworm ova, from either contaminated fingers or food (Fig. 11.56). The larvae are liberated from eggs in the stomach, penetrate the intestinal mucosa and are carried to many parts of the body, where they develop and form cysticerci, 0.5–1 cm cysts that contain the head of a young worm. They do not grow further or migrate. Common locations are the subcutaneous tissue, skeletal muscles and brain (Fig. 11.57).

Clinical features

Superficial cysts can be palpated under the skin or mucosa as pea-like ovoid bodies, but cause few or no symptoms and will eventually die and become calcified.

Fig. 11.57 Neurocysticercosis. T2-weighted axial image of the brain showing multiple lesions of neurocysticercosis (large arrows show the largest lesions).

Heavy brain infections, especially in children, may cause features of encephalitis. More commonly, however, cerebral signs do not occur until the larvae die, 5–20 years later. Epilepsy, including new-onset focal seizures, personality changes, staggering gait and signs of hydrocephalus are the most common features.

Investigations

Calcified cysts in muscles can be recognised radiologically. In the brain, however, less calcification takes place and larvae are only occasionally visible by plain X-ray; CT or magnetic resonance imaging (MRI) will usually show them. Epileptic fits starting in adult life suggest the possibility of cysticercosis if the patient has lived in or travelled to an endemic area. The subcutaneous tissue should be palpated and any nodule excised for histology. Radiological examination of the skeletal muscles may be helpful. Antibody detection is available for serodiagnosis.

Management and prevention

Albendazole (15 mg/kg daily for a minimum of 8 days) has now become the drug of choice for parenchymal neurocysticercosis. Praziquantel (50 mg/kg in 3 divided doses daily for 10 days) is another option. Prednisolone (10 mg 3 times daily) is also given for 14 days, starting 1 day before the albendazole or praziquantel. In addition, antiepileptic drugs should be given until the reaction in the brain has subsided. Operative intervention is indicated for hydrocephalus. Studies from India and Peru suggest that most small, solitary cerebral cysts will resolve without treatment.

Echinococcus granulosus (*Taenia echinococcus*) and hydatid disease

Dogs are the definitive hosts of the tiny tapeworm *E. granulosus*. The larval stage, a hydatid cyst, normally occurs in sheep, cattle,

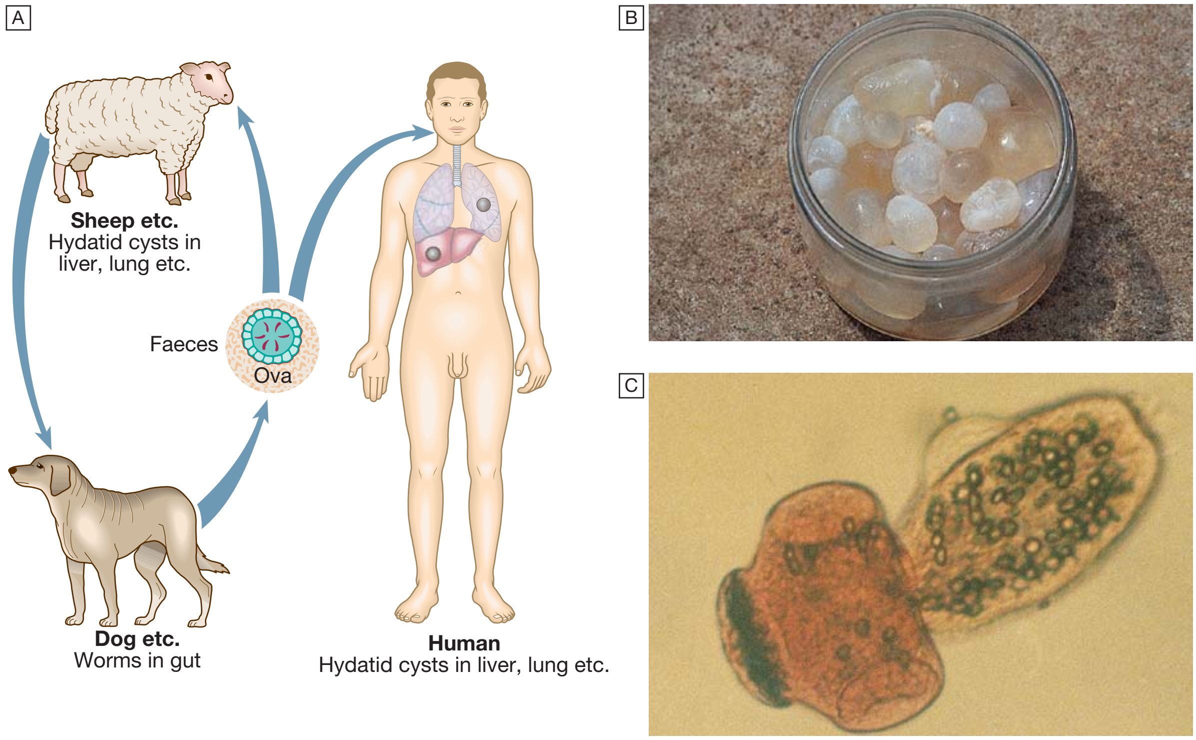

Fig. 11.58 Hydatid disease. A Life cycle of *Echinococcus granulosus*. B Daughter cysts removed at surgery. C Within the daughter cysts are the protoscolices.

camels and other animals that are infected from contaminated pastures or water. By handling a dog or drinking contaminated water, humans may ingest eggs (Fig. 11.58). The embryo is liberated from the ovum in the small intestine and invades the blood stream, spreading to the liver. The resultant cyst grows very slowly, sometimes intermittently. It is composed of an enveloping fibrous pericyst, laminated hyaline membrane (ectocyst) and inner germinal layers (endocyst) that give rise to daughter cysts, or a germinating cystic brood capsule in which larvae (protoscolices) develop. Over time, some cysts calcify and become non-viable. The disease is common in the Middle East, North and East Africa, Australia and Argentina. Foci of infection persist in the UK in rural Wales and Scotland. *E. multilocularis*, which has a cycle between foxes and voles, causes a similar but more severe infection, 'alveolar hydatid disease', which invades the liver like cancer.

Clinical features

A hydatid cyst is typically acquired in childhood and, after growing for years, may cause pressure symptoms. These vary, depending on the site involved. In nearly 75% of patients with hydatid disease, the right lobe of the liver is invaded and contains a single cyst. In others, a cyst may be found in lung, bone, brain or elsewhere.

Investigations

The diagnosis depends on the clinical, radiological and ultrasound findings in a patient that has close contact with dogs in an endemic area. Complement fixation and ELISA are positive in 70–90% of patients.

Management and prevention

Hydatid cysts should be excised wherever possible. Great care is taken to avoid spillage and cavities are sterilised with 0.5% silver nitrate or 2.7% sodium chloride. Albendazole (400 mg twice daily for 3 months) should also be used and is often combined with PAIR (percutaneous puncture, aspiration, injection of scolicidal agent and re-aspiration). Praziquantel (20 mg/kg twice daily for 14 days) also kills protoscolices perioperatively.

Prevention is difficult when there is a close association with dogs. Personal hygiene, satisfactory disposal of carcasses, meat inspection and deworming of dogs reduces the prevalence of disease.

Other tapeworms

Other cestodes' adult or larval stages may infect humans. Sparganosis is a condition in which an immature worm develops in humans, usually subcutaneously, as a result of eating or applying to the skin the secondary or tertiary intermediate host, such as frogs or snakes.

Ectoparasites

Ectoparasites only interact with the outermost surfaces of the host; see also page 1241.

Jiggers (tungiasis)

This is widespread in tropical America and Africa, and is caused by the sand flea *Tunga penetrans*. The pregnant flea burrows into the skin around toes and produces large numbers of eggs.

The burrows are intensely irritating and the whole inflammatory nodule should be removed with a sterile needle. Secondary infection of lesions is common.

Myiasis

Myiasis is due to skin infestation with larvae of the South American botfly, *Dermatobia hominis*, or the African tumbu fly, *Cordylobia anthropophaga*. The larvae develop in a subcutaneous space with a central sinus. This orifice is the air source for the larvae, and periodically the larval respiratory spiracles protrude through the sinus. Patients with myiasis feel movement within the larval burrow and can experience intermittent sharp, lancinating pains. Myiasis is diagnosed clinically and should be suspected with any furuncular lesion accompanied by pain and a crawling sensation in the skin. The larva may be suffocated by blocking the respiratory orifice with petroleum jelly and gently removing it with tweezers. Secondary infection of myiasis is rare and rapid healing follows removal of intact larvae.

Fungal infections

Fungal infections, or mycoses, are classified as superficial, subcutaneous or systemic (deep), depending on the degree of tissue invasion. They are caused by filamentous fungi (moulds), by yeasts or by fungi that vary between these two forms, depending on environmental conditions (dimorphic fungi; Fig. 11.59).

Superficial mycoses

Superficial cutaneous fungal infections caused by dermatophyte fungi are described in Chapter 29.

Candidiasis (thrush)

Superficial candidiasis is caused by *Candida* spp., mainly *C. albicans.* Manifestations include oropharyngeal (pp. 790 and 1240) and vaginal candidiasis ('thrush'), intertrigo and chronic paronychia. Superficial candidiasis often follows antibiotic therapy. Intertrigo is characterised by inflammation in skin folds with surrounding 'satellite lesions'. Chronic paronychia is associated with frequent wetting of the hands. Superficial candidiasis is treated mainly with topical azoles (p. 126), oral azoles being reserved for refractory or recurrent disease. Severe oropharyngeal and oesophageal candidiasis is a consequence of $CD4^+$ T-lymphocyte depletion/dysfunction, as in HIV infection (p. 316). Recurrent vaginal or penile candidiasis may be a manifestation of diabetes mellitus. Rarely, mutations in the autoimmune regulator gene (*AIRE*) or signal transducer and activator of transcription 1 (*STAT1*) cause a syndrome of chronic mucocutaneous candidiasis (p. 689). This is characterised by *Candida* infections of skin, mucosa and nails, with hyperkeratotic nails and erythematous periungual skin. Patients have cell-mediated immune defects against *Candida* and may have polyendocrinopathy and autoimmune features.

Subcutaneous mycoses

Chromoblastomycosis

Chromoblastomycosis is a predominantly tropical or subtropical disease caused by environmental dematiaceous (dark-pigmented) fungi, most commonly *Fonsecaea pedrosoi.* Other causes include *F. compacta, Cladophialophora carrionii* and *Phialophora verrucosa.* The disease is a cutaneous/subcutaneous mycosis acquired by traumatic inoculation. Commonly affected areas

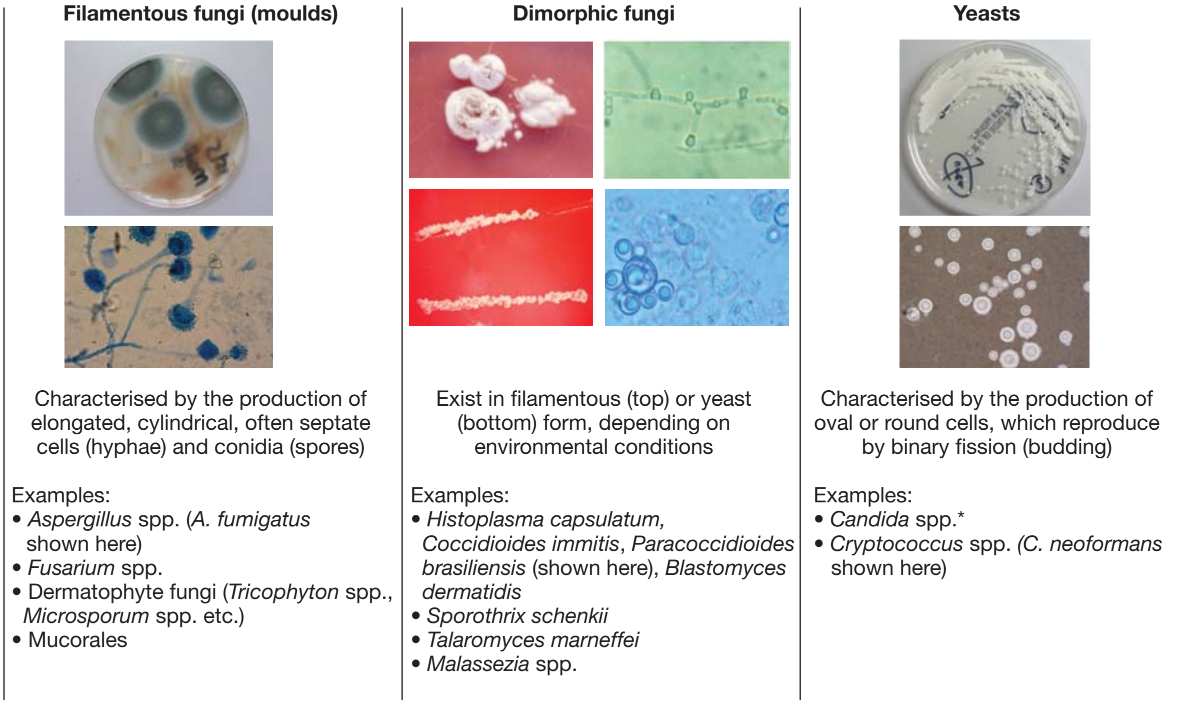

Fig. 11.59 Classification of medically important fungi. Fungal classification is based on simple morphological characteristics. *Pneumocystis jirovecii* is morphologically distinct from other fungi and does not fit into this classification. *Although *Candida albicans* exists in a number of forms, including filamentous (hyphae and pseudohyphae), it is generally encountered in its yeast form so is classified in this category. *Insets (dimorphic fungi) Courtesy of Beatriz Gomez and Angela Restrepo, CIB, Medellín, Colombia.*

include the foot, ankle and lower leg. Lesions may start several months after the initial injury, and medical attention is often sought several years later. The initial lesion is a papule. Further papules develop and coalesce to form irregular plaques. Nodular lesions may produce a characteristic 'cauliflower' appearance.

Diagnosis is by histopathological examination of infected material, which shows dematiaceous, rounded, thick-walled 'sclerotic bodies' with septa at right angles to each other. The aetiological agent is confirmed by culture. Therapeutic approaches include antifungal agents, cryosurgery and surgical excision, alone or in combination, but the optimal therapy is unknown. Itraconazole and terbinafine are the most effective antifungal agents. However, posaconazole has also been used with a good outcome.

Mycetoma (eumycetoma and actinomycetoma)

Mycetoma is a chronic suppurative infection of the deep soft tissues and bones, most commonly of the limbs but also of the abdominal or chest wall or head. It is caused by either filamentous fungi, Eumyces (eumycetoma – 40%) or aerobic Actinomycetes (actinomycetoma – 60%). Many fungi cause eumycetomas, the most common being *Madurella mycetomatis*, *M. grisea*, *Leptosphaeria senegalensis* and *Scedosporium apiospermum*; causes of actinomycetoma include *Nocardia, Streptomyces* and *Actinomadura* spp. Both groups produce characteristically coloured 'grains' (microcolonies), the colour depending on the organism (black grains – eumycetoma, red and yellow grains – actinomycetoma, white grains – either). The disease occurs mostly in the tropics and subtropics.

Clinical features

The disease is acquired by inoculation (e.g. from a thorn) and most commonly affects the foot (Madura foot). Mycetoma begins as a painless swelling at the implantation site, which becomes chronic and progressive, grows and spreads steadily within the soft tissues, eventually extending into bone. Nodules develop under the epidermis and these rupture, revealing sinuses through which grains may be discharged. Sinuses heal with scarring, while fresh sinuses appear elsewhere. Deeper tissue invasion and bone involvement are less rapid and extensive in eumycetoma than actinomycetoma. There is little pain and usually no fever or lymphadenopathy, but there is progressive disability.

Investigations

Diagnosis of mycetoma involves identification of grains in pus, and/or histopathological examination of tissue. Culture is necessary for species identification and susceptibility testing. Serological tests are not available.

Management

Eumycetoma is usually treated with a combination of surgery and antifungal therapy. Antifungal susceptibility testing, if available, is recommended, although clinical outcome does not necessarily correspond to in vitro test results. Itraconazole and ketoconazole (both 200–400 mg/day) are used most commonly. Success has also been reported with terbinafine monotherapy, and refractory cases have responded to voriconazole or posaconazole. Amphotericin B is not usually effective. Therapy is continued for 6–12 months or longer. In extreme cases, amputation may be required. Actinomycetoma is treated with prolonged antibiotic combinations, most commonly streptomycin and dapsone. Dapsone is replaced by co-trimoxazole in intolerance or refractory disease. Success has also been reported wth co-trimoxazole plus amikacin, with rifampicin added in difficult cases and to prevent recurrence.

Phaeohyphomycosis

Phaeohyphomycoses are a heterogeneous group of fungal diseases caused by a large number (more than 70) of dematiaceous fungi. In phaeohyphomycosis, the tissue form of the fungus is predominantly mycelial (filamentous), as opposed to eumycetoma (grain) or chromoblastomycosis (sclerotic body). Disease may be superficial, subcutaneous or deep. The most serious manifestation is cerebral phaeohyphomycosis, which presents with a ring-enhancing, space-occupying cerebral lesion. Optimal therapy for this condition has not been established but usually consists of neurosurgical intervention and antifungal (usually triazole) therapy. Causative agents are *Cladophialophora bantiana*, *Fonsecaea* spp. and *Rhinocladiella mackenziei*, which occurs mainly in the Middle East and is usually fatal.

Sporotrichosis

Sporotrichosis is caused by *Sporothrix schenckii*, a dimorphic fungal saprophyte of plants in tropical and subtropical regions. Disease is caused by dermal inoculation of the fungus, usually from a thorn (occasionally from a cat scratch). In fixed cutaneous sporotrichosis, a subcutaneous nodule develops at the site of infection and subsequently ulcerates, with a purulent discharge. The disease may then spread along the cutaneous lymphatic channels, resulting in multiple cutaneous nodules that ulcerate and discharge (lymphocutaneous sporotrichosis). Rarer forms include cutaneous disease presenting with arthritis. Later, draining sinuses may form. Pulmonary sporotrichosis occurs as a result of inhalation of the conidia (spores) and causes chronic cavitary fibronodular disease with haemoptysis and constitutional symptoms. Disseminated disease may occur, especially in patients with HIV.

Investigations

Typical yeast forms detected on histology confirm diagnosis but are rarely seen; the fungus can also be cultured from biopsy specimen. A latex agglutination test detects *S. schenckii* antibodies in serum.

Management

Cutaneous and lymphocutaneous disease is treated with itraconazole (200–400 mg daily, prescribed as the oral solution, which has better bioavailability than the capsule formulation) for 3–6 months. Alternative agents include a saturated solution of potassium iodide (SSKI, given orally), initiated with 5 drops and increased to 40–50 drops 3 times daily, or terbinafine (500 mg twice daily). Localised hyperthermia may be used in pregnancy (to avoid azole use). Osteoarticular disease requires a longer course of therapy (at least 12 months). Severe or life-threatening disease is treated with amphotericin B (lipid formulation preferred).

Systemic mycoses

Aspergillosis

Aspergillosis is an opportunistic systemic mycosis, which affects the respiratory tract predominantly. It is described on page 596.

Candidiasis

Systemic candidiasis is an opportunistic mycosis caused by *Candida* spp. The most common cause is *C. albicans.* Other agents include *C. dubliniensis*, *C. glabrata*, *C. krusei*, *C. parapsilosis* and *C. tropicalis*. *Candida* species identification often predicts susceptibility to fluconazole: *C. krusei* is universally resistant, many *C. glabrata* isolates have reduced susceptibility or are resistant, and other species are mostly susceptible. Candidiasis is usually an endogenous disease that originates from oropharyngeal, genitourinary or skin colonisation, although nosocomial spread occurs. *C. auris* is an emerging species, which has a particular propensity for nosocomial transmission.

Syndromes of systemic candidiasis

Acute disseminated candidiasis

This usually presents as candidaemia (isolation of *Candida* spp. from the blood). The main predisposing factor is the presence of a central venous catheter. Other major factors include recent abdominal surgery, total parenteral nutrition (TPN), recent antimicrobial therapy and localised *Candida* colonisation. Up to 40% of cases will have ophthalmic involvement, with characteristic retinal 'cotton wool' exudates. As this is a sight-threatening condition, candidaemic patients should have a full ophthalmoscopy review. Skin lesions (non-tender pink/red nodules) may be seen. Although predominantly a disease of intensive care and surgical patients, acute disseminated candidiasis and/or *Candida* endophthalmitis is seen occasionally in injection drug-users, due to candidal contamination of citric acid or lemon juice used to dissolve heroin.

Chronic disseminated candidiasis (hepatosplenic candidiasis)

Persistent fever in a neutropenic patient, despite antibacterial therapy and neutrophil recovery, associated with the development of abdominal pain, raised alkaline phosphatase and multiple lesions in abdominal organs (e.g. liver, spleen and/or kidneys) on radiological imaging, suggests a diagnosis of hepatosplenic candidiasis. This represents a form of immune reconstitution syndrome (p. 104) in patients recovering from neutropenia and usually lasts for several months, despite appropriate therapy.

Other manifestations

Renal tract candidiasis, osteomyelitis, septic arthritis, peritonitis, meningitis and endocarditis are all well recognised and are usually sequelae of acute disseminated disease. Diagnosis and treatment of these conditions require specialist mycological advice.

Management

Blood cultures positive for *Candida* spp. must never be ignored. Acute disseminated candidiasis is treated with antifungal therapy, removal of any in-dwelling central venous catheter (whether known to be the source of infection or not) and removal of any documented source. Candidaemia should be treated initially with an echinocandin (p. 126), with subsequent adjustment (usually to intravenous or oral fluconazole) guided by clinical response, species identification and susceptibility testing. Treatment should continue for a minimum of 14 days. Alternative therapies include voriconazole and amphotericin B formulations.

Chronic disseminated candidiasis requires prolonged treatment over several months with fluconazole or other agents, depending on species and clinical response. The duration of the condition may be reduced by adjuvant therapy with systemic glucocorticoids.

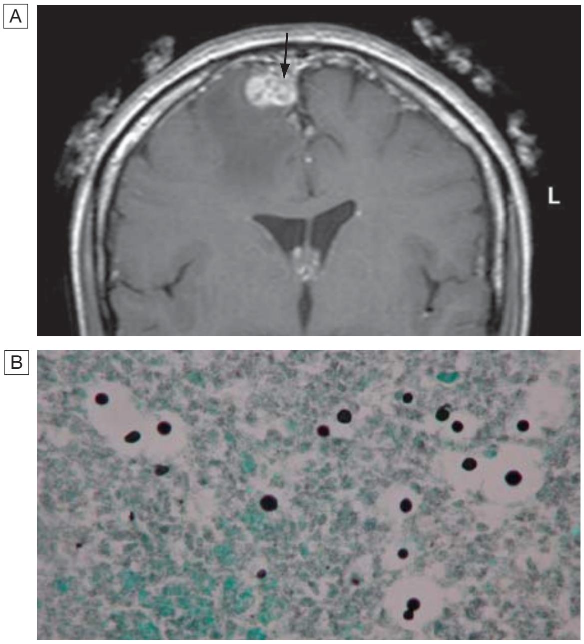

Fig. 11.60 Cryptococcal disease. A 23-year-old HIV-positive male developed headache and left-sided weakness. **A** MRI scan of the brain showed a space-occupying lesion (arrow) with surrounding oedema. **B** Histopathological examination of the lesion stained with Grocott's silver stain showed encapsulated yeasts. *Cryptococcus neoformans* was cultured.

Cryptococcosis

Cryptococcosis is a systemic mycosis caused by two environmental yeast species, *Cr. neoformans* and *Cr. gattii*. *Cr. neoformans* is distributed worldwide and is primarily an opportunistic pathogen, most commonly associated with HIV infection (p. 321). *Cr. gattii* is a primary pathogen with a widespread distribution that includes Australasia, Africa, Canada (Vancouver Island) and the north-western USA.

Cryptococcosis is acquired by inhalation of yeasts. These may disseminate to any organ, most commonly the CNS and skin. The manifestations of *Cr. neoformans* are most severe in immunocompromised individuals. Conversely, *Cr. gattii* causes severe disease in immunocompetent hosts. Disseminated cryptococcosis (sepsis with cryptococci present in the blood stream or at multiple sites) is largely restricted to immunocompromised patients. CNS manifestations of cryptococcosis include meningitis (p. 321) and cryptococcoma (Fig. 11.60), the latter more likely with *Cr. gattii* infection. Manifestations of pulmonary cryptococcosis range from severe pneumonia (in more immunocompromised patients) to asymptomatic disease with single or multiple pulmonary nodules, sometimes exhibiting cavitation (in patients with lesser immunosuppression). Cryptococcal nodules may mimic other causes of lung pathology, such as tuberculosis or malignancy, and diagnosis requires histopathology and/or culture.

Treatment of severe cryptococcosis is the same as for cryptococcal meningitis, initially with liposomal amphotericin B (p. 321). Mild pulmonary disease is usually treated with fluconazole, although for asymptomatic nodules resection of the lesions is likely to be sufficient.

Fusariosis

Fusarium spp. cause disseminated disease in patients with prolonged neutropenia. The disease presents with

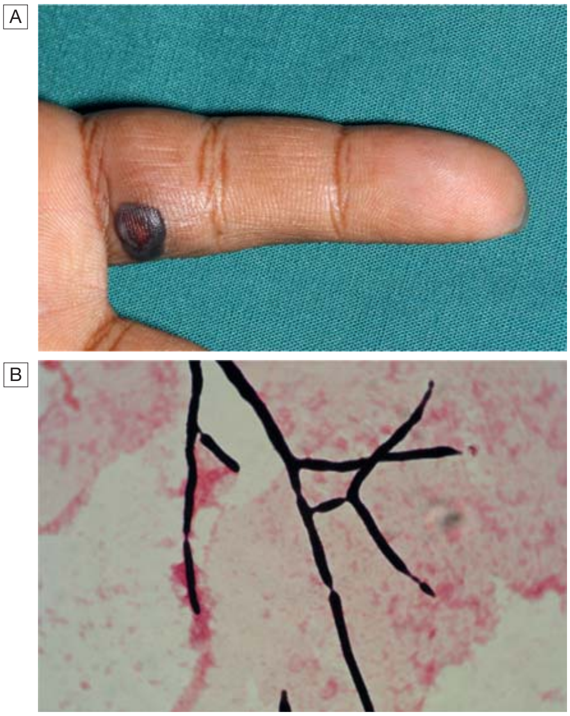

Fig. 11.61 ***Fusarium* infection.** A patient presented with fever and skin nodules after developing neutropenia secondary to haematopoietic stem cell transplantation and chemotherapy for relapsed leukaemia. *Fusarium solani* was cultured from skin lesions and blood cultures. **A** Tender, erythematous papules/nodules on upper arm. **B** Gram stain of *Fusarium* in blood culture medium.

antibiotic-resistant fever and evidence of dissemination (e.g. skin nodules, endophthalmitis, septic arthritis, pulmonary disease; Fig. 11.61). In contrast to *Aspergillus* spp., *Fusarium* spp. is often recovered from blood cultures. Treatment is challenging because of resistance to antifungal agents; voriconazole, posaconazole or lipid-formulated amphotericin B is most often prescribed.

Mucormycosis

Mucormycosis is a severe but uncommon opportunistic systemic mycosis caused by a number of 'mucoraceous' moulds, most commonly *Lichtheimia* (formerly *Absidia*) spp., *Rhizomucor* spp., *Mucor* spp. and *Rhizopus* spp. Disease patterns include rhinocerebral/craniofacial, pulmonary, cutaneous and systemic disease. All are characterised by the rapid development of severe tissue necrosis, which is almost always fatal if left untreated. The most common predisposing factors are profound immunosuppression from neutropenia and/or haematopoietic stem cell transplantation, uncontrolled diabetes mellitus, iron chelation therapy with desferrioxamine and severe burns.

Definitive diagnosis is by culture but histopathological confirmation is required, as the fungi may be environmental contaminants. Treatment requires a combination of antifungal therapy and surgical débridement, with correction of predisposing factor(s) if possible. High-dose lipid-formulated amphotericin B is most commonly used. Posaconazole is active against many mucoraceous moulds in vitro and may be used as a second-line agent or as oral 'step-down' therapy.

Talaromyces (formerly *Penicillium*) *marneffei* infection

T. marneffei is a thermally dimorphic pathogen (filamentous in environmental conditions and yeast at body temperature), which causes disease in South-east Asia, mainly in association with HIV infection (although immunocompetent patients may also be infected). Acquisition is usually by inhalation of environmental spores, with primary lung infection followed by haematogenous dissemination. A generalised papular rash, which progresses to widespread necrosis and ulceration, is a characteristic feature. Skin lesions may resemble molluscum contagiosum. Diagnosis is by histopathology and/or culture of respiratory secretions, blood or any infected clinical material (e.g. skin lesions, bone marrow, biopsies). Treatment involves an amphotericin B formulation followed by itraconazole (in severe infection), or itraconazole alone.

Histoplasmosis

11

Histoplasmosis is a primary systemic mycosis caused by the dimorphic fungus *Histoplasma capsulatum*. *H. capsulatum* var. *capsulatum* is endemic to east-central USA (especially the Mississippi and Ohio river valleys), parts of Canada, Latin America, the Caribbean, East and South-east Asia, and Africa. It occurs sporadically in Australia and India, and is very rare in Europe. *H. capsulatum* var. *duboisii* is found in West Africa and Madagascar.

The primary reservoir of *H. capsulatum* is soil enriched by bird and bat droppings, in which the fungus remains viable for many years. Infection is by inhalation of infected dust. Natural infections are found in bats, which represent a secondary reservoir of infection. Histoplasmosis is a specific hazard for explorers of caves and people who clear out bird (including chicken) roosts.

Pathology

The organism is inhaled in the form of conidia or hyphal fragments and transforms to the yeast phase during infection. Conidia or yeasts are phagocytosed by alveolar macrophages and neutrophils, and this may be followed by haematogenous dissemination to any organ. Subsequent development of a T-lymphocyte response brings the infection under control, resulting in a latent state in most exposed individuals.

Clinical features

Disease severity depends on the quantity of spores inhaled and the immune status of the host. In most cases, infection is asymptomatic. Pulmonary symptoms are the most common presentation, with fever, non-productive cough and an influenza-like illness. Erythema nodosum, myalgia and joint pain frequently occur, and chest radiography may reveal a pneumonitis with hilar or mediastinal lymphadenopathy.

Patients with pre-existing lung disease, such as chronic obstructive pulmonary disease (COPD) or emphysema, may develop chronic pulmonary histoplasmosis (CPH). The predominant features of this condition, which may easily be mistaken for tuberculosis, are fever, cough, dyspnoea, weight loss and night sweats. Radiological findings include fibrosis, nodules, cavitation and hilar/mediastinal lymphadenopathy.

Disease caused by *H. capsulatum* var. *duboisii* presents more commonly with papulonodular and ulcerating lesions of the skin and underlying subcutaneous tissue and bone (sometimes referred to as 'African histoplasmosis'). Multiple lesions of the ribs are common and the bones of the limbs may be affected. Lung involvement is relatively rare. Radiological examination may show rounded foci of bone destruction, sometimes associated

with abscess formation. Other disease patterns include a visceral form with liver and splenic invasion, and disseminated disease.

Acute disseminated histoplasmosis is seen with immunocompromise, including HIV infection. Features include fever, pancytopenia, hepatosplenomegaly, lymphadenopathy and often a papular skin eruption. Chronic disseminated disease presents with fever, anorexia and weight loss. Cutaneous and mucosal lesions, lymphadenopathy, hepatosplenomegaly and meningitis may develop. *Emergomyces africanus* (formerly *Emmonsia* sp.) is a dimorphic fungus recently described in South Africa, which causes a disseminated histoplasmosis-like illness, mainly associated with HIV infection. Histopathologically, yeast forms appear similar to histoplasmosis and can be distinguished only by PCR.

Investigations

Histoplasmosis should be suspected in endemic areas with every undiagnosed infection in which there are pulmonary signs, enlarged lymph nodes, hepatosplenomegaly or characteristic cutaneous/bony lesions. Radiological examination in long-standing cases may show calcified lesions in the lungs, spleen or other organs. In the more acute phases of the disease, single or multiple soft pulmonary shadows with enlarged tracheobronchial nodes are seen on chest X-ray.

Laboratory diagnosis is by direct detection (histopathology or antigen detection), culture and serology; although antigen detection is the most effective method, it is not widely available. Serology utilises complement fixation testing or immunodiffusion; interpretation is complex and requires a specialist. *Histoplasma* antigen may be detectable in blood or urine. Culture is definitive but slow (up to 12 weeks). Histopathology may show characteristic intracellular yeasts. Diagnosis of subcutaneous or bony infection is mainly by histopathological examination and/or culture.

Management

Mild pulmonary disease does not require treatment. However, if prolonged, it may be treated with itraconazole. More severe pulmonary disease is treated with an amphotericin B formulation for 2 weeks, followed by itraconazole for 12 weeks, with methylprednisolone added for the first 2 weeks of therapy if there is hypoxia or ARDS. CPH is treated with itraconazole oral solution for 12–24 months, and disseminated histoplasmosis with an amphotericin B formulation followed by itraconazole. Lipid formulations of amphotericin B are preferred but their use is subject to availability. In subcutaneous and bone infection, patterns of remission and relapse are more common than cure. A solitary bony lesion may require local surgical treatment only.

Coccidioidomycosis

This is a primary systemic mycosis caused by the dimorphic fungi *Coccidioides immitis* and *C. posadasii*, found in the south-western USA and Central and South America. The disease is acquired by inhalation of conidia (arthrospores). In 60% of cases it is asymptomatic but in the remainder it affects the lungs, lymph nodes and skin. Rarely (in approximately 0.5%), it may spread haematogenously to bones, adrenal glands, meninges and other organs, particularly in those with immunocompromise.

Pulmonary coccidioidomycosis has two forms: primary and progressive. If symptomatic, primary coccidioidomycosis presents with cough, fever, chest pain, dyspnoea and (commonly) arthritis and a rash (erythema multiforme). Progressive disease presents with systemic upset (e.g. fever, weight loss, anorexia) and features of lobar pneumonia, and may resemble tuberculosis.

Coccidioides meningitis (which may be associated with CSF eosinophils) is the most severe disease manifestation; it is fatal if untreated and requires life-long suppressive therapy with antifungal azoles.

Investigations and management

Diagnosis is by direct histopathological detection in specimens, culture of infected tissue or fluids, or antibody detection. IgM may be detected after 1–3 weeks of disease by precipitin tests. IgG appears later and is detected with the complement fixation test. Change in IgG titre may be used to monitor clinical progress.

Treatment depends on specific disease manifestations and ranges from regular clinical reassessment without antifungal therapy (in mild pulmonary, asymptomatic cavitary or single nodular disease) to high-dose treatment with an antifungal azole, which may be continued indefinitely (e.g. in meningitis). Amphotericin B is used in diffuse pneumonia, disseminated disease and, intrathecally, in meningitis. Posaconazole has been used successfully in refractory disease.

Paracoccidioidomycosis

This is a primary systemic mycosis caused by inhalation of the dimorphic fungus *Paracoccidioides brasiliensis*, which is restricted to South America. The disease affects the lungs, mucous membranes (painful destructive ulceration in 50% of cases), skin, lymph nodes and adrenal glands (hypoadrenalism). Diagnosis is by microscopy and culture of lesions, and antibody detection. Oral itraconazole solution (200 mg/day) has demonstrated 98% efficacy and is currently the treatment of choice (mean duration 6 months). Ketoconazole, fluconazole, voriconazole and 2–3-year courses of sulphonamides are alternatives. Amphotericin B is used in severe or refractory disease, followed by an azole or sulphonamide.

Blastomycosis

Blastomyces dermatitidis is a dimorphic fungus endemic to restricted parts of North America, mainly around the Mississippi and Ohio rivers. Very occasionally, it is reported from Africa. The disease usually presents as a chronic pneumonia similar to pulmonary tuberculosis. Bones, skin and the genitourinary tract may also be affected. Diagnosis is by culture of the organism or identification of the characteristic yeast form in a clinical specimen. Antibody detection is rarely helpful. Treatment is with amphotericin B (severe disease) or itraconazole.

i HIV clinical staging classifications

<table>
<tr><th>World Health Organisation (WHO) clinical stage
(used in low- and middle-income countries)</th><th>Centers for Disease Control (CDC) clinical categories
(used in high-income countries)</th></tr>
<tr><td>Stage 1
Asymptomatic
Persistent generalised lymphadenopathy</td><td>Category A
Primary HIV infection
Asymptomatic
Persistent generalised lymphadenopathy</td></tr>
<tr><td>Stage 2
Unexplained moderate weight loss (<10% of body weight)
Recurrent upper respiratory tract infections
Herpes zoster
Angular cheilitis
Recurrent oral ulceration
Papular pruritic eruptions
Seborrhoeic dermatitis
Fungal nail infections</td><td rowspan="2">Category B
Bacillary angiomatosis
Candidiasis, oropharyngeal (thrush)
Candidiasis, vulvovaginal; persistent, frequent or poorly responsive to therapy
Cervical dysplasia (moderate or severe)/cervical carcinoma in situ
Constitutional symptoms, such as fever (38.5°C) or diarrhoea lasting >1 month
Oral hairy leucoplakia
Herpes zoster, involving two distinct episodes or more than one dermatome
Idiopathic thrombocytopenic purpura
Listeriosis
Pelvic inflammatory disease, particularly if complicated by tubo-ovarian abscess
Peripheral neuropathy</td></tr>
<tr><td>Stage 3
Unexplained severe weight loss (>10% of body weight)
Unexplained chronic diarrhoea for >1 month
Unexplained persistent fever (>37.5°C for >1 month)
Persistent oral candidiasis
Oral hairy leucoplakia
Pulmonary tuberculosis
Severe bacterial infections
Acute necrotising ulcerative stomatitis, gingivitis or periodontitis
Unexplained anaemia (<80 g/L (8 g/dL)), neutropenia (<0.5×10^9/L)
and/or chronic thrombocytopenia (<50×10^9/L)</td></tr>
<tr><td>Stage 4</td><td>Category C</td></tr>
<tr><td colspan="2">Candidiasis of oesophagus, trachea, bronchi or lungs

Epidemiology

The acquired immunodeficiency syndrome (AIDS) was first recognised in 1981, although the earliest documented case of HIV infection has been traced to a blood sample from the Democratic Republic of Congo in 1959. AIDS is caused by the human immunodeficiency virus (HIV), which progressively impairs cellular immunity. The origin of HIV is a zoonotic infection with simian immunodeficiency viruses (SIV) from African primates, probably first infecting local hunters. SIVs do not cause disease in their natural primate hosts. HIV-1 was transmitted from chimpanzees and HIV-2 from sooty mangabey monkeys. HIV-1 is the cause of the global HIV pandemic, while HIV-2, which causes a similar illness to HIV-1 but progresses more slowly and is less transmissible, is restricted mainly to western Africa. It has been estimated that both HIV-1 and HIV-2 first infected humans about 100 years ago. HIV-2 will not be discussed further in this chapter.

There are three groups of HIV-1, representing three separate transmission events from chimpanzees: M ('major', worldwide distribution), O ('outlier') and N ('non-major and non-outlier'). Groups O and N are restricted to West Africa. Group M consists of nine subtypes: A–D, F–H, J and K (subtypes E and I were subsequently shown to be recombinants of other subtypes). Globally, subtype C (which predominates in sub-Saharan Africa and India) accounts for half of infections and appears to be more readily transmitted. Subtype B predominates in Western Europe, the Americas and Australia. In Europe, the prevalence of non-B subtypes is increasing because of migration. Subtypes A and D are associated with slower and faster disease progression, respectively.

Global and regional epidemics

In 2015 it was estimated that there were 36.7 million people living with HIV/AIDS, 2.1 million new infections and 1.1 million AIDS-related deaths. The global epidemiology of HIV has been changed by expanding access to combination antiretroviral therapy (ART), which reached 17 million people in 2015: the annual number of AIDS-related deaths has almost halved since the peak in 2005, the number of new infections has decreased by 40% since the peak in 1997, and the number of people living with HIV has increased. Regions have marked differences in HIV prevalence, incidence and dominant modes of transmission (Box 12.1). HIV has had a devastating impact in sub-Saharan Africa, particularly in southern Africa, where average life expectancy of the general population fell to below 40 years before the introduction of ART.

Modes of transmission

HIV is transmitted by sexual contact, by exposure to blood (e.g. injection drug use, occupational exposure in health-care workers) and blood products, or to infants of HIV-infected mothers (who may be infected in utero, perinatally or via breastfeeding). Worldwide, the major route of transmission is heterosexual. The risk of contracting HIV after exposure to infected body fluid is dependent on the integrity of the exposed site, the type and volume of fluid, and the level of viraemia in the source person. The approximate transmission risk after exposure is given in Box 12.2. Factors that increase the risk of transmission are listed in Box 12.3.

A high proportion of patients with haemophilia in high-income countries had been infected through contaminated blood products by the time HIV antibody screening was adopted in 1985. Routine screening of blood and blood products for HIV infection has virtually eliminated this as a mode of transmission. However, the World Health Organisation (WHO) estimates that, because of the lack of adequate screening facilities in resource-poor countries, 5–10% of blood transfusions globally are with HIV-infected blood.

12.2 Risk of HIV transmission after single exposure to an HIV-infected source

HIV exposure	Approximate risk
Sexual	
Vaginal intercourse: female to male	0.05%
Vaginal intercourse: male to female	0.1%
Anal intercourse: insertive	0.05%
Anal intercourse: receptive	0.5%
Oral intercourse: insertive	0.005%
Oral intercourse: receptive	0.01%
Blood exposure	
Blood transfusion	90%
Intravenous drug-users sharing needles	0.67%
Percutaneous needlestick injury	0.3%
Mucous membrane splash	0.09%
Mother to child	
Vaginal delivery	15%
Breastfeeding (per month)	0.5%

12.1 Regional HIV prevalence in 2015, incidence trend and dominant mode of transmission

Region	People living with HIV (millions)	HIV incidence trend (2011–2015)	Dominant transmission
Sub-Saharan Africa	25.5	Decreasing	Heterosexual
Asia and Pacific	5.1	Stable	IDU, heterosexual
Latin America and Caribbean	2	Stable	MSM, heterosexual
Western and Central Europe, and North America	2.4	Stable	MSM
Eastern Europe and Central Asia	1.5	Increasing	IDU
Middle East and North Africa	0.23	Stable	IDU, MSM

(IDU = injection drug-users; MSM = men who have sex with men)

i 12.3 Factors increasing the risk of transmission of HIV

Common to all transmission categories	
• High viral load	
Sexual transmission	
• STIs, especially genital ulcers • Cervical ectopy • Rectal or vaginal lacerations • Menstruation • Uncircumcised male partner	• Receptive anal intercourse • Depot intramuscular progesterone contraceptive use
Injection drug use transmission	
• Sharing equipment • Linked commercial sex • Intravenous use	• Concomitant cocaine use • Incarceration
Occupational transmission	
• Deep injury • Visible blood on device	• Needle was in a blood vessel
Vertical transmission	
• Prolonged rupture of membranes	• Older gestational age
(STIs = sexually transmitted infections)	

Virology and immunology

HIV is an enveloped ribonucleic acid (RNA) retrovirus from the lentivirus family. After mucosal exposure, HIV is transported via dendritic cells to the lymph nodes, where infection becomes established. This is followed by viraemia and dissemination to lymphoid organs, which are the main sites of viral replication.

Each mature virion has a lipid membrane lined by a matrix protein that is studded with glycoprotein (gp) 120 and gp41 spikes. The inner cone-shaped protein core (p24) houses two copies of the single-stranded RNA genome and viral enzymes. The HIV genome consists of three characteristic retroviral genes – *gag* (encodes a polyprotein that is processed into structural proteins, including p24), *pol* (codes for the enzymes reverse transcriptase, integrase and protease) and *env* (codes for envelope proteins gp120 and gp41) – as well as six regulatory genes.

HIV infects cells bearing the CD4 receptor; these are T-helper lymphocytes, monocyte–macrophages, dendritic cells, and microglial cells in the central nervous system (CNS). Entry into the cell commences with binding of gp120 to the CD4 receptor (Fig. 12.1), which results in a conformational change in gp120 that permits binding to one of two chemokine co-receptors (CXCR4 or CCR5). The chemokine co-receptor CCR5 is utilised during initial infection, but later on the virus may adapt to use CXCR4. Individuals who are homozygous for the CCR5 delta

12

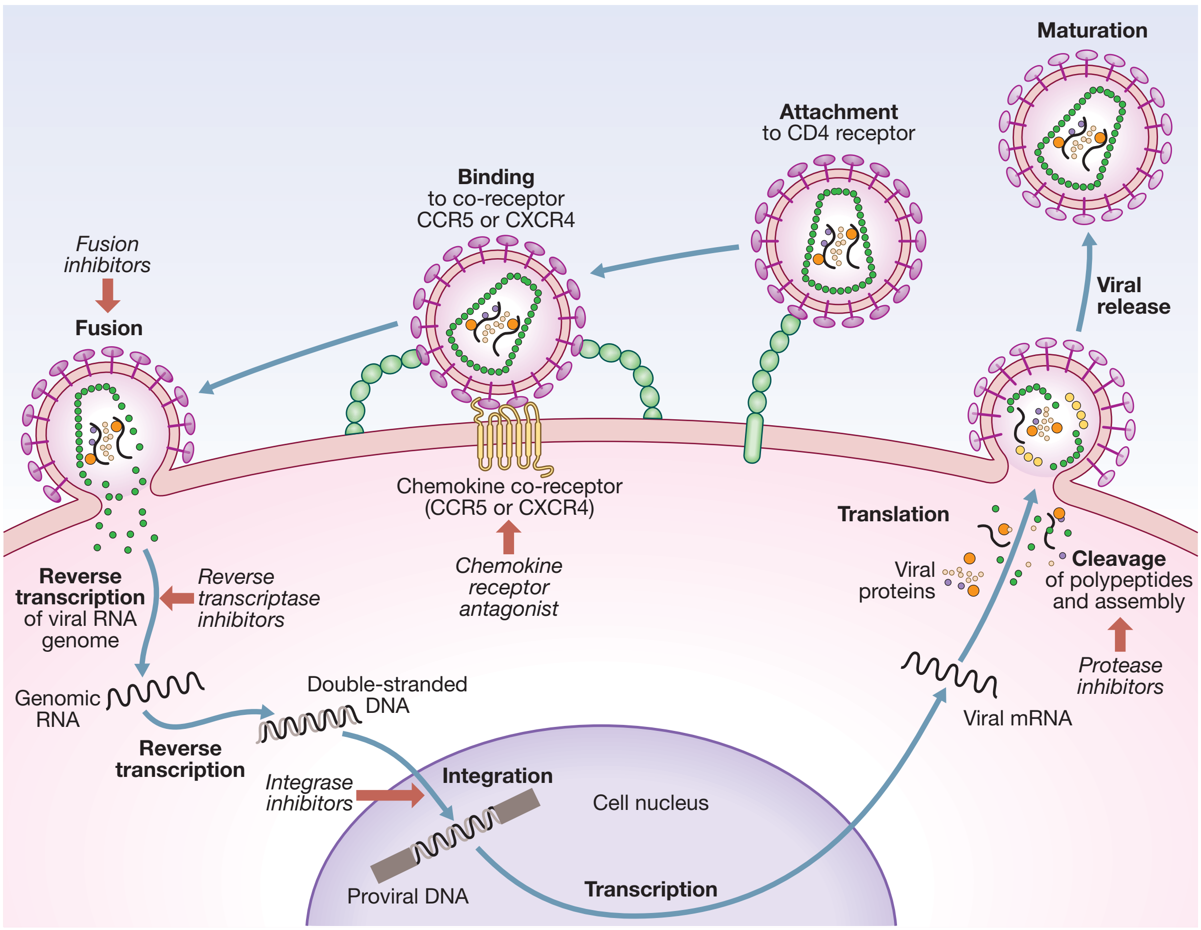

Fig. 12.1 Life cycle of HIV. Red arrows indicate sites of action of antiretroviral drugs.

32 mutation do not express CCR5 on CD4 cells and are immune to HIV infection. Chemokine co-receptor binding is followed by membrane fusion and cellular entry involving gp41. After penetrating the cell and uncoating, a deoxyribonucleic acid (DNA) copy is transcribed from the RNA genome by the reverse transcriptase enzyme, which is carried by the infecting virion. Reverse transcription is an error-prone process and multiple mutations arise with ongoing replication, which results in considerable viral genetic heterogeneity. Viral DNA is transported into the nucleus and integrated within the host cell genome by the integrase enzyme. Integrated virus is known as proviral DNA and persists for the life of the cell. Cells infected with proviral HIV DNA produce new virions only if they undergo cellular activation, resulting in the transcription of viral messenger RNA (mRNA) copies, which are then translated into viral peptide chains. The precursor polyproteins are then cleaved by the viral protease enzyme to form new viral structural proteins and enzymes that migrate to the cell surface and are assembled using the host cellular apparatus to produce infectious viral particles; these bud from the cell surface, incorporating the host cell membrane into the viral envelope. The mature virion then infects other CD4 cells and the process is repeated. CD4 lymphocytes that are replicating HIV have a very short survival time of about 1 day. It has been estimated that in asymptomatic HIV-infected people, more than 10^{10} virions are produced and 10^{9} CD4 lymphocytes destroyed each day. The CD4 lymphocytes are destroyed primarily by the host immune response rather than by cytopathic effects of HIV.

A small percentage of T-helper lymphocytes enter a post-integration latent phase. Latently infected cells are important as sanctuary sites from antiretroviral drugs, which act only on replicating virus. Current ART is unable to eradicate HIV infection due to the persistence of proviral DNA in long-lived latent CD4 cells.

The host immune response to HIV infection is both humoral, with the development of antibodies to a wide range of antigens, and cellular, with a dramatic expansion of HIV-specific CD8 cytotoxic T lymphocytes, resulting in a CD8 lymphocytosis and reversal of the usual CD4:CD8 ratio. CD8 cytotoxic T lymphocytes kill activated CD4 cells that are replicating HIV, but not latently infected CD4 cells. HIV evades destruction despite this vigorous immune response, in part because the highly conserved regions of gp120 and gp41 that are necessary for viral attachment and entry are covered by highly variable glycoprotein loops that change over time as a result of mutations selected for by the immune response. The initial peak of viraemia in primary infection settles to a plateau phase of persistent chronic viraemia. With time, there is gradual attrition of the T-helper lymphocyte population and, as these cells are pivotal in orchestrating the immune response, the patient becomes susceptible to opportunistic diseases. The predominant opportunist infections in HIV-infected people are the consequences of impaired cell-mediated rather than antibody-mediated immunity (e.g. mycobacteria, herpesviruses). However, there is also a B-lymphocyte defect with impaired antibody production to new antigens and dysregulated antibody production with a polyclonal increase in gamma globulins, resulting in an increased risk of infection with encapsulated bacteria, notably *Streptococcus pneumoniae*.

The immune activation in response to HIV infection does not completely resolve on effective ART. This residual inflammatory state has been implicated in the pathogenesis of several non-AIDS morbidities that occur at a higher rate in HIV-infected people on ART than in the general population: cardiovascular, neurological and liver disease, chronic kidney disease and non-AIDS cancers.

Diagnosis and investigations

Diagnosing HIV infection

Globally, the trend is towards universal HIV testing, rather than testing only those patients at high risk or those with manifestations of HIV infection. However, in the UK, testing is still targeted to high-risk groups (Box 12.4). HIV is diagnosed by detecting host antibodies either with rapid point-of-care tests or in the laboratory, where enzyme-linked immunosorbent assay (ELISA) tests are usually done. Most tests detect antibodies to both HIV-1 and HIV-2. A positive antibody test from two different immunoassays is sufficient to confirm infection. Western blot assays can also be used to confirm infection but they are expensive and sometimes yield indeterminate results. Screening tests often include an assay for p24 antigen in addition to antibodies, in order to detect patients with primary infection before the antibody response occurs. Nucleic acid amplification tests (usually polymerase chain reaction, PCR) to detect HIV RNA are used to diagnose infections in infants of HIV-infected mothers, who carry maternal antibodies to HIV for up to 15 months irrespective of whether they are infected, and to diagnose primary infection before

12.4 Patients who should be offered and recommended HIV testing in the UK

Patients accessing specialist sexual health services (including genitourinary medicine)

- All patients who attend for testing or treatment

Patients accessing primary care (including emergency care) and secondary care

- All patients attending their first appointment at:
  - Drug dependency programmes
  - Pregnancy termination services
  - Services treating hepatitis B or C, lymphoma or tuberculosis
- All patients who:
  - Have symptoms that may indicate HIV or for which HIV is part of the differential diagnosis
  - Are from a country or group with high rate of HIV infection
  - Are male, or trans women, who have sex with men
  - Report sexual contact with someone from a country with high rate of HIV infection
  - Disclose high-risk sexual practices, e.g. 'chemsex' (p. 332)
  - Are diagnosed with, or request testing for, a sexually transmitted infection
  - Report a history of injecting drug use
  - Are the sexual partners of people known to be HIV-positive or at high risk of HIV
- In areas of high[2] and extremely high[3] prevalence:
  - All patients not previously diagnosed with HIV who register with a general practice or undergo blood testing for any reason
- In areas of extremely high prevalence[3]:
  - All emergency care and secondary care patients not previously diagnosed with HIV
  - At each general practice consultation consider offering opportunistic HIV testing

Prison inmates

- All new inmates not previously diagnosed with HIV

[1]Adapted from *National Institute for Health and Care Excellence NG60 – HIV testing: increasing uptake among people who may have undiagnosed HIV NICE guideline* (Dec. 2016). [2]Prevalence of diagnosed HIV is 2–5 per 1000 people aged 15–59. [3]Prevalence of diagnosed HIV is ≥ 5 per 1000 people aged 15–59.

12.5 How to carry out pre-test counselling

- Discuss meaning of positive and negative test results
- Realise importance of maintaining confidentiality
- Identify person to whom positive result could be disclosed
- Explore knowledge and explain natural history of HIV
- Discuss transmission and risk reduction
- Assess coping strategy
- Explain test procedure
- Obtain informed consent

12.6 How to carry out post-test counselling

Test result negative

- Discuss transmission and need for behaviour modification
- Advise second test 3 months after last exposure

Test result positive

- Explain meaning of result
- Organise medical follow-up
- Assess coping strategy
- Stress importance of disclosure
- Explain value of antiretroviral therapy
- Provide written information and useful Internet resources
- Discuss confidentiality issues
- Organise emotional and practical support (names/phone numbers)
- Facilitate notification of sexual partners

12.7 Baseline investigations

- CD4 count
- Viral load
- Hepatitis B surface antigen
- Hepatitis C antibody
- Liver function tests
- Full blood count
- Urinalysis, serum creatinine
- Syphilis serology
- Cervical smear in women
- Serum cryptococcal antigen (if CD4 < 100)
- Tuberculin skin test
- Sexually transmitted infection screen

antibodies have developed. PCR is more sensitive than p24 antigen detection for diagnosing primary infection.

The purpose of HIV testing is not simply to identify infected individuals, but also to educate people about prevention and transmission of the virus. Counselling in the client's home language is essential both before testing and after the result is obtained (Boxes 12.5 and 12.6). There are major advantages to using rapid point-of-care HIV tests in that pre- and post-test counselling can be done at the same visit.

A number of baseline investigations should be done at the initial medical evaluation (Box 12.7). The extent of these investigations will depend on the resources available.

Viral load and CD4 counts

CD4 counts

CD4 lymphocyte counts are usually determined by flow cytometry but cheaper methods have been developed for low-income countries. The CD4 count is the most clinically useful laboratory indicator of the degree of immune suppression; it is used, together with clinical staging, in decisions to start prophylaxis against opportunistic infections, and is of great value in the differential diagnosis of clinical problems.

The CD4 count varies by up to 20% from day to day and is also transiently reduced by intercurrent infections. Due to this variability, major therapeutic decisions should not be taken on the basis of a single count. The percentage of lymphocytes that are $CD4^+$, rather than the absolute count, is routinely used in paediatrics, as the normal CD4 counts in infants and young children are much higher than in adults. In adults, the CD4 percentage is occasionally useful when evaluating significant reductions in an individual's CD4 count, which may be associated with transient lymphopenia due to intercurrent infection or pregnancy. In this case, the CD4 percentage will be unchanged.

The normal CD4 count is over 500 cells/mm^3. The rate of decline in CD4 count is highly variable. People with CD4 counts between 200 and 500 cells/mm^3 have a low risk of developing major opportunistic infections. Morbidity due to inflammatory dermatoses, herpes zoster, oral candidiasis, tuberculosis, bacterial pneumonia and HIV-related immune disorders (e.g. immune thrombocytopenia) becomes increasingly common as CD4 counts decline. Once the count is below 200 cells/mm^3, there is severe immune suppression and a high risk of AIDS-defining conditions. It is important to note that patients can be asymptomatic despite very low CD4 counts and that major opportunistic diseases occasionally present with high CD4 counts.

12

The CD4 count should be performed every 3–6 months in patients on ART, together with measurement of the viral load.

Viral load

The level of viraemia is measured by quantitative PCR of HIV RNA, known as the viral load. Determining the viral load is crucial for monitoring responses to ART (p. 324). People with high viral loads (e.g. > 100 000 copies/mL) experience more rapid declines in CD4 count, while those with low viral loads (< 1000 copies/mL) usually have slow or even no decline in CD4 counts.

Transient increases in viral load occur with intercurrent infections and immunisations, so the test should be done at least 2 weeks afterwards. Viral loads are variable; only changes in viral load of more than 0.5 $\log_{10}$ copies/mL are considered clinically significant.

Clinical manifestations of HIV

Clinical staging of patients should be done at the initial medical examination, as it provides prognostic information and is a key criterion for initiating prophylaxis against opportunistic infections. Two clinical staging systems are used internationally (p. 307). In both, patients are staged according to the most severe manifestation and do not improve their classification. For example, a patient who is asymptomatic following a major opportunistic disease (AIDS) remains at stage 4 or category C of the WHO and CDC systems, respectively, and never reverts to earlier stages. Finally, patients do not always progress steadily through all stages and may present with AIDS, having been asymptomatic.

Primary HIV infection

Primary infection is symptomatic in more than 50% of cases but the diagnosis is often missed. The incubation period is usually 2–4 weeks after exposure. The duration of symptoms is variable but is seldom longer than 2 weeks. The clinical manifestations (Box 12.8) resemble those of infectious mononucleosis/glandular fever (p. 241), but the presence of maculopapular rash or mucosal ulceration strongly suggests primary HIV infection

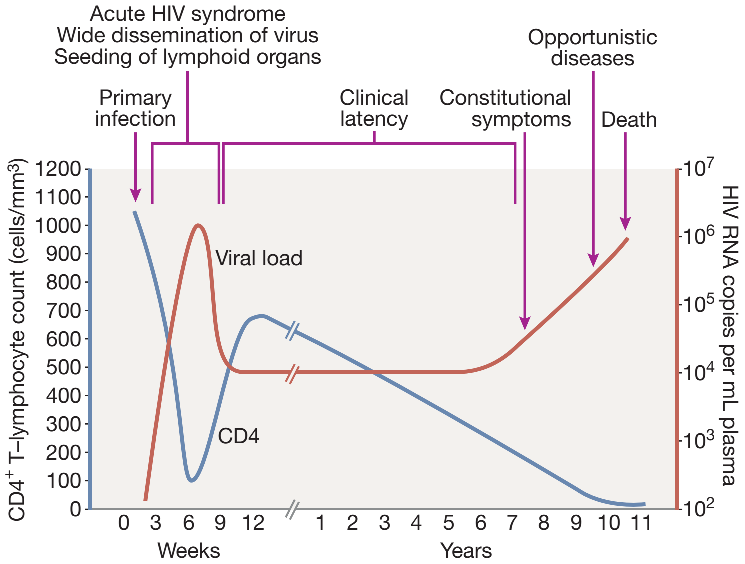

Fig. 12.2 Virological and immunological progression of untreated HIV infection.

12.8 Clinical features of primary infection	
• Fever	• Diarrhoea
• Maculopapular rash	• Headache
• Pharyngitis	• Oral and genital ulceration
• Lymphadenopathy	• Meningo-encephalitis
• Myalgia/arthralgia	• Bell's palsy

rather than the other viral causes of infectious mononucleosis. In infectious mononucleosis due to Epstein–Barr virus (EBV) or in cytomegalovirus (CMV), rashes generally occur only if aminopenicillins are given. Atypical lymphocytosis occurs less frequently than in EBV infection. Transient lymphopenia, including CD4 lymphocytes, is found in most cases (Fig. 12.2), which may result in opportunistic infections, notably oropharyngeal candidiasis. Major opportunistic infections like *Pneumocystis jirovecii* pneumonia (PJP) may rarely occur. Thrombocytopenia and moderate elevation of liver enzymes are commonly present. The differential diagnosis of primary HIV includes acute EBV, primary CMV infection, rubella, primary toxoplasmosis and secondary syphilis.

Early diagnosis is made by detecting HIV RNA by PCR or p24 antigenaemia. The appearance of specific anti-HIV antibodies in serum (seroconversion) occurs 2–12 weeks after the development of symptoms. The window period during which antibody tests may be false negative is prolonged when post-exposure prophylaxis has been used.

Asymptomatic infection

A prolonged period of clinical latency follows primary infection, during which infected individuals are asymptomatic. Persistent generalised lymphadenopathy with nodes typically <2 cm diameter is a common finding. Eventually, the lymph nodes regress, with destruction of node architecture as disease advances.

Viraemia peaks during primary infection and then drops as the immune response develops, to reach a plateau about 3 months later. The level of viraemia post seroconversion is a predictor of the rate of decline in CD4 counts, which is highly variable and explained in part by genetic factors affecting the immune response. The median time from infection to the development of AIDS in adults is about 9 years (see Fig. 12.2). A small proportion of untreated HIV-infected people are long-term non-progressors, with CD4 counts in the reference range for 10 years or more. Some long-term non-progressors have undetectable viral loads and are known as 'elite controllers'.

Minor HIV-associated disorders

A wide range of disorders indicating some impairment of cellular immunity occur in most patients before they develop AIDS (CDC category B or WHO stages 2 and 3). Careful examination of the mouth is important when patients are being followed up, as oral candidiasis and oral hairy leucoplakia are common conditions that require initiation of prophylaxis against opportunistic infections, irrespective of the CD4 count.

Acquired immunodeficiency syndrome

AIDS is defined by the development of specified opportunistic infections, cancers and severe manifestations of HIV itself (p. 307). CDC category C is the most widely used definition of AIDS. WHO updated its classification more recently and added a few conditions of similar prognosis to its stage 4 disease.

Presenting problems in HIV infection

HIV itself is associated with a wide variety of clinical manifestations, and opportunistic diseases add many more. All body systems can be affected by HIV. The CD4 count is useful in differential diagnosis (Box 12.9): opportunistic diseases that may present at higher CD4 counts become increasingly common as CD4 counts decline, so the CD4 count helps to rule out certain disorders. For example, in a patient with a pulmonary infiltrate and a CD4 count of 350 cells/mm^3, pulmonary tuberculosis is a likely diagnosis and PJP is very unlikely, but if the patient's CD4 count is 50 cells/mm^3, both PJP and tuberculosis are likely.

Globally, tuberculosis is the most common cause of morbidity and mortality in HIV-infected patients. Tuberculosis should be considered in the differential diagnosis of most presenting problems in patients from communities where tuberculosis is common.

12.9 CD4 count and risk of common HIV-associated diseases

<500 cells/mm³	
• Tuberculosis • Bacterial pneumonia • Herpes zoster • Oropharyngeal candidiasis • Non-typhoid salmonellosis	• Kaposi's sarcoma • Non-Hodgkin lymphoma • HIV-associated idiopathic thrombocytopenic purpura
<200 cells/mm³	
• *Pneumocystis jirovecii* pneumonia • Chronic herpes simplex ulcers • Oesophageal candidiasis • *Cystoisospora belli* (syn. *Isospora belli*) diarrhoea	• HIV wasting syndrome • HIV-associated dementia • Peripheral neuropathy • Endemic mycoses
<100 cells/mm	
• Cerebral toxoplasmosis • Cryptococcal meningitis • Cryptosporidiosis and microsporidiosis • Primary CNS lymphoma	• Cytomegalovirus • Disseminated *Mycobacterium avium* complex (MAC) • Progressive multifocal leucoencephalopathy

Lymphadenopathy

Persistent generalised lymphadenopathy due to HIV is described above under asymptomatic infection. Lymphadenopathy may also be due to malignancy (Kaposi's sarcoma or lymphoma) or infections, especially tuberculosis, which is an extremely common cause in low- and middle-income countries. Tuberculous lymph nodes are often matted and may become fluctuant due to extensive caseous necrosis; inexperienced clinicians often perform incision and drainage inappropriately when simple aspiration is all that is required. Symmetrical generalised lymphadenopathy may occur in disseminated tuberculosis. Lymphoma typically presents with large, firm, asymmetric nodes. Rapid enlargement of a node, asymmetric enlargement or lymphadenopathy associated with constitutional symptoms (even if the nodes are symmetrical) warrants further investigation. Lymph node needle aspiration (using a wide-bore needle such as 19G if tuberculosis is suspected) should be performed. One slide should be air-dried and sent for staining for acid-fast bacilli, which has about a 70% yield in tuberculosis. The other slide should be fixed and sent for cytology. If caseous liquid is aspirated, this should be sent for mycobacterial culture or PCR. If needle aspiration is unhelpful, or if lymphoma or Kaposi's sarcoma is suspected, excision biopsy should be performed.

Weight loss

Weight loss is a very common finding in advanced HIV infection. The HIV wasting syndrome is an AIDS-defining condition and is defined as weight loss of more than 10% of body weight, plus either unexplained chronic diarrhoea (lasting over 1 month) or chronic weakness and unexplained prolonged fever (lasting over 1 month). This is a diagnosis of exclusion. If the weight loss is rapid (more than 1 kg a month), then major opportunistic infections or cancers become more likely. Painful oral conditions and nausea from drugs contribute by limiting intake. Depression is very common and can cause significant weight loss. Measurement of C-reactive protein is helpful in the work-up of weight loss, as this is markedly raised with most opportunistic diseases but not with HIV itself. Erythrocyte sedimentation rate (ESR) is elevated by HIV infection and is therefore not useful. The presence of fever or diarrhoea is helpful in the differential diagnosis of weight loss (Fig. 12.3).

Fever

Fever is a very common presenting feature. Common causes of prolonged fever with weight loss are listed in Figure 12.3. Non-typhoid *Salmonella* bacteraemia, which commonly presents with fever in low-income countries, is accompanied by diarrhoea in only about 50% of patients. Pyrexia of unknown origin (PUO) in HIV infection is defined as temperature over 38°C with no cause found after 4 weeks in outpatients or 3 days in inpatients, and initial investigations such as chest X-rays, urinalysis and

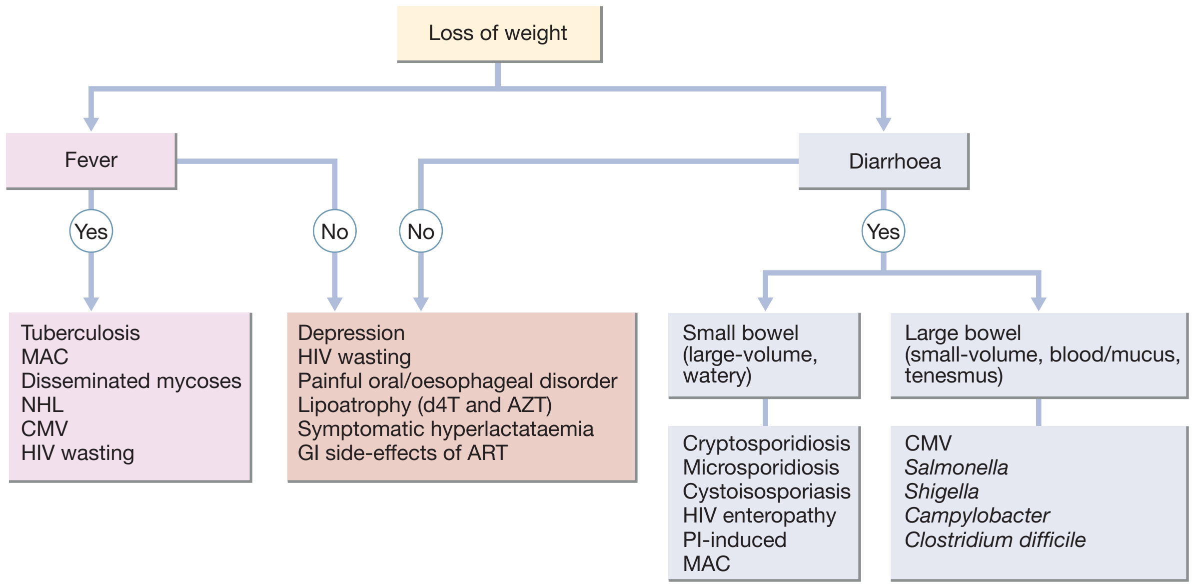

Fig. 12.3 Presentation and differential diagnosis of weight loss. (ART = antiretroviral therapy; AZT = zidovudine; CMV = cytomegalovirus; d4T = stavudine; KS = Kaposi's sarcoma; MAC = *Mycobacterium avium* complex; NHL = non-Hodgkin lymphoma; PI = protease inhibitor)

Fig. 12.4. Disseminated histoplasmosis presenting with diffuse papular rash and fever. Skin biopsy was diagnostic. *Courtesy of Professor Graeme Meintjes.*

blood cultures have failed to identify the cause. HIV itself can present with prolonged fever but this is a diagnosis of exclusion, as a treatable cause will be found in most patients. Abdominal imaging, preferably by computed tomography (CT), should be requested. Abdominal nodes (especially if they are hypodense in the centre) or splenic microabscesses strongly suggest tuberculosis. Mycobacterial blood cultures, which can also detect fungi, should be performed. Bone marrow aspirate and trephine biopsy are helpful if the full blood count shows cytopenias. Liver biopsy may be helpful if the liver enzymes are elevated but is invasive and seldom necessary. Mycobacterial and fungal stains and cultures should be done on all biopsies. Chest X-rays should be repeated after about a week, as micronodular or interstitial infiltrates may have become apparent (see p. 319 for differential diagnosis).

Tuberculosis is by far the most common cause of PUO in low- and middle-income countries, and in these settings a trial of empirical therapy is warranted after cultures have been sent. In high-income countries, disseminated *Mycobacterium avium* complex (MAC) infection is an important cause of PUO, often also presenting with diarrhoea and splenomegaly. Disseminated endemic mycoses (e.g. histoplasmosis, coccidioidomycosis, talaromycosis) present with PUO, often with papular skin eruptions or mucosal ulcerations (Fig. 12.4). Skin biopsy for histology and fungal culture is often diagnostic.

Mucocutaneous disease

The skin and mouth must be carefully examined, as mucocutaneous manifestations are extremely common in HIV and many prognostically important conditions can be diagnosed by simple inspection. The differential diagnosis of dermatological conditions is simplified by categorising disorders according to the lesion type (Box 12.10). Some common dermatological diseases, notably psoriasis, are exacerbated by HIV. The risk of many drug rashes is increased in HIV-infected patients. Skin biopsy should be taken, and sent for histology and culture for mycobacteria and fungi, in patients with papular rashes or if there are constitutional symptoms coinciding with the development of the rash.

12.10 Differential diagnosis of skin conditions by lesion type

Scaly rashes	
• Seborrhoeic dermatitis • Psoriasis* (exacerbated by HIV) • Tinea corporis*	• Dry skin/ichthyosis • Norwegian scabies* • Drug rashes*
Pruritic papules	
• Pruritic papular eruption ('itchy red bump disease')	• Eosinophilic folliculitis • Scabies*
Papules and nodules (non-pruritic)	
• Molluscum contagiosum* • Secondary syphilis • Kaposi's sarcoma • Bacillary angiomatosis • Cryptococcosis	• Warts* • Disseminated endemic mycoses (histoplasmosis, coccidioidomycosis and talaromycosis)
Blisters	
• Herpes simplex • Herpes zoster • Fixed drug eruptions	• Drug rashes (especially toxic epidermal necrolysis)
Mucocutaneous ulcers	
• Ecthyma • Herpes simplex • Aphthous ulcers (minor and major)	• Histoplasmosis • Drug rashes (Stevens–Johnson syndrome)
Hyperpigmentation	
• Post-inflammatory (especially pruritic papular eruption) • Zidovudine	• Emtricitabine (palms and soles)

*See Chapter 29 for more information.

Seborrhoeic dermatitis

Seborrhoeic dermatitis is very common in HIV. The severity increases as the CD4 count falls. It presents as scaly red patches, typically in the nasolabial folds and in hairy areas. Fungal infections are thought to play a role in the pathogenesis of this condition. It responds well to a combined topical antifungal and glucocorticoid. Selenium sulphide shampoo is helpful for scalp involvement.

Fig. 12.5 Severe mucocutaneous herpes simplex. Chronic anogenital or perioral ulcers are very common in advanced HIV infection.

12.11 Treatment of common opportunistic infections in adults with AIDS

Opportunistic infection	Treatment	Alternative treatment	Secondary prophylaxis*
Pneumocystis jirovecii pneumonia	Co-trimoxazole 20/100 mg/kg/day (in 4 divided doses) for 21 days; maximum per dose 320/1600 mg Early adjunctive prednisone 40 mg twice daily, if hypoxic	Clindamycin 900 mg 3 times daily IV (switch to 600 mg 3 times daily PO once improving) plus primaquine 30 mg daily for 21 days	Co-trimoxazole 160/800 mg daily
Cerebral toxoplasmosis	Sulfadiazine 15 mg/kg 4 times daily plus pyrimethamine 200 mg stat, then 75 mg daily plus folinic acid 15–25 mg daily for 6 weeks	Co-trimoxazole 320/1600 mg twice daily for 4 weeks, then 160/800 mg twice daily for 3 months	Co-trimoxazole 160/800 mg daily
Cryptococcosis	Liposomal amphotericin B 4 mg/kg/day IV plus flucytosine 25 mg/kg 4 times daily for 14 days, followed by fluconazole 400 mg daily for 8 weeks	Amphotericin B 1 mg/kg/day IV plus fluconazole 800 mg daily for 14 days, followed by fluconazole 400 mg daily for 8 weeks	Fluconazole 200 mg daily (for minimum of 1 year)
Oesophageal candidiasis	Fluconazole 200 mg daily for 14 days	Itraconazole 200 mg daily for 14–21 days	Not usually recommended
Disseminated *Mycobacterium avium* complex	Clarithromycin 500 mg twice daily plus ethambutol 15 mg/kg daily	Azithromycin 500 mg daily plus ethambutol 15 mg/kg daily	Continue treatment for minimum of 1 year
Herpes simplex ulcers	Aciclovir 400 mg 3 times daily for 5–10 days	Valaciclovir 500 mg or famciclovir 125 mg twice daily for 5–10 days	Aciclovir 400 mg twice daily only if recurrences are frequent/severe
Cystoisospora belli diarrhoea	Co-trimoxazole 160/800 mg 4 times daily for 10 days	Ciprofloxacin 500 mg twice daily for 10 days	Co-trimoxazole 160/800 mg daily

*Secondary prophylaxis may be discontinued once CD4 counts have increased to > 200 cells/mm^3 on antiretroviral therapy for at least 3 months.

12

Herpes simplex infections

Recurrences of herpes simplex infection are very common and primarily affect the nasolabial and anogenital areas (Fig. 12.5). As immune suppression worsens, the ulcers take longer to heal and become more extensive. Ulcers that persist for more than 4 weeks are AIDS-defining. The diagnosis is clinical, but PCR of vesicle fluid or from ulcer swabs may be diagnostic with unusual presentations. Response to a course of antiviral drug such as aciclovir is good but relapses are common. Frequent relapses that persist despite ART should be treated with aciclovir 400 mg twice daily for 6–12 months (Box 12.11).

Herpes zoster

This usually presents with a pathognomonic vesicular rash on an erythematous base in a dermatomal distribution (p. 239). The median CD4 count at the first episode of zoster is 350 cells/mm^3. In patients with advanced HIV disease, the rash may be multidermatomal and recurrent episodes may occur. Disseminated zoster is rare. In HIV-infected patients, zoster is generally more extensive and has a longer duration, and there is a higher risk of developing post-herpetic neuralgia. High doses of aciclovir or its congeners should be given for all cases with active disease, irrespective of the time since the onset of the rash. Post-herpetic neuralgia is difficult to manage. Analgesic adjuvants, e.g. amitriptyline and pregabalin, should be commenced in all patients with prolonged pain. Topical capsaicin has modest efficacy.

Kaposi's sarcoma

Kaposi's sarcoma (KS) is a spindle-cell tumour of lympho-endothelial origin. All forms of KS are due to sexually transmitted human herpesvirus 8, also known as KS-associated herpesvirus. KS occurs in four patterns:

- *classic KS*: rare, indolent and restricted largely to elderly Mediterranean or Jewish men
- *endemic KS*: occurs in sub-Saharan Africa, is more aggressive, presents at earlier ages than classic KS, and affects men more than women
- *KS in patients on immunosuppressant drugs*: usually transplant recipients, who experience disseminated disease
- *AIDS-associated KS*.

In Africa, the male-to-female ratio of AIDS-associated KS is much lower than is seen with endemic KS, but men are still more affected than women, despite the fact that the seroprevalence of human herpesvirus 8 is the same in both sexes.

AIDS-associated KS is always a multicentric disease. Early mucocutaneous lesions are macular and may be difficult to diagnose. Subsequently, lesions become papular or nodular, and may ulcerate. KS lesions typically have a red–purple colour (Fig. 12.6 and p. 306) but may become hyperpigmented, especially in dark-skinned patients. As the disease progresses, the skin lesions become more numerous and larger. Lymphoedema is common, as lymphatic vessels are infiltrated. KS also commonly spreads to lymph nodes and viscerally, especially to the lungs and gastrointestinal tract. Visceral disease occasionally occurs in the absence of mucocutaneous involvement. B symptoms of fever, night sweats and weight loss may occur.

KS may respond to ART. Chemotherapy should be reserved for those patients who fail to remit on ART, or be given together with ART if there are poor prognostic features such as visceral involvement, oedema, ulcerated lesions and B symptoms.

Bacillary angiomatosis

Bacillary angiomatosis is a bacterial infection caused by *Bartonella henselae* or *B. quintana*. Skin lesions range from solitary superficial red–purple lesions resembling KS or pyogenic granuloma, to

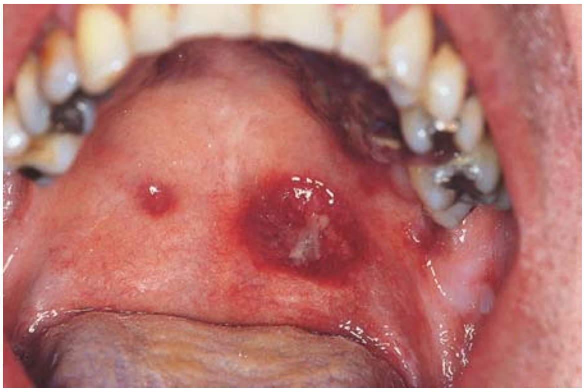

Fig. 12.6 Oral Kaposi's sarcoma. A full examination is important to detect disease that may affect the palate, gums, fauces or tongue.

multiple subcutaneous nodules or plaques. Lesions are painful and may bleed or ulcerate. The infection may become disseminated with fevers, lymphadenopathy and hepatosplenomegaly. Diagnosis is made by biopsy of a lesion and Warthin–Starry silver staining, which reveals aggregates of bacilli. Treatment with doxycycline or azithromycin is effective.

Papular pruritic eruption

Papular pruritic eruption ('itchy red bump disease') is an intensely itchy, symmetrical rash affecting the trunk and extremities. It is thought to be due to an allergic reaction to insect bites. In sub-Saharan Africa, it is the most common skin manifestation of HIV. Post-inflammatory hyperpigmentation is common. Topical glucocorticoids, emollients and antihistamines are useful but response is variable. Measures to reduce insect bites are logical but difficult to implement in low-income settings.

Drug rashes

Cutaneous hypersensitivity to drugs is said to occur 100 times more frequently in HIV infection. The most common type is an erythematous maculopapular rash, which may be scaly. The drugs most commonly associated with rashes are sulphonamides and non-nucleoside reverse transcriptase inhibitors (NNRTIs – see below). Severe, life-threatening features of drug rashes include blistering (when this affects more than 30% of surface area it is known as toxic epidermal necrolysis), involvement of mucous membranes (Stevens–Johnson syndrome, pp. 1224 and 1254), or systemic involvement with fever or organ dysfunction (especially hepatitis, which is often delayed for a week or two after the rash develops). Because sulphonamides are important in the treatment and prophylaxis of opportunistic infections, rechallenge or desensitisation is often attempted in patients who have previously experienced rashes, provided the reaction was not life-threatening. Details of rashes caused by ART are given below.

Oral conditions

Oropharyngeal candidiasis is very common. It is nearly always caused by *C. albicans* (p. 300), but azole-resistant *Candida* species may be selected for if there have been repeated courses of azole drugs. Pseudomembranous candidiasis is the most common manifestation, with white patches on the buccal mucosa (p. 306) that can be scraped off to reveal a red raw surface. Erythematous candidiasis is more difficult to diagnose and presents with a reddened mucosa and a smooth shiny tongue. Angular cheilitis due to *Candida* is a common manifestation. Topical antifungals are usually effective. Antifungal lozenges are more effective than antifungal solutions. Systemic azole therapy, usually fluconazole, should be given if topical therapy fails or if there are oesophageal symptoms.

Oral hairy leucoplakia (p. 306) appears as corrugated white plaques running vertically on the side of the tongue and is virtually pathognomonic of HIV disease. It is usually asymptomatic and is due to EBV.

Oral ulcers are common. Herpetiform oral ulcers occur in primary infection. Herpes simplex typically affects the nasolabial area but may cause oral ulcers. In early disease, minor aphthous ulcers are common. In advanced disease, giant aphthous ulcers occur. These destroy tissue, are painful and need to be differentiated from herpes simplex and CMV ulcers by biopsy. They respond to systemic glucocorticoids and ART. A number of disseminated endemic mycoses, notably histoplasmosis (p. 303), may cause oral ulcers, usually associated with constitutional symptoms. Finally, superficial oral ulcers may occur as part of the Stevens–Johnson syndrome, usually caused by sulphonamides or NNRTIs.

KS often involves the mouth, especially the hard palate (see above and Fig. 12.6). Nodular oral lesions are associated with a worse prognosis.

Gingivitis is very common. Good oral hygiene and regular dental check-ups are important. Acute necrotising ulcerative gingivitis and periostitis (p. 306) can result in loss of teeth; they should be treated with a course of metronidazole and a dental referral should be made.

Nail disorders

Fungal infections (onychomycosis, p. 1240) are very common and often involve multiple nails. Blue–black discoloration of nails is common and may be due to HIV or to the antiretroviral drug zidovudine.

Gastrointestinal disease

Oesophageal diseases

Oesophageal candidiasis (Fig. 12.7) is the most common cause of pain on swallowing (odynophagia), dysphagia and regurgitation. Concomitant oral candidiasis is present in about 70% of patients. Systemic azole therapy, e.g. fluconazole 200 mg daily for 14 days, is usually curative but relapses are common (Box 12.11). Patients whose oesophageal symptoms fail to respond to azoles should be investigated with oesophagoscopy. Major aphthous ulceration and CMV ulcers are the most likely causes and need to be differentiated by biopsy. Occasionally, herpes simplex oesophagitis or KS is responsible.

Diarrhoea

Chronic diarrhoea is a very common presenting problem in patients with advanced HIV, especially in areas where there is no access to safe water. It is a major cause of wasting. The differential diagnosis of diarrhoea depends on whether the presentation is with large- or small-bowel symptoms (see Fig. 12.3). The presentation and aetiology of acute diarrhoea are similar to those in HIV-uninfected patients.

12.12 Common causes of chronic watery diarrhoea

	Cryptosporidiosis	Microsporidiosis	Cystoisosporiasis (formerly isosporiasis)
Organism	Protozoan	Fungus	Protozoan
Species	*Cryptosporidium parvum* *C. hominis*	*Enterozoon bieneusi* *Encephalitozoon intestinalis* etc.	*Cystoisospora belli*
Animal host	Multiple	Multiple	No
Distribution	Global	Global	Tropics
Stool examination	Acid-fast stain	Trichrome stain Polymerase chain reaction	Acid-fast stain
Specific treatment	No established therapy	Albendazole (some species)	Co-trimoxazole

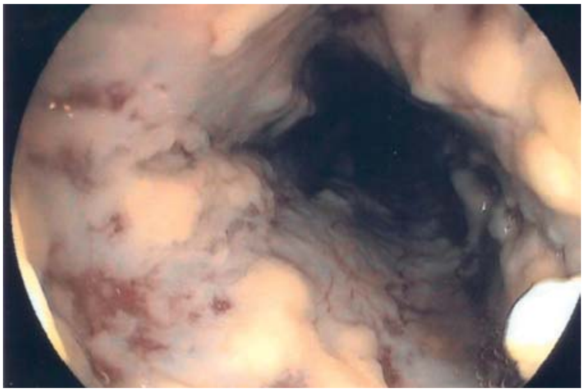

Fig. 12.7 Oesophageal candidiasis. Endoscopy showing typical pseudomembranous candidiasis.

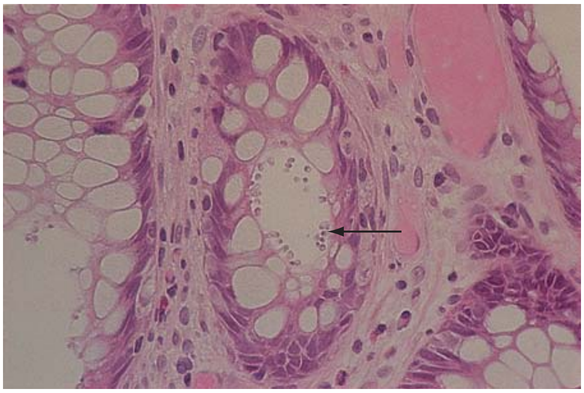

Fig. 12.8 Cryptosporidiosis. Duodenal biopsy may be necessary to confirm cryptosporidiosis or microsporidiosis. The arrow indicates an oöcyst.

Large-bowel diarrhoea

Acute diarrhoea caused by the bacterial enteric pathogens *Campylobacter*, *Shigella* and *Salmonella* occurs more frequently than in HIV-uninfected people and the illness is more severe. Bacteraemia is much more common, notably due to non-typhoid *Salmonella* (p. 262). Diarrhoea caused by *Clostridium difficile* should be considered if there has been prior exposure to antibiotics, as is often the case in patients with symptomatic HIV.

CMV colitis presents with chronic large-bowel symptoms and fever in patients with CD4 counts below 100 cells/mm^3. On colonoscopy, ulcers are seen, mostly involving the left side of the colon. Biopsy of ulcers shows typical 'owl's-eye' inclusion bodies.

Small-bowel diarrhoea

Chronic small-bowel diarrhoea may be due to HIV enteropathy but this is a diagnosis of exclusion. It typically presents with chronic watery diarrhoea and wasting without fever. Infection with one of three unicellular organisms is responsible for most cases: cryptosporidiosis, microsporidiosis and cystoisosporiasis (formerly known as isosporiasis) (Box 12.12). All three organisms are intracellular parasites that invade enterocytes. If the diagnosis is not made by stool microscopy on at least two specimens, a duodenal biopsy should be performed (Fig. 12.8). Electron microscopy is essential for speciation of microsporidia.

About 40% of patients with disseminated MAC infections have watery diarrhoea. Fever is a prominent feature of MAC infection, which helps differentiate it from cryptosporidiosis, microsporidiosis and cystoisosporiasis. Intestinal tuberculosis typically involves the ileocaecal area and may present with fever, weight loss and diarrhoea, but the diarrhoea is seldom profuse.

Hepatobiliary disease

Chronic viral hepatitis

Hepatitis B and/or C (HBV and HCV) co-infection is common in HIV-infected people due to shared risk factors for transmission. The natural history of both HBV and HCV is altered by HIV co-infection. In the ART era, chronic liver disease from viral hepatitis has emerged as a major cause of morbidity and mortality. HBV and HCV are further described on pages 873 and 877.

Hepatitis B

HBV infection is common in several groups of people at risk of HIV infection: residents of low- and middle-income countries, injection drug-users, haemophiliacs and MSM. HIV co-infection increases HBV viraemia, is associated with less elevation of transaminase (presumably due to immune suppression), and increases the risk of liver fibrosis and hepatocellular carcinoma. Several nucleoside reverse transcriptase inhibitors (NRTIs; lamivudine, emtricitabine and tenofovir) are also effective against HBV. HBV status should be checked at baseline in all HIV-infected patients. Treatment with anti-HBV drugs should be considered for all patients who have active HBV replication (HBeAg-positive or HBV DNA >2000 IU/mL) and/or evidence of inflammation or fibrosis on liver biopsy (see also p. 876). A flare of hepatitis may be associated with improved immune function after starting ART or discontinuing

antiretrovirals that have anti-HBV activity. HBV co-infection increases the risk of antiretroviral hepatotoxicity.

Hepatitis C

HCV infection is extremely common in injection drug-users and haemophiliacs. HIV co-infection increases HCV viraemia and increases the risk of liver fibrosis and hepatocellular carcinoma. Treatment for HCV should preferably be deferred in patients with CD4 counts <200 cells/mm^3 until they are stable on ART. As with HBV co-infection, a flare of hepatitis may be associated with improved immune function after starting ART, and there is an increased risk of antiretroviral hepatotoxicity. Response to anti-HCV therapy is similar to that seen in HIV-uninfected people, but there are important drug–drug interactions between several antiretrovirals and the newer HCV protease inhibitors.

HIV cholangiopathy

HIV cholangiopathy, a form of secondary sclerosing cholangitis (p. 888), may occur in patients with severe immune suppression. In some patients, coexisting intestinal infection with CMV, cryptosporidiosis or microsporidiosis is present, but it is uncertain if these organisms play an aetiological role. Papillary stenosis is common and is amenable to cautery via endoscopic retrograde cholangiopancreatography (ERCP), which provides symptomatic relief. Acalculous cholecystitis is a common complication of cholangiopathy. ART may improve the condition.

Respiratory disease

Pulmonary disease is very common and is the major reason for hospital admission. Most patients who are admitted for respiratory diseases will have either bacterial pneumonia, pulmonary tuberculosis or PJP. PJP is more common in high-income countries, while tuberculosis is more common in low- and middle-income countries. An approach to the differential diagnosis of all three conditions is given in Box 12.13.

Pneumocystis jirovecii pneumonia

The key presenting feature of *Pneumocystis jirovecii* pneumonia (PJP) is progressive dyspnoea with a duration of less than 12 weeks. Dry cough and fever are common. The chest X-ray typically shows a bilateral interstitial infiltrate spreading out from the hilar regions (Fig. 12.9) but may be normal initially. High-resolution CT scan is more sensitive than chest X-ray, usually showing typical 'ground-glass' interstitial infiltrates. Pneumatoceles may occur and may rupture, resulting in a pneumothorax. The diagnosis is made with silver stains, PCR or immunofluorescence of broncho-alveolar lavage or induced sputum (note that spontaneously produced sputum should not be sent, as the yield is low). Treatment is with high-dose co-trimoxazole, together with adjunctive systemic glucocorticoids if the patient is hypoxic (see Box 12.11).

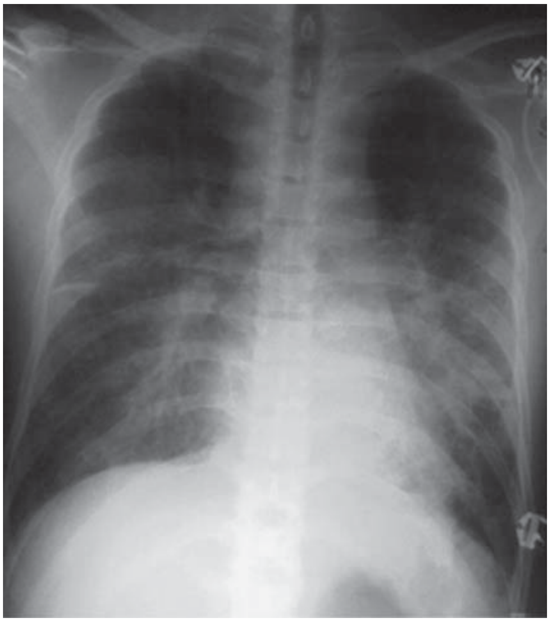

Fig. 12.9 ***Pneumocystis* pneumonia: typical chest X-ray appearance.** Note the interstitial bilateral infiltrate.

i 12.13 Comparative features of bacterial pneumonia, *Pneumocystis jirovecii* pneumonia and pulmonary tuberculosis

	Bacterial pneumonia	*Pneumocystis jirovecii* pneumonia	Pulmonary tuberculosis
Duration	Acute	Subacute	Variable
Dyspnoea	Common	Prominent	Occasional
White cell count	Increased	Normal	Variable
Chest X-ray			
Infiltrate	Consolidation	Interstitial	Variable
Bilateral infiltrate	Occasional	Usual	Common
Effusion	Occasional	No	Common
Nodes	Rare	No	Common
C-reactive protein	Markedly increased	Variable	Increased

Pulmonary tuberculosis

Tuberculosis is the most common cause of admission in countries with a high tuberculosis incidence. Pulmonary tuberculosis in patients with mild immune suppression typically presents as in HIV-uninfected patients, with a chronic illness and apical pulmonary cavities (p. 588). However, in patients with CD4 counts below 200 cells/mm^3, there are four important differences in the clinical presentation of pulmonary tuberculosis:

- Tuberculosis progresses more rapidly, with a subacute or even acute presentation. The diagnosis therefore needs to be made and therapy commenced promptly. A trial of empirical therapy is often started while awaiting the results of mycobacterial cultures.
- The chest X-ray appearance alters: cavities are rarely seen, pulmonary infiltrates are no longer predominantly in apical areas, and pleural effusions and hilar or mediastinal lymphadenopathy are common (Fig. 12.10). A normal chest X-ray is not unusual in symptomatic patients with tuberculosis confirmed on sputum culture. These atypical findings can result in a delayed or missed diagnosis.
- Sputum smears, which are positive in most HIV-uninfected adults with pulmonary tuberculosis, are negative in more than half of patients. The main reason for this is the absence of pulmonary cavities.
- Many patients have disseminated tuberculosis, sometimes with a classic miliary pattern on chest X-ray, but more

Fig. 12.10 Chest X-ray of pulmonary tuberculosis in advanced HIV infection. Lower-zone infiltrates and hilar or mediastinal nodes in a patient with a CD4 count of < 200 cells/mm^3.

commonly presenting with pulmonary infiltrates together with extrapulmonary tuberculosis. The most common sites of concomitant extrapulmonary tuberculosis are the pleura and lymph nodes. Acid-fast bacilli are more often found on wide-needle aspirate of nodes than on sputum (p. 313). Pleural aspirate showing a lymphocytic exudate suggests tuberculosis as a likely cause and pleural biopsy will usually confirm the diagnosis.

Tuberculosis in HIV-infected patients responds well to standard short-course therapy (p. 592).

Bacterial pneumonia

The incidence of bacterial pneumonia is increased about 100-fold by HIV infection. The severity, likelihood of bacteraemia, risk of recurrent pneumonia, and mortality are all increased compared with HIV-uninfected patients. The aetiology is similar to that of community-acquired pneumonia in HIV-uninfected patients with co-morbidity: *S. pneumoniae* is the most common cause, followed by *Haemophilus influenzae*, Enterobacteriaceae (e.g. *Klebsiella pneumoniae*) and *Staphylococcus aureus*. The prevalence of atypical bacteria in HIV-infected patients with pneumonia is similar to that in the general population. Treatment is with a broad-spectrum β-lactam (e.g. ceftriaxone, amoxicillin–clavulanate), with the addition of a macrolide if the pneumonia is severe.

Uncommon bacteria causing pneumonia include *Pseudomonas aeruginosa*, *Nocardia* (which mimics tuberculosis) and *Rhodococcus equi* (which can cause pulmonary cavities).

Miscellaneous causes of pulmonary infiltrates

Pulmonary cryptococcosis may present as a component of disseminated disease or be limited to the lungs. The chest X-ray appearances are variable. Cryptococcomas occur less commonly than in HIV-uninfected people. The most common radiographic pattern seen in HIV infection is patchy consolidation, often with small areas of cavitation resembling tuberculosis. Pleural involvement is rare. The disseminated endemic mycoses (histoplasmosis, coccidioidomycosis and talaromycosis) often cause diffuse pulmonary infiltrates, mimicking miliary tuberculosis.

Lymphoid interstitial pneumonitis is a slowly progressive disorder causing a diffuse reticulonodular infiltrate. It is caused by a benign polyclonal lymphocytic interstitial infiltrate and is part of the diffuse infiltrative lymphocytosis syndrome (DILS – see p. 321). Patients may have other features of DILS, notably parotidomegaly.

KS often spreads to the lungs. Typical chest X-ray appearances are large, irregular nodules, linear reticular patterns and pleural effusions. Bronchoscopy is diagnostic.

Nervous system and eye disease

The central and peripheral nervous systems are commonly involved in HIV, either as a direct consequence of HIV infection or due to opportunistic diseases. An approach to common presentations is outlined in Figure 12.11.

Cognitive impairment

HIV-associated neurocognitive disorders

HIV is a neurotropic virus and invades the CNS early during infection. Meningo-encephalitis may occur at seroconversion. About 50% of HIV-infected people have abnormal neuropsychiatric testing. The term HIV-associated neurocognitive disorder (HAND) describes a spectrum of disorders: asymptomatic neurocognitive impairment (which is the most common), minor neurocognitive disorder and HIV-associated dementia (also called HIV encephalopathy). The proportion of patients with symptomatic HAND increases with declining CD4 counts. HIV-associated dementia is a subcortical dementia characterised by impairment of executive function, psychomotor retardation and impaired memory. There is no diagnostic test for HIV-associated dementia. CT or magnetic resonance imaging (MRI) shows diffuse cerebral atrophy out of keeping with age. It is important to exclude depression, cryptococcal meningitis and neurosyphilis. ART usually improves HIV-associated dementia but milder forms of HAND often persist.

Progressive multifocal leucoencephalopathy

Progressive multifocal leucoencephalopathy (PML) is a progressive disease that presents with stroke-like episodes and cognitive

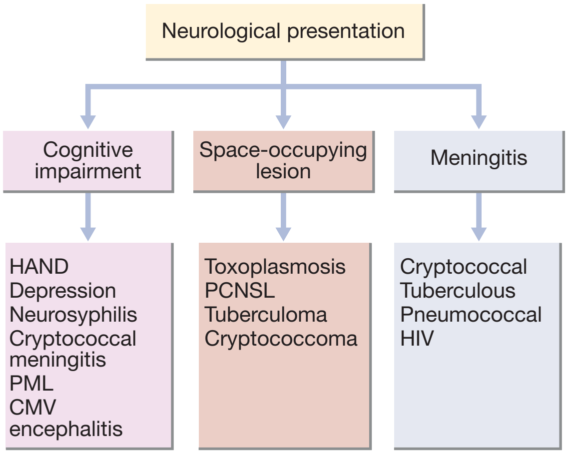

Fig. 12.11 Presentation and differential diagnosis of HIV-related neurological disorders. (CMV = cytomegalovirus; HAND = HIV-associated neurocognitive disorder; PCNSL = primary CNS lymphoma; PML = progressive multifocal leucoencephalopathy)

12

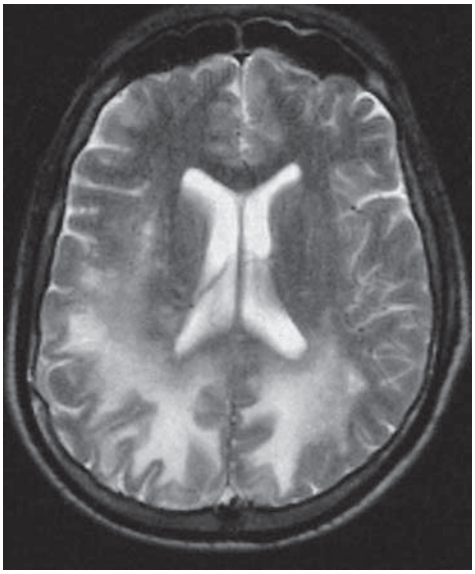

Fig. 12.12 Progressive multifocal leucoencephalopathy. Non-enhancing white-matter lesions without surrounding oedema are seen.

impairment. Vision is often impaired due to involvement of the occipital cortex. PML is caused by the JC virus. A combination of characteristic appearances on MRI (Fig. 12.12) and detection of JC virus DNA in the cerebrospinal fluid (CSF) by PCR is diagnostic. No specific treatment exists and prognosis remains poor despite ART.

CMV encephalitis

This presents with behavioural disturbance, cognitive impairment and a reduced level of consciousness. Focal signs may also occur. Detection of CMV DNA in the CSF supports the diagnosis. Response to anti-CMV therapy is usually poor.

Space-occupying lesions

Space-occupying lesions in AIDS patients typically present over days to weeks. The most common cause is toxoplasmosis. As toxoplasmosis responds rapidly to therapy, a trial of anti-toxoplasmosis therapy should be given to all patients presenting with space-occupying lesions while the results of diagnostic tests are being awaited.

Cerebral toxoplasmosis

Cerebral toxoplasmosis is caused by reactivation of residual *Toxoplasma gondii* cysts from past infection, which results in the development of space-occupying lesions. The characteristic findings on imaging are multiple space-occupying lesions with ring enhancement on contrast and surrounding oedema (Fig. 12.13). *Toxoplasma* serology shows evidence of previous exposure (positive immunoglobulin (Ig)G antibodies); a negative serological test effectively rules out toxoplasmosis but a positive test is not specific. The standard therapy for toxoplasmosis is sulfadiazine with pyrimethamine, together with folinic acid, to reduce the risk of bone marrow suppression (see Box 12.11). However, co-trimoxazole has been shown to be as effective and less toxic, and is also more widely available. Response to a trial of therapy is usually diagnostic, with clinical improvement in 1–2 weeks and shrinkage of lesions on imaging in 2–4 weeks. Definitive diagnosis is by brain biopsy but this is seldom necessary.

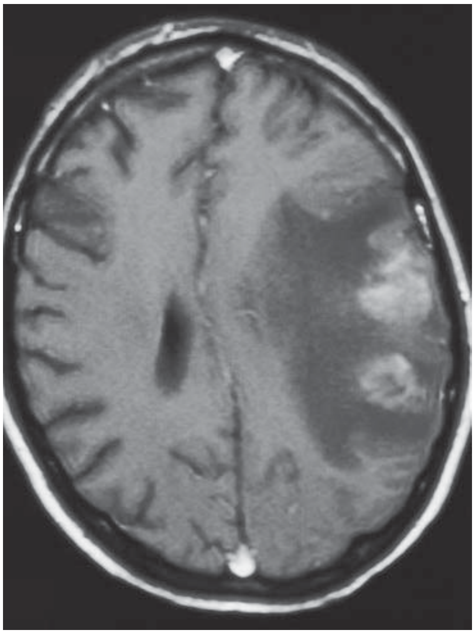

Fig. 12.13 Cerebral toxoplasmosis. Multiple ring-enhancing lesions with surrounding oedema are characteristic.

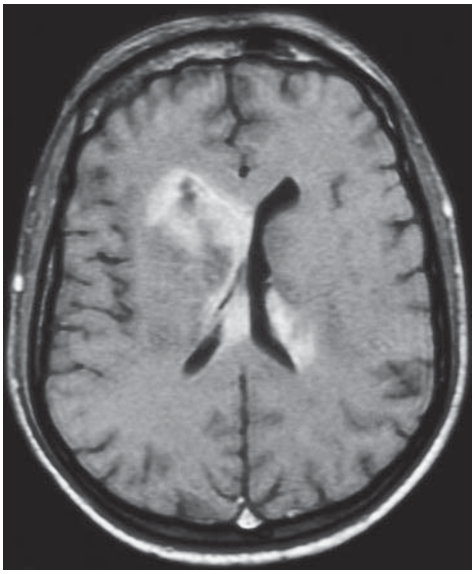

Fig. 12.14 Primary CNS lymphoma. A single enhancing periventricular lesion with moderate oedema is typical.

Primary CNS lymphoma

Primary CNS lymphomas (PCNSLs) are high-grade B-cell lymphomas associated with EBV infection. Characteristically, imaging demonstrates a single homogeneously enhancing, periventricular lesion with surrounding oedema (Fig. 12.14). If it is considered safe to perform a lumbar puncture, PCR for EBV DNA in the CSF has a high sensitivity and specificity for PCNSL. Brain biopsy is definitive but carries a risk of morbidity and may be non-diagnostic in up to one-third. The prognosis is poor.

Tuberculoma

Lesions resemble toxoplasmosis on imaging, except that oedema tends to be less marked and single lesions occur more commonly.

There may be evidence of tuberculosis elsewhere. The CSF may show features consistent with tuberculous meningitis. Response to antituberculosis therapy is slow and paradoxical expansion of lesions despite therapy is not uncommon.

Stroke

There is a higher incidence of stroke in patients with HIV disease. Atherosclerosis is accelerated by the presence of inflammation due to the immune response to HIV, which is not completely suppressed by ART, and by dyslipidaemia caused by some antiretroviral drugs. HIV vasculopathy, which is thought to be a vasculitis, can also cause a stroke. It is important to exclude tuberculous meningitis and meningovascular syphilis in all patients who present with a stroke.

Meningitis

Cryptococcal meningitis

Cryptococcus neoformans is the most common cause of meningitis in AIDS patients. Patients usually present subacutely with headache, vomiting and decreased level of consciousness. Neck stiffness is present in less than half. CSF pleocytosis is often mild or even absent, and protein and glucose concentrations are variable. It is important to request CSF cryptococcal antigen tests in all HIV-infected patients undergoing lumbar puncture, as this test has a high sensitivity and specificity. Treatment is with amphotericin B (plus flucytosine if available) for 2 weeks, followed by fluconazole (see Box 12.11). Raised intracranial pressure is common and should be treated with repeated therapeutic lumbar punctures, removing sufficient CSF to reduce pressure to less than 20 cmH_2O. (Most experts are reluctant to withdraw more than 30 mL at a time.)

Tuberculous meningitis

The presentation and CSF findings of tuberculous meningitis are similar to those in HIV-uninfected patients (p. 1120), except that concomitant tuberculosis at other sites is more common in HIV infection.

Peripheral nerve disease

HIV infection causes axonal degeneration, resulting in a sensorimotor peripheral neuropathy in about one-third of AIDS patients. The incidence increases with lower CD4 counts, older age and increased height. Sensory symptoms predominate. Treatment involves foot care, analgesia and analgesic adjuvants. ART has minimal effect on halting or reversing the process. The NRTIs stavudine and didanosine, now largely abandoned due to their toxicity, can cause drug-induced peripheral neuropathy, which is typically more painful and more rapidly progressive than HIV neuropathy.

Acute inflammatory demyelinating polyneuropathy is an uncommon manifestation, usually occurring in primary infection. It resembles Guillain–Barré syndrome (p. 1140), except that CSF pleocytosis is more prominent. Mononeuritis may also occur, commonly involving the facial nerve.

Myelopathy and radiculopathy

The most common cause of myelopathy in HIV infection is cord compression from tuberculous spondylitis. Vacuolar myelopathy is seen in advanced disease and is due to HIV. It typically presents with a slowly progressive paraparesis with no sensory level. MRI of the spine is normal but is an important investigation to exclude other causes. Most patients have concomitant HIV-associated dementia.

CMV polyradiculitis presents with painful legs, progressive flaccid paraparesis, saddle anaesthesia, absent reflexes and sphincter dysfunction. CSF shows a neutrophil pleocytosis (which is unusual for a viral infection), and the detection of CMV DNA by PCR confirms the diagnosis. Functional recovery is poor despite treatment with ganciclovir or valganciclovir.

Psychiatric disease

Significant psychiatric morbidity is very common and is a major risk factor for poor adherence. Reactive depression is the most common disorder. Diagnosis is often difficult, as many patients have concomitant HAND. Substance misuse is common in many groups of people at risk of HIV. Some antiretroviral drugs can cause psychiatric adverse effects and these are detailed on page 326.

Retinopathy

CMV retinitis presents with painless, progressive visual loss in patients with severe immune suppression. On fundoscopy, the vitreous is clear. Haemorrhages and exudates are seen in the retina (p. 306), often with sheathing of vessels ('frosted branch angiitis'). The disease usually starts unilaterally but progressive bilateral involvement occurs in most untreated patients. Diagnosis is usually clinical, but if there is doubt, demonstrating CMV DNA by PCR of vitreous fluid is diagnostic. Treatment with ganciclovir or valganciclovir stops progression of the disease but lost vision does not recover. Some patients may develop immune recovery uveitis in response to ART, with intraocular inflammation, macular oedema and cataract formation that require prompt treatment with oral and intraocular glucocorticoids to prevent further visual loss.

Three other conditions may mimic CMV retinitis: ocular toxoplasmosis, which typically presents with a vitritis and retinitis without retinal haemorrhages; HIV retinopathy, a microangiopathy that causes cotton wool spots, which are not sight-threatening; and varicella zoster virus, which can cause rapidly progressive outer retinal necrosis.

Rheumatological disease

The immune dysregulation associated with HIV infection may result in autoantibody formation, usually in low titres. Mild arthralgias and a fibromyalgia-like syndrome are common in HIV-infected people.

Arthritis

HIV can cause a seronegative arthritis, which resembles rheumatoid arthritis. A more benign oligoarthritis may also occur. Reactive arthritis is more severe in HIV infection (p. 1031).

Diffuse infiltrative lymphocytosis syndrome

Diffuse infiltrative lymphocytosis syndrome (DILS) is a benign disorder involving polyclonal CD8 lymphocytic infiltration of tissues, which has some features in common with Sjögren's syndrome (p. 1038). It is linked to human leucocyte antigen (HLA)-DRB1. Most patients have a marked CD8 lymphocytosis. DILS usually presents in patients with mild immune suppression. The most common manifestation is bilateral parotid gland enlargement; the glands are often massive, with lymphoepithelial cysts

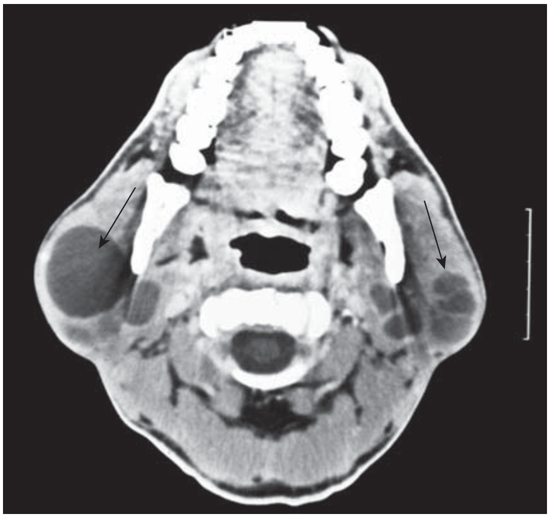

Fig. 12.15 CT scan of parotid glands showing multiple cysts (arrows) in a patient with the diffuse infiltrative lymphocytosis syndrome.

on histology (Fig. 12.15). Sicca symptoms are common but usually mild. Lymphocytic interstitial pneumonitis is the most common manifestation outside the salivary glands. Generalised lymphadenopathy may occur, with nodes larger than those seen with persistent generalised lymphadenopathy of HIV. Hepatitis, mononeuritis, polyarthritis and polymyositis may also occur. The manifestations outside the salivary glands usually respond to systemic glucocorticoids. Parotid gland enlargement may be treated by aspiration of parotid cysts and instillation of a sclerosant for cosmetic reasons, and surgery is best avoided. DILS may regress on ART but response is variable.

Haematological abnormalities

Disorders of all three major cell lines may occur in HIV. In advanced disease, haematopoiesis is impaired due to the direct effect of HIV and by cytokines. Pancytopenia may occur as a consequence of HIV but it is important to exclude a disorder infiltrating the bone marrow, such as mycobacterial or fungal infections, or lymphoma.

Anaemia

Normochromic, normocytic anaemia is very common in advanced HIV disease. Opportunistic diseases may cause anaemia of chronic disease (e.g. tuberculosis) or marrow infiltration (e.g. MAC, tuberculosis, lymphoma, fungi). Anaemia is a common adverse effect of zidovudine, which also causes a macrocytosis. Red cell aplasia is rare and may be caused either by parvovirus B19 infection or by lamivudine.

Neutropenia

Isolated neutropenia is occasionally due to HIV but is nearly always caused by drug toxicity (e.g. zidovudine, co-trimoxazole, ganciclovir).

Thrombocytopenia

Mild thrombocytopenia is common in HIV-infected people. Transient thrombocytopenia is frequently found in primary infection. The most common disorder causing severe thrombocytopenia is immune-mediated platelet destruction resembling idiopathic thrombocytopenic purpura (p. 971). This responds to glucocorticoids or intravenous immunoglobulin, together with ART. Splenectomy should be avoided if possible because it further increases the risk of infection with encapsulated bacteria. Severe thrombocytopenia with a microangiopathic anaemia also occurs in a thrombotic thrombocytopenic purpura-like illness (p. 979), which has a better prognosis and fewer relapses than the classical disease.

Renal disease

Acute kidney injury is common, usually due to acute infection or nephrotoxicity of drugs (e.g. tenofovir (p. 412), amphotericin B (p. 126)) HIV-associated nephropathy (HIVAN) is the most important cause of chronic kidney disease (CKD) and is seen most frequently in patients of African descent and those with low CD4 counts. Progression to end-stage disease is more rapid than with most other causes of CKD, and renal size is usually preserved. HIVAN presents with nephrotic syndrome, CKD or a combination of both. ART has some effect in slowing progression of HIVAN. Other important HIV-associated renal diseases include HIV immune complex kidney diseases and thrombotic microangiopathy. With the overall improvement in life expectancy from ART, conditions such as diabetes mellitus, hypertension and vascular disease add to the burden of CKD. Outcomes of renal transplantation are good in patients on ART.

Cardiac disease

HIV-associated cardiomyopathy resembles idiopathic dilated cardiomyopathy (p. 539) but progresses more rapidly. ART may improve cardiac failure but does not reverse established cardiomyopathy. Pericardial disease due to opportunistic diseases is not uncommon. Globally, the most common cause is tuberculous pericardial effusions. Tuberculous constrictive pericarditis is less common than in HIV-uninfected people. KS and lymphoma may cause pericardial effusions. Septic pericarditis, usually due to *S. pneumoniae*, is uncommon.

HIV is associated with an increased risk of myocardial infarction due to accelerated atherogenesis caused by the inflammatory state, which is not completely suppressed by ART, and by dyslipidaemia caused by some antiretroviral drugs.

HIV-related cancers

The AIDS-defining cancers are KS (see above), cervical cancer and non-Hodgkin lymphoma (NHL, p. 964). NHL may occur at any CD4 count but is more commonly seen with counts below 200 cells/mm^3. Almost all NHLs are B-cell tumours and most are stage 3 or 4. Long-term remission rates similar to those in patients without HIV can be achieved with NHL in AIDS patients using ART and chemotherapy (including the anti-B-cell monoclonal antibody rituximab if it is a B-cell tumour).

The incidence of a number of other cancers induced by viruses is also increased in HIV-infected people (Box 12.14). Regular cytological examination of the cervix, and of the anus in people who practise anal sex, should be performed to detect pre-malignant lesions, which are easier to treat. In general, the incidence of cancers that are not induced by viruses is similar to that in the general population.

12.14 Approximate incidence ratio of virus-related cancers compared to the general population

Viral cancers	Incidence ratio
Human herpesvirus 8-related	
Kaposi's sarcoma	3600
Epstein–Barr virus-related	
Non-Hodgkin lymphoma	80
Hodgkin lymphoma	10
Human papillomavirus-related	
Cervical cancer	6
Vulval cancer	6
Anal cancer	30
Penile cancer	4
Hepatitis B/C virus-related	
Hepatocellular carcinoma	5

Prevention of opportunistic infections

The best way to prevent opportunistic infections is to improve the CD4 count with ART. However, infections continue to occur in the ART era as CD4 counts take time to improve if ART is initiated in patients with profound immune suppression, immune reconstitution on ART is often suboptimal, and CD4 counts may decline because antiretroviral resistance develops.

Preventing exposure

The best method for avoiding infection is to prevent exposure to the infectious agent. This is possible only for a few opportunistic infections, however. Furthermore, many opportunistic infections occur after reactivation of latent/dormant infection after prior exposure; examples include herpes simplex virus, zoster (shingles), CMV, toxoplasmosis, cryptococcosis and the endemic mycoses.

Safe water and food

Cryptosporidiosis, microsporidiosis and cystoisosporiasis may be water-borne. If there is no access to safe water, then water should be boiled before drinking. Food-borne illnesses are also important in HIV infection, notably *Salmonella* species. *Toxoplasma* exposure is related to eating raw or undercooked meat. People living with HIV infection need to be informed about food hygiene and the importance of adequately cooked meat.

Tuberculosis

Preventing exposure to tuberculosis is important when there is an infectious case in the household, in clinics and in hospitals. Adequate ventilation, masks and safe coughing procedures reduce the risk of exposure.

Malaria vector control

All HIV-infected individuals living in malarious areas should practise vector control, as malaria occurs more frequently and is more severe in HIV-infected people. The most cost-effective way to achieve this is by using insecticide-impregnated bed nets. Other modalities of vector control that are of benefit to the community, such as reducing standing water and spraying with residual insecticides and larvicides, should also be implemented.

Safer sex

HIV-infected individuals should practise safer sex in order to reduce the transmission of HIV. Even if their partners are HIV-infected, condoms should be used, as HIV mutants that have developed antiretroviral drug resistance can be transmitted. Safer sex will also lower the risk of acquiring herpes simplex virus and human herpesvirus 8.

Pets

Toxoplasma gondii can be acquired from kittens or cat litter, and people living with HIV infection should avoid handling either. Cryptosporidiosis can be transmitted from animals, and patients should be advised to wash their hands after handling animals.

Chemoprophylaxis

Chemoprophylaxis is the use of antimicrobial agents to prevent infections. Primary prophylaxis is used to prevent opportunistic infections that have not yet occurred. Secondary prophylaxis is used to prevent recurrence of opportunistic infections because many may recur after an initial response to therapy (see Box 12.11). Secondary prophylaxis can be discontinued when ART results in immune reconstitution, with CD4 counts increasing to over 200 cells/mm^3, but for CMV and MAC, prophylaxis can be stopped if CD4 counts increase to more than 100 cells/mm^3.

12

Co-trimoxazole primary prophylaxis

Co-trimoxazole reduces the incidence of a number of opportunistic infections (Box 12.15), resulting in lower hospitalisation and mortality rates. The indications for initiating co-trimoxazole are either clinical evidence of immune suppression (WHO clinical stages 3 or 4) or laboratory evidence of immune suppression (CD4 count <200 cells/mm^3). In low-income countries where malaria and/or severe bacterial infections are highly prevalent, the WHO recommends initiating co-trimoxazole regardless of CD4 counts or clinical stage. The recommended dose of co-trimoxazole is 960 mg daily, but trials have shown that half this dose is as effective and may be associated with less toxicity. Co-trimoxazole prophylaxis can be discontinued when CD4 counts increase to more than 200 cells/mm^3 on ART, except in low-income countries where it should be continued life-long.

Co-trimoxazole prophylaxis is well tolerated. The most common side-effect is hypersensitivity, causing a maculo-papular rash. If therapy is discontinued, desensitisation or rechallenge under antihistamine cover should be attempted, unless the rash was accompanied by systemic symptoms or mucosal involvement. Prophylactic doses of co-trimoxazole can also cause neutropenia, but this is very uncommon and routine monitoring of blood counts is not necessary. If co-trimoxazole cannot be tolerated, then

12.15 Opportunistic infections reduced by co-trimoxazole

- *Pneumocystis jirovecii* pneumonia
- Cerebral toxoplasmosis
- Bacterial pneumonia
- Bacteraemia
- Cystoisosporiasis
- Malaria

dapsone 100 mg daily should be substituted. Dapsone is equally effective at reducing the incidence of *P. jirovecii* pneumonia, but has little or no effect on reducing the other opportunistic infections prevented by co-trimoxazole.

Tuberculosis preventive therapy

Trials in patients not on ART showed that preventive therapy, either with isoniazid or combinations of rifamycins with isoniazid, reduces the risk of tuberculosis only in HIV-infected patients with a positive tuberculin skin test. In HIV infection, induration of 5 mm or more on a Mantoux test is regarded as positive. Recent evidence indicates that tuberculin skin tests do not predict benefit in patients starting ART or established on ART in high tuberculosis prevalence settings.

There is no CD4 count or clinical threshold for starting or stopping tuberculosis preventive therapy. It is important to rule out active tuberculosis before starting preventive therapy, and symptom screening has been shown to be adequate to achieve this (Box 12.16). The usual duration of isoniazid preventive therapy is 6 months but this does not provide long-term reduction in the risk of tuberculosis. Isoniazid for 36 months has been shown to be much more effective in people with a positive tuberculin skin test. Rifampicin or rifapentine combined with isoniazid for 12 weeks has been shown to be at least as effective as 6–12 months of isoniazid.

Mycobacterium avium complex prophylaxis

In high-income countries, a macrolide (azithromycin or clarithromycin) is recommended to prevent MAC in patients with a CD4 count below 50 cells/mm^3, which can be discontinued once the CD4 count has risen to over 100 cells/mm^3 on ART. MAC is uncommon in low- and middle-income countries and primary prophylaxis is thus not warranted.

Preventing cryptococcosis

Serum cryptococcal antigen test should be done in patients with a CD4 count below 100 cells/mm^3. If this is positive, pre-emptive therapy with fluconazole should be commenced.

Immunisation

There are significant problems associated with vaccination in HIV infection. Firstly, vaccination with live organisms is contraindicated in patients with severe immune suppression, as this may result in disease from the attenuated organisms. Secondly, immune responses to vaccination are impaired in HIV-infected patients. If the CD4 count is below 200 cells/mm^3, then immune responses to immunisation are very poor. Therefore it is preferable to wait until the CD4 count has increased to more than 200 cells/mm^3 on ART before immunisation is given, and essential if live virus vaccines are used. All patients should be given a conjugate pneumococcal vaccine and annual influenza vaccination. Hepatitis B vaccination should be given to those who are not immune. In the UK, the following additional vaccines are also recommended:

- *hepatitis A*: in those at risk
- *human papillomavirus*: in people <40 years old
- *measles, mumps and rubella (MMR)*: in those with negative measles serology
- *meningococcus*: in people <25 years old, those with asplenia or complement deficiency, during outbreaks
- *diphtheria/tetanus/acellular pertussis (dTaP)/inactivated poliovirus vaccine (IPV)*: meeting general indications
- *chickenpox*: if seronegative; those who are seropositive should receive the shingles vaccine.

Bacille Calmette–Guérin (BCG) is contraindicated in all HIV-infected people.

12.16 Symptom screen for tuberculosis before isoniazid preventive therapy

All of the following must be absent:
- Active cough
- Night sweats
- Weight loss
- Fever

Antiretroviral therapy

ART has transformed HIV from a progressive illness with a fatal outcome into a chronic manageable disease with a near-normal life expectancy.

The goals of ART are to:

- reduce the viral load to an undetectable level for as long as possible
- improve the CD4 count to over 200 cells/mm^3 so that severe HIV-related disease is unlikely
- improve the quantity and quality of life without unacceptable drug toxicity
- reduce HIV transmission.

Many of the antiretroviral drugs that were initially used have largely been abandoned because of toxicity or poor efficacy. The drugs that are currently recommended are shown in Box 12.17, and their targets in the HIV life cycle in Figure 12.1.

Selecting antiretroviral regimens

The standard combination antiretroviral regimens are two NRTIs together with an NNRTI, protease inhibitor (PI) or integrase inhibitor. Dual NRTI combinations are usually emtricitabine or lamivudine (they have the same mechanism of action and so are never combined), together with one of abacavir, tenofovir or zidovudine. It is possible to construct effective regimens without NRTIs if there is intolerance or resistance to the NRTIs. Currently used PIs should always be administered with ritonavir, which

12.17 Commonly used antiretroviral drugs

Classes	Drugs
Nucleoside reverse transcriptase inhibitors (NRTIs)	Abacavir, emtricitabine, lamivudine, tenofovir, zidovudine*
Non-nucleoside reverse transcriptase inhibitors (NNRTIs)	Efavirenz*, rilpivirine (only if viral load <100 000)
Protease inhibitors (PIs)	Atazanavir, darunavir, lopinavir*
Integrase inhibitors	Raltegravir, dolutegravir, elvitegravir
Chemokine receptor inhibitor	Maraviroc

*These drugs are no longer recommended as first-line options in high-income countries due to their toxicity.

itself is a PI that is toxic in therapeutic doses. Low doses of ritonavir dramatically increase the concentrations and elimination half-lives of other PIs by inhibiting the efflux pump P-glycoprotein and the cytochrome P450 isoenzyme CYP3A.

Most guidelines from high-income countries, including the UK, allow clinicians to choose a starting regimen of dual NRTIs combined with an NNRTI, or a PI or an integrase inhibitor, as these three regimens have similar efficacy. Subsequent ART regimen switches for virological failure are guided by the results of resistance testing (see below). For low- and middle-income countries, the WHO recommends a public health approach to using ART with standardised first-line (NNRTI plus dual NRTIs) and second-line (ritonavir-boosted PI plus dual NRTIs) regimens. NNRTIs are preferred by the WHO in first-line regimens, as they are cheaper than PIs and better tolerated. Furthermore, NNRTIs need to be given with two fully active NRTIs because they have a low genetic barrier to resistance (see below), whereas PI-containing regimens are effective even when there are some mutations conferring resistance to the NRTIs. PIs in second-line regimens are therefore preferable in settings where resistance testing is not widely available. The public health approach to using ART can be implemented by nurses and has been successfully applied in resource-poor settings.

Criteria for starting ART

Guidelines now recommend starting ART in all people with confirmed HIV infection, irrespective of CD4 count or clinical status. Early initiation of ART, compared with the previous strategy of deferring ART until CD4 thresholds or clinical disease occurs, has been shown to reduce morbidity and mortality, and has the additional benefit of reducing the risk of transmission.

It is seldom necessary to start ART urgently. Several consultations are required to give patients insight into the need for life-long ART, to stress the importance of adherence and to formulate a personal treatment plan. Disclosure of HIV status, joining support groups and using patient-nominated treatment supporters should be encouraged, as these have been shown to improve adherence. Recognition and management of depression and substance abuse is also important.

In patients with major opportunistic infections, ART should generally be started within 2 weeks, with two important exceptions: in cryptococcal meningitis, ART should be deferred for 5 weeks, as earlier initiation increases the risk of death; and in tuberculosis, ART should be deferred until 8 weeks (except if the CD4 count is <50 cells/mm^3), as earlier initiation increases the risk of the immune reconstitution inflammatory syndrome (see below).

Monitoring efficacy

The most important measure of ART efficacy is the viral load. A baseline viral load should be measured prior to initiating treatment. Viral load measurement should be repeated 4 weeks after starting ART, when there should be at least a 10-fold decrease. The viral load should be suppressed after 6 months. Once the viral load is suppressed, measurement should be repeated 6-monthly. Failure of ART is defined by the viral load becoming detectable after suppression. In most guidelines, a viral load threshold is used to define virological failure, e.g. more than 200 (UK) or more than 1000 (WHO) copies/mL. Adherence support should be enhanced if virological failure is detected, and measurement of the viral load repeated to confirm failure before switching to a new ART regimen.

CD4 counts are generally monitored every 6 months together with the viral load, but there is little point in repeating the CD4 count in patients who maintain virological suppression and whose CD4 count is >350 cells/mm^3. The CD4 count increases rapidly in the first month, followed by a more gradual increase. In the first year, the CD4 count typically increases by 100–150 cells/mm^3, and about 80 cells/mm^3 per annum thereafter until the reference range is reached, provided the viral load is suppressed. However, CD4 responses are highly variable: in about 15–30% of patients the CD4 count does not increase despite virological suppression, and in a similar proportion of patients the CD4 response is good despite the presence of virological failure. If ART is stopped, the CD4 count rapidly falls to the baseline value before ART was commenced.

Antiretroviral resistance

Reverse transcription is error-prone, generating a large number of mutations. If the viral load is suppressed on ART, viral replication is suppressed and resistance mutations will not be selected. If ART is taken and there is ongoing replication, due to either resistant mutations or suboptimal adherence, mutations conferring resistance to antiretroviral drugs will be selected. Antiretroviral drugs differ in their ability to select for resistant mutations. Some drugs (e.g. emtricitabine, lamivudine, efavirenz) have a low genetic barrier to resistance, rapidly selecting for a single mutation conferring high-level resistance. PIs and some NRTIs (e.g. zidovudine) select for resistance mutations slowly, and multiple resistant mutations often need to accumulate before the drug's efficacy is lost. Patients who develop antiretroviral resistance may transmit resistant virus to others and will eventually develop clinical failure.

Antiretroviral resistance is assessed by sequencing the relevant viral genes to detect mutations that are known to confer resistance. The patient must be taking ART when the test is performed, as otherwise the wild-type virus will predominate and resistant mutations will not be detected. The resistant proviral DNA is archived in latent CD4 cells and will re-emerge rapidly on re-exposure to the antiretroviral. In regions where resistance testing is affordable, it is recommended at baseline (to detect primary resistance) and at every confirmed virological failure, in order to select the most appropriate antiretrovirals in a new regimen.

ART complications

Immune reconstitution inflammatory syndrome

Immune reconstitution inflammatory syndrome (IRIS) is a common early complication of ART, especially in patients who start ART with CD4 counts below 50 cells/mm^3. IRIS presents either with paradoxical deterioration of an existing opportunistic disease (including infections that are responding to appropriate therapy) or with the unmasking of a new infection. The clinical presentation of IRIS events is often characterised by an exaggerated immune response, with pronounced inflammatory features. For example, patients with CMV retinitis developing IRIS on ART develop a uveitis; inflammatory haloes occur around KS lesions. Paradoxical tuberculosis IRIS events are common but it is important to exclude multidrug resistance, which could be responsible for the deterioration. IRIS is associated with a mortality of around 5% but this is higher when it complicates CNS infections.

The management of IRIS is to continue ART and to ensure that the opportunistic disease is adequately treated. Symptomatic treatments are helpful. Glucocorticoids are often used for more severe IRIS manifestations but they should not be given to patients with KS, as this can result in rapid progression of KS lesions.

Lipodystrophy

Long-term use of ART is associated with changes in body fat distribution called lipodystrophy, which can present either with fat accumulation (e.g. visceral fat, 'buffalo hump') or with subcutaneous fat loss ('lipoatrophy', Fig. 12.16), or with both fat loss and accumulation. The thymidine analogue NRTIs (stavudine and, to a lesser extent, zidovudine) are associated with fat loss. Switching to the non-thymidine NRTIs, abacavir or tenofovir, will result in very gradual improvement of lipoatrophy.

Previously, PIs were thought to be the cause of fat accumulation. However, recent studies have shown that all classes of antiretrovirals are associated with fat gain to a similar extent, and visceral adiposity is similar to that seen in the general population. Although not yet fully resolved, the current weight of evidence is that fat gain on ART is a return to normal by treating HIV infection.

12.18 HIV infection in old age

- **Epidemiology**: the HIV-infected population is ageing due to the life-prolonging effects of ART.
- **Immunity**: age-related decline increases the risk of infections. CD4 counts decline more rapidly as age extends beyond 40 years, resulting in faster disease progression. CD4 responses to ART decrease with increasing age.
- **Dementia**: HIV causes cerebral atrophy and neurocognitive disorders; dementia is therefore more common and more severe than in the HIV-uninfected elderly.
- **Vascular disease**: HIV is associated with an increased risk, exacerbated by some antiretrovirals that increase the risk of vascular disease by causing dyslipidaemia or insulin resistance.
- **Polypharmacy**: treatment of co-morbidities is complex due to the many drug interactions with antiretrovirals.

Fig. 12.16 Fat loss complicating long-term use of the thymidine analogue NRTIs stavudine and zidovudine.

Hypersensitivity rashes

These are common but must be differentiated from the other causes described on page 314. The NRTI abacavir typically causes a systemic hypersensitivity reaction, which is limited to people with HLA-B*5701, about 50% of whom will develop a hypersensitivity reaction. HLA testing should be done before abacavir is given and the drug should not be prescribed for people who are HLA-B*5701-positive, which is rare in people of African descent. Rechallenge must never be attempted after abacavir hypersensitivity, as fatal reactions may occur.

Drug rashes are very common with NNRTIs. When the NNRTI rash is mild and not accompanied by systemic involvement, the suspected drug is often continued and antihistamines are administered. The rash usually resolves. If it worsens or if systemic features develop, the NNRTI should be discontinued.

Other adverse effects

The NNRTI efavirenz causes insomnia, agitation, euphoria or dysphoria in many patients but tolerance to its neuropsychiatric effects develops in a few weeks in most patients. The NRTI zidovudine can cause anaemia and neutropenia, and tenofovir may cause nephrotoxicity and loss of bone mineral density. Some PIs are associated with dyslipidaemias and may increase the risk of myocardial infarction.

ART in special situations

Pregnancy

All pregnant women should have HIV testing at an early stage in pregnancy. The CD4 count falls by about 25% during pregnancy due to haemodilution. The course of HIV disease progression is not altered by pregnancy. In the pre-ART era, the rate of mother-to-child transmission was 15–40%, with rates being influenced by several factors (see Box 12.3).

ART has dramatically reduced the risk of mother-to-child transmission of HIV to less than 1%. All pregnant women should start ART at the beginning of the second trimester, unless they have advanced disease, when ART should be started in the first trimester.

Caesarean section is associated with a lower risk of mother-to-child transmission than vaginal delivery, but the mode of delivery does not affect transmission risk if the viral load is suppressed on ART.

HIV is also transmitted by breastfeeding. In high-income countries, exclusive formula feeding is generally recommended. In resource-poor settings, however, formula feeding is associated with a risk of infant morbidity and mortality, which may negate the benefit of not transmitting HIV to the infant. There is minimal risk of transmitting HIV by breastfeeding in women with a suppressed viral load on ART. Furthermore, providing antiretrovirals to infants (usually nevirapine monotherapy) while they are breastfeeding has been shown to reduce the risk of transmission. Breastfeeding is therefore now encouraged in resource-poor settings. Infants should be exclusively breastfed for the first 6 months, as mixed

feeding (with formula or solids) is associated with a higher risk of transmission.

Diagnosis of HIV in infancy requires the detection of HIV RNA by PCR, as maternal antibodies to HIV, which persist for up to 15 months, will give a false-positive result on antibody assays. PCR should ideally be carried out within 6 weeks of birth to facilitate early ART initiation. If the baby is breastfed, the PCR should be repeated 2 weeks after weaning.

Prevention of HIV

An effective HIV vaccine remains elusive due to the extensive genetic diversity of HIV and the lack of a safe attenuated virus. Measures for the prevention of HIV transmission are shown in Box 12.19.

Pre-exposure prophylaxis

Pre-exposure prophylaxis (PrEP) with daily tenofovir plus emtricitabine has been shown to reduce the risk of HIV acquisition in people at ongoing high risk (e.g. from sex or injecting drug use) and is well tolerated. Regular HIV testing should be done in people on PrEP.

Post-exposure prophylaxis

Post-exposure prophylaxis (PEP) is recommended when the risk is deemed to be significant after a careful risk assessment, in both occupational and non-occupational settings. The first dose should be given as soon as possible, preferably within 6–8 hours. There is no point in starting PEP after 72 hours. Tenofovir together with emtricitabine is the most widely used dual NRTI combination, together with either a PI or an integrase inhibitor. PEP should not be given if the exposed person is HIV-infected. HIV antibody testing should be performed at 3 months after exposure.

i 12.19 Prevention measures for HIV transmission

Sexual

- Sex education programmes in schools
- Easily accessible voluntary counselling and testing centres
- Promotion of safer sex practices (delaying sexual debut, condom use, fewer sexual partners)
- Effective ART for HIV-infected individuals
- Pre-exposure prophylaxis for high-risk groups
- Male circumcision
- Post-exposure prophylaxis

Parenteral

- Blood product transmission: donor questionnaire, routine screening of donated blood
- Injection drug use: education, needle/syringe exchange, avoidance of 'shooting galleries', methadone maintenance programmes

Perinatal

- Routine 'opt-out' antenatal HIV antibody testing
- Measures to reduce vertical transmission (see text)

Occupational

- Education/training: universal precautions, needlestick injury avoidance
- Post-exposure prophylaxis

i Investigations for STIs in heterosexual males

- First-void urine (FVU)* is the specimen of choice for the combined nucleic acid amplification test (NAAT) for gonorrhoea and chlamydia
- Alternatively, for gonorrhoea, a urethral swab plated directly on a selective medium such as modified New York City (MNYC), or sent in an appropriate transport medium, can be cultured to allow for assessment of antimicrobial sensitivities
- Serological test for syphilis (STS), e.g. enzyme immunoassay (EIA) for antitreponemal immunoglobulin G (IgG) antibody
- Human immunodeficiency virus (HIV) test (see note)

*A urethral swab can be submitted if the patient is unable to pass urine.

i Investigations for STIs in men who have sex with men

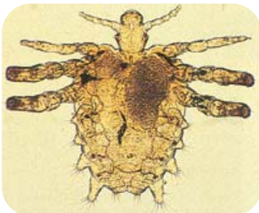
- FVU*, and pharyngeal and rectal swabs for combined NAAT for gonorrhoea and chlamydia
- STS (repeat testing may be necessary in the event of negative test results in the first few weeks following exposure)
- Serological tests for hepatitis A/B (with a view to vaccination if seronegative)
- HIV test (see note)

*A urethral swab can be submitted if the patient is unable to pass urine.

HIV testing

It should always be standard practice to offer HIV testing as part of screening for sexually transmitted infection (STI) because the benefits of early diagnosis outweigh other considerations. Extensive pre-test counselling is not required in most instances, but it is important to establish efficient pathways for referral of patients at high risk for whom the clinician wishes specialist support, and for those diagnosed as HIV-positive.

Clinical examination in women



4 Labia majora and minora

13

i Investigations for STIs in women

- Self-taken vaginal swab, or clinician-obtained cervical or vaginal swab, for combined NAAT for gonorrhoea and chlamydia
- Alternatively, for gonorrhoea, cervical and urethral swabs plated directly on a selective medium such as MNYC, or sent in appropriate transport medium, can be cultured to allow for assessment of antimicrobial sensitivities
- Wet mount for microscopy or high vaginal swab (HVS) for culture of *Trichomonas*
- STS, e.g. EIA for antitreponemal IgG antibody
- HIV test (see note)

i Management goals in suspected STI

- Relief of any symptoms
- Screening for treatable STI that may not be causing symptoms
- Tracing and treatment of sexual contacts who may also be infected
- Advice to reduce risk of infection in the future

i Those at particular risk from STIs*

- Sex workers, male and female
- Clients of sex workers
- Men who have sex with men
- Injecting drug users (sex for money or drugs) and their partners
- Frequent travellers

*Adapted from WHO/UNAIDS, 1997.

Sexually transmitted infections (STIs) are a group of contagious conditions whose principal mode of transmission is by intimate sexual activity involving the moist mucous membranes of the penis, vulva, vagina, cervix, anus, rectum, mouth and pharynx, along with their adjacent skin surfaces. A wide range of infections may be sexually transmitted, including syphilis, gonorrhoea, human immunodeficiency virus (HIV), genital herpes, genital warts, chlamydia and trichomoniasis. Bacterial vaginosis and genital candidiasis are not regarded as STIs, although they are common causes of vaginal discharge in sexually active women. Chancroid, lymphogranuloma venereum (LGV) and granuloma inguinale are usually seen in tropical countries. Hepatitis viruses A, B, C and D (p. 871) may be acquired sexually, as well as by other routes. Although primarily transmitted by mosquito bite, cases of male-to-female sexual transmission of Zika virus have been described and the virus is known to persist in semen for several months (p. 247).

The World Health Organization (WHO) estimates that 357 million curable STIs (*Trichomonas vaginalis*, *Chlamydia trachomatis*, gonorrhoea and syphilis) occur worldwide each year. In the UK in 2014, the most common treatable STIs diagnosed were chlamydia (220 000 cases) and gonorrhoea (nearly 40 000 cases). Genital warts are the second most common complaint seen in genitourinary medicine (GUM) departments. In addition to causing morbidity themselves, STIs may increase the risk of transmitting or acquiring HIV infection (Ch. 12).

As coincident infection with more than one STI is seen frequently, GUM clinics routinely offer a full set of investigations at the patient's first visit (pp. 330–331), regardless of the reason for attendance. In other settings, less comprehensive investigation may be appropriate.

The extent of the examination largely reflects the likelihood of HIV infection or syphilis. Most heterosexuals in the UK are at such low risk of these infections that routine extragenital examination is unnecessary. This is not the case in parts of the world where HIV is endemic, or for men who have sex with men (MSM) in the UK. In other words, the extent of the examination is determined by the sexual history (Box 13.1).

Approach to patients with a suspected STI

Patients concerned about the possible acquisition of an STI are often anxious. Staff must be friendly, sympathetic and reassuring; they should have the ability to put patients at ease, while emphasising that clinic attendance is confidential. The history focuses on genital symptoms, with reference to genital ulceration, rash, irritation, pain, swelling and urinary symptoms, especially dysuria. In men, the clinician should ask about urethral discharge, and in women, vaginal discharge, pelvic pain or dyspareunia. Enquiry about general health should include menstrual and obstetric history, cervical cytology, recent medication, especially with antimicrobial or antiviral agents, previous STI and allergy. Immunisation status for hepatitis A and B should be noted, as should information about alcohol intake and recreational drug use. Some MSM use new psychoactive substances (NPS), formerly referred to in the UK as 'legal highs', to enhance their sexual experience. Often described as 'chemsex', this has been associated with outbreaks of infections including syphilis, LGV and hepatitis C.

A detailed sexual history is imperative (Box 13.1), as this informs the clinician of the degree of risk for certain infections, as well as specific sites that should be sampled; for example, rectal samples should be taken from men who have had unprotected anal sex with other men. Sexual partners, whether male or female, and casual or regular, should be recorded. Sexual practices – insertive or receptive vaginal, anal, orogenital or oroanal – should be noted, as should choice of contraception for women, and condom use for both sexes.

STI during pregnancy

Many STIs can be transmitted from mother to child in pregnancy, either transplacentally or during delivery. Possible outcomes are highlighted in Box 13.2.

STI in children

The presence of an STI in a child may be indicative of sexual abuse, although vertical transmission may explain some presentations in the first 2 years. In an older child and in adolescents, STI may

13.1 How to take a sexual history

- In your lifetime, have your sexual partners been male, female or both?
- Do you have a regular sexual partner at present?
- If yes:
  - How long have you been together?
  - When did you last have sex with anyone else?
- If no:
  - When did you last have sex?
  - Was this a regular or a casual partner?
- Do/did you use a condom?

13.2 Possible outcomes of STI in pregnancy

Organism	Mode of transmission	Outcome for fetus/neonate	Outcome for mother
Treponema pallidum	Transplacental	Ranges from no effect to severe stigmata or miscarriage/stillbirth	None directly relating to the pregnancy
Neisseria gonorrhoeae	Intrapartum	Severe conjunctivitis	Possibility of ascending infection postpartum
Chlamydia trachomatis	Intrapartum	Conjunctivitis, pneumonia	Possibility of ascending infection postpartum
Herpes simplex	Usually intrapartum, but transplacental infection may occur rarely	Ranges from no effect to severe disseminated infection	Rarely, primary infection during 2nd/3rd trimesters becomes disseminated, with high maternal mortality
Human papillomaviruses	Intrapartum	Anogenital warts or laryngeal papillomas are very rare	Warts may become more florid during pregnancy, but usually regress postpartum

be the result of voluntary sexual activity. Specific issues regarding the management of STI and other infections in adolescence are discussed in Box 11.25 (p. 235).

Presenting problems in men

Urethral discharge

In the UK the most important causes of urethral discharge are gonorrhoea and chlamydia. In a significant minority of cases, tests for both of these infections are negative, a scenario often referred to as non-specific urethritis (NSU). Some of these cases may be caused by *Trichomonas vaginalis*, herpes simplex virus (HSV), mycoplasmas, ureaplasmas or adenoviruses. A small minority seem not to have an infectious aetiology.

Gonococcal urethritis usually causes symptoms within 7 days of exposure. The discharge is typically profuse and purulent. Chlamydial urethritis has an incubation period of 1–4 weeks, and tends to result in milder symptoms than gonorrhoea; there is overlap, however, and microbiological confirmation should always be sought.

Investigations

A presumptive diagnosis of urethritis can be made from a Gram-stained smear of the urethral exudate (Fig. 13.1), which will demonstrate significant numbers of polymorphonuclear leucocytes (≥5 per high-power field). A working diagnosis of gonococcal urethritis is made if Gram-negative intracellular diplococci (GNDC) are seen; if no GNDC are seen, a label of NSU is applied.

If microscopy is not available, urine samples and/or swabs should be taken and empirical antimicrobials prescribed. A first-void urine (FVU) sample should be submitted for a combined nucleic acid amplification test (NAAT) for gonorrhoea and chlamydia; a urethral swab is an alternative if the patient cannot pass urine. When gonorrhoea is suspected, a urethral swab should be sent for culture and antimicrobial sensitivities of *Neisseria gonorrhoeae*. Tests for other potential causes of urethritis are not performed routinely.

A swab should also be taken from the pharynx because gonococcal infection here is not reliably eradicated by single-dose therapy. In MSM, swabs for gonorrhoea and chlamydia should be taken from the rectum.

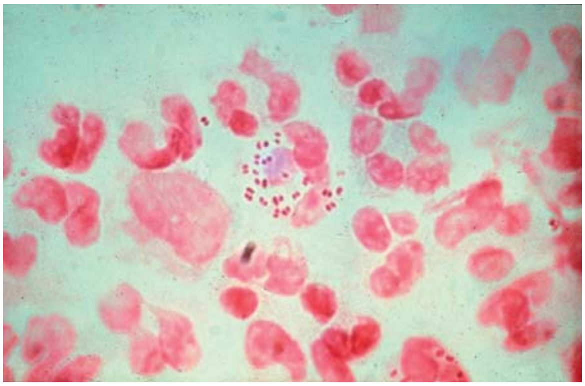

Fig. 13.1 A Gram-stained urethral smear from a man with gonococcal urethritis. Gram-negative diplococci are seen within polymorphonuclear leucocytes.

Management

This depends on local epidemiology and the availability of diagnostic resources. Treatment is often presumptive, with prescription of multiple antimicrobials to cover the possibility of gonorrhoea and/or chlamydia. This is likely to include a single-dose treatment for gonorrhoea, which is desirable because it eliminates the risk of non-adherence. The recommended agents for treating gonorrhoea vary according to local antimicrobial resistance patterns (p. 340). Appropriate treatment for chlamydia (p. 340) should also be prescribed because concurrent infection is present in up to 50% of men with gonorrhoea. Non-gonococcal, non-chlamydial urethritis is treated as for chlamydia.

Patients should be advised to avoid sexual contact until it is confirmed that any infection has resolved and, whenever possible, recent sexual contacts should be traced. The task of contact tracing – also called partner notification – is best performed by trained nurses based in GUM clinics; it is standard practice in the UK to treat current sexual partners of men with gonococcal or non-specific urethritis without waiting for microbiological confirmation.

If symptoms clear, a routine test of cure is not necessary, but patients should be re-interviewed to confirm that there was no immediate vomiting or diarrhoea after treatment, that there has been no risk of reinfection, and that traceable partners have sought medical advice.

13

Genital itch and/or rash

Patients may present with many combinations of penile/genital symptoms, which may be acute or chronic, and infectious or non-infectious. Box 13.3 provides a guide to diagnosis.

Balanitis refers to inflammation of the glans penis, often extending to the under-surface of the prepuce, in which case it is called balanoposthitis. Tight prepuce and poor hygiene may be aggravating factors. Candidiasis is sometimes associated with immune deficiency, diabetes mellitus, and the use of broad-spectrum antimicrobials, glucocorticoids or antimitotic drugs. Local saline bathing is usually helpful, especially when no cause is found.

Genital ulceration

The most common cause of ulceration is genital herpes. Classically, multiple painful ulcers affect the glans, coronal sulcus or shaft of penis (Fig. 13.2), but solitary lesions occur rarely. Perianal ulcers may be seen in MSM. The diagnosis is made by gently scraping material from lesions and sending this in an appropriate transport medium for culture or detection of HSV DNA by polymerase chain reaction (PCR). Increasingly, laboratories will also test for *Treponema pallidum* by PCR.

In the UK, the possibility of syphilis or any other ulcerating STI is much less likely unless the patient is an MSM and/or has had a sexual partner from a region where tropical STIs are more common. The classic lesion of primary syphilis (chancre) is single, painless and indurated; however, multiple lesions are seen rarely and anal chancres are often painful. Diagnosis is made in GUM clinics by dark-ground microscopy and/or PCR on a swab from a chancre, but in other settings by serological tests for syphilis (p. 338). Other rare infective causes seen in the UK include varicella zoster virus (p. 238) and trauma with secondary infection. Tropical STIs, such as chancroid,

13.3 Differential diagnosis of genital itch and/or rash in men

Likely diagnosis	Acute or chronic	Itch	Pain	Discharge (non-urethral)	Specific characteristics	Diagnostic test	Treatment
Subclinical urethritis	Either	±	–	±	Often intermittent	Gram stain and urethral swabs	As for urethral discharge
Candidiasis	Acute	✓	–	White	Post-coital	Microscopy	Antifungal cream, e.g. clotrimazole
Anaerobic (erosive) balanitis	Acute	±	–	Yellow	Offensive	Clinical	Saline bathing ± metronidazole
***Pthirus pubis* ('crab lice') infection**	Either	✓	–	–	Lice and nits seen attached to pubic hairs	Can be by microscopy but usually visual	According to local policy – often permethrin
Lichen planus (p. 1252)	Either	±	–	–	Violaceous papules ± Wickham's striae	Clinical	None or mild topical glucocorticoid, e.g. hydrocortisone
Lichen sclerosus	Chronic	±	–	–	Ivory–white plaques, scarring	Clinical or biopsy	Strong topical glucocorticoid, e.g. clobetasol
Plasma cell balanitis of Zoon	Chronic	✓	–	±	Shiny, inflamed circumscribed areas	Clinical or biopsy	Strong topical glucocorticoid, e.g. clobetasol
Dermatoses, e.g. eczema or psoriasis	Either	✓	–	–	Similar to lesions elsewhere on skin	Clinical	Mild topical glucocorticoid, e.g. hydrocortisone
Genital herpes	Acute	±	✓	–	Atypical ulcers are not uncommon	Swab for HSV PCR	Oral antiviral, e.g. aciclovir
Circinate balanitis	Either	–	–	–	Painless erosions with raised edges; usually as part of sexually acquired reactive arthritis (SARA, p. 1031)	Clinical	Mild topical glucocorticoid, e.g. hydrocortisone

(HSV PCR = herpes simplex virus polymerase chain reaction)

Fig. 13.2 Penile herpes simplex (HSV-2) infection.

LGV and granuloma inguinale, are described in Box 13.12 (p. 341). Inflammatory causes include Stevens–Johnson syndrome (pp. 1224 and 1254), Behçet's disease (p. 1043) and fixed drug reactions. In older patients, malignant and pre-malignant conditions, such as squamous cell carcinoma and erythroplasia of Queyrat (intra-epidermal carcinoma), should be considered.

Genital lumps

The most common cause of genital 'lumps' is warts (p. 342). These are classically found in areas of friction during sex, such as the parafrenal skin and prepuce of the penis. Warts may also be seen in the urethral meatus, and less commonly on the shaft or around the base of the penis. Perianal warts are surprisingly common in men who do not have anal sex.

The differential diagnosis includes molluscum contagiosum and skin tags. Adolescent boys may confuse normal anatomical features such as coronal papillae (p. 330), parafrenal glands or sebaceous glands (Fordyce spots) with warts.

Proctitis in men who have sex with men

STIs that may cause proctitis in MSM include gonorrhoea, chlamydia, herpes and syphilis. The substrains of *Chlamydia trachomatis* that cause LGV (L1–3) have been associated with outbreaks of severe proctitis in Northern Europe, including the UK. Symptoms include mucopurulent anal discharge, rectal bleeding, pain and tenesmus.

Examination may show mucopus and erythema with contact bleeding (p. 330). In addition to the diagnostic tests listed on page 330, a PCR test for HSV and a request for identification of the LGV substrain should be arranged if chlamydial infection is detected. Treatment is directed at the individual infections.

MSM may also present with gastrointestinal symptoms from infection with organisms such as *Entamoeba histolytica* (p. 286), *Shigella* spp. (p. 265), *Campylobacter* spp. (p. 262) and *Cryptosporidium* spp. (pp. 287 and 317).

Presenting problems in women

Vaginal discharge

The natural vaginal discharge may vary considerably, especially under differing hormonal influences such as puberty, pregnancy or prescribed contraception. A sudden or recent change in discharge, especially if associated with alteration of colour and/or smell, or vulval itch/irritation, is more likely than a gradual or long-standing change to indicate an infective cause.

Local epidemiology is particularly important when assessing possible causes. In the UK, most cases of vaginal discharge are not sexually transmitted, being due to either candidal infection or bacterial vaginosis (BV). Worldwide, the most common treatable STI causing vaginal discharge is trichomoniasis; other possibilities include gonorrhoea and chlamydia. HSV may cause increased discharge, although vulval pain and dysuria are usually the predominant symptoms. Non-infective causes include retained tampons, malignancy and/or fistulae.

Speculum examination often allows a relatively accurate diagnosis, with appropriate treatment to follow (Box 13.4). If the discharge is homogeneous and off-white in colour, vaginal pH is greater than 4.5, and Gram stain microscopy reveals scanty or absent lactobacilli with significant numbers of Gram-variable organisms, some of which may be coating vaginal squamous cells (so-called Clue cells, Fig. 13.3), the likely diagnosis is BV. If there is vulval and vaginal erythema, the discharge is curdy in nature, vaginal pH is less than 4.5, and Gram stain microscopy reveals fungal spores and pseudohyphae, the diagnosis is candidiasis. Trichomoniasis tends to cause a profuse yellow or green discharge and is usually associated with significant vulvovaginal inflammation. Diagnosis is made by observing motile flagellate protozoa on a wet-mount microscopy slide of vaginal material and/or by culture.

If examination reveals the discharge to be cervical in origin, the possibility of chlamydial or gonococcal infection is increased and appropriate cervical or vaginal swabs should be taken (p. 331). In addition, Gram stain of cervical and urethral material may reveal GNDC, allowing presumptive treatment for gonorrhoea to be given. If gonococcal cervicitis is suspected, swabs should also be taken from the pharynx and rectum; infections at these sites are not reliably eradicated by single-dose therapy and a test of cure will therefore be required.

GUM clinics in the UK may offer sexually active women presenting with vaginal discharge an STI screen (p. 331). In other settings, such as primary care or gynaecology, testing for chlamydia and gonorrhoea may be considered in young women (<25 years old), those who have changed partner recently, and those not using a barrier method of contraception, even if a non-STI cause of discharge is suspected clinically.

Treatment of infections causing vaginal discharge is shown in Box 13.4.

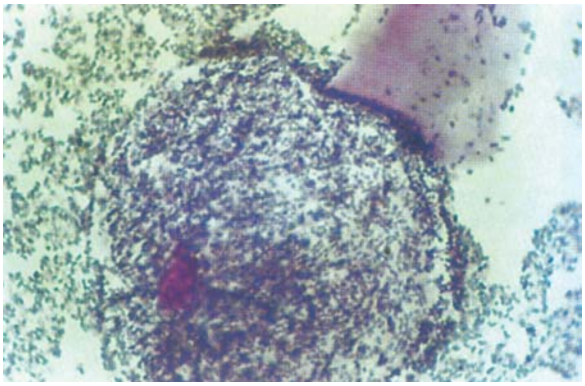

Fig. 13.3 Gram stain of a Clue cell from a patient with bacterial vaginosis. The margin of this vaginal epithelial cell is obscured by a coating of anaerobic organisms. *From McMillan A, Young H, Ogilvie MM, Scott GR. Clinical practice in sexually transmissible infections. Saunders, Elsevier Inc.; 2002.*

i 13.4 Infections that cause vaginal discharge

Cause	Clinical features	Treatment (in pregnancy seek specialist advice)
Candidiasis	Vulval and vaginal inflammation Curdy white discharge adherent to walls of vagina Low vaginal pH	Clotrimazole[1] 500 mg pessary once at night and clotrimazole cream twice daily *or* Econazole[1] pessary 150 mg for 3 nights and econazole cream twice daily (topical creams for 7 days) *or* Fluconazole[2] 150 mg orally stat
Trichomoniasis	Vulval and vaginal inflammation Frothy yellow/green discharge	Metronidazole[3] 400 mg twice daily orally for 5–7 days *or* Metronidazole[3] 2 g orally as a single dose
Bacterial vaginosis	No inflammation White homogeneous discharge High vaginal pH	Metronidazole[3] 2 g stat or 400 mg twice daily orally for 5–7 days Metronidazole[3] vaginal gel 0.75% daily for 5 days Clindamycin[1,4] vaginal cream 2% daily for 7 days
Streptococcal/staphylococcal infection	Purulent vaginal discharge	Choice of antibiotic depends on sensitivity tests

[1]Clotrimazole, econazole and clindamycin damage latex condoms and diaphragms. [2]Avoid in pregnancy and breastfeeding. [3]Avoid alcoholic drinks until 48 hours after finishing treatment. Avoid high-dose regimens in pregnancy or breastfeeding. [4]*Clostridium difficile* colitis has been reported with the use of clindamycin cream.

Lower abdominal pain

Pelvic inflammatory disease (PID, infection or inflammation of the Fallopian tubes and surrounding structures) is part of the extensive differential diagnosis of lower abdominal pain in women, especially those who are sexually active. The possibility of PID is increased if, in addition to acute/subacute pain, there is dyspareunia, abnormal vaginal discharge and/or bleeding. There may also be systemic features, such as fever and malaise. On examination, lower abdominal pain is usually bilateral, and vaginal examination reveals adnexal tenderness with or without cervical excitation. Unfortunately, a definitive diagnosis can only be made by laparoscopy. A pregnancy test should be performed (as well as the diagnostic tests on p. 331) because the differential diagnosis includes ectopic pregnancy.

Broad-spectrum antibiotics, including those active against gonorrhoea and chlamydia, such as ofloxacin and metronidazole, should be prescribed if PID is suspected, along with appropriate analgesia. Delaying treatment increases the likelihood of adverse sequelae, such as abscess formation, and tubal scarring that may lead to ectopic pregnancy or infertility. Hospital admission may be indicated for severe symptoms.

Genital ulceration

The most common cause of ulceration is genital herpes. Classically, multiple painful ulcers affect the introitus, labia and perineum, but solitary lesions occur rarely. Inguinal lymphadenopathy and systemic features, such as fever and malaise, are more common than in men. Diagnosis is made by gently scraping material from lesions and sending this in an appropriate transport medium for culture or detection of HSV DNA by PCR. Increasingly, laboratories will also test such samples for *Treponema pallidum* by PCR. In the UK, the possibility of any other ulcerating STI is unlikely unless the patient has had a sexual partner from a region where tropical STIs are more common (see Box 13.12).

Inflammatory causes include lichen sclerosus, Stevens–Johnson syndrome (pp. 1224 and 1254), Behçet's disease (p. 1043) and fixed drug reactions. In older patients, malignant and pre-malignant conditions, such as squamous cell carcinoma, should be considered.

Genital lumps

The most common cause of genital 'lumps' is warts. These are classically found in areas of friction during sex, such as the fourchette and perineum. Perianal warts are surprisingly common in women who do not have anal sex.

The differential diagnosis includes molluscum contagiosum, skin tags, and normal papillae or sebaceous glands.

Chronic vulval pain and/or itch

Women may present with a range of chronic symptoms that may be intermittent or continuous (Box 13.5).

Recurrent candidiasis may lead to hypersensitivity to candidal antigens, with itch and erythema becoming more prominent than increased discharge. Effective treatment may require regular oral antifungals, e.g. fluconazole 150 g once a week, plus a combined antifungal/glucocorticoid cream.

Prevention of STI

Case-finding

Early diagnosis and treatment facilitated by active case-finding will help to reduce the spread of infection by limiting the period of infectivity; tracing and treating sexual partners will also reduce the risk of reinfection. Unfortunately, the majority of individuals with an STI are asymptomatic and therefore unlikely to seek medical attention. Improving access to diagnosis in primary care or non-medical settings, especially through opportunistic testing, may help. However, the impact of medical intervention through improved access alone is likely to be small.

Changing behaviour

The prevalence of STIs is driven largely by sexual behaviour. Primary prevention encompasses efforts to delay the onset of sexual activity and limit the number of sexual partners thereafter. Encouraging the use of barrier methods of contraception will also help to reduce the risk of transmitting or acquiring STIs. This

13.5 Chronic vulval pain and/or itch

Likely diagnosis	Itch	Pain	Specific characteristics	Diagnostic test	Treatment
Candidiasis	✓	±	Usually cyclical	Microscopy (culture for yeasts other than *Candida albicans* in recurrent/refractory disease)	Oral antifungal, e.g. fluconazole 150 mg
Lichen planus	±	–	Violaceous papules ± Wickham's striae	Clinical	No treatment, or mild topical glucocorticoid, e.g. hydrocortisone
Lichen sclerosus	±	–	Ivory–white plaques, scarring ± labial resorption	Clinical or biopsy	Strong topical glucocorticoid, e.g. clobetasol
Vestibulitis	–	✓	Dyspareunia common, pain on touching erythematous area	Clinical	Refer to specialist vulva clinic
Vulvodynia	–	✓	Pain usually neuropathic in nature	Clinical	Refer to specialist vulva clinic
Dermatoses, e.g. eczema or psoriasis	✓	–	Similar to lesions elsewhere on skin	Clinical	Mild topical glucocorticoid, e.g. hydrocortisone
Genital herpes	±	✓	Atypical ulcers are not uncommon	Swab for HSV PCR	Oral antiviral, e.g. aciclovir

(HSV PCR = herpes simplex virus polymerase chain reaction)

is especially important in the setting of 'sexual concurrency', where sexual relationships overlap.

Unfortunately, there is contradictory evidence as to which (if any) interventions can reduce sexual activity. Knowledge alone does not translate into behaviour change, and broader issues, such as poor parental role modelling, low self-esteem, peer group pressure in the context of the increased sexualisation of our societies, gender power imbalance and homophobia, all need to be addressed. Throughout the world there is a critical need to enable women to protect themselves from undisciplined and coercive male sexual activity. Economic collapse and the turmoil of war regularly lead to situations where women are raped or must turn to prostitution to feed themselves and their children, and an inability to negotiate safe sex increases their risk of acquiring STI, including HIV.

Sexually transmitted bacterial infections

Syphilis

Syphilis is caused by infection, through abrasions in the skin or mucous membranes, with the spirochaete *Treponema pallidum*. In adults the infection is usually sexually acquired; however, transmission by kissing, blood transfusion and percutaneous injury has been reported. Transplacental infection of the fetus can occur.

The natural history of untreated syphilis is variable. Infection may remain latent throughout, or clinical features may develop at any time. The classification of syphilis is shown in Box 13.6. All infected patients should be treated. Penicillin remains the drug of choice for all stages of infection.

Acquired syphilis

Early syphilis

Primary syphilis

The incubation period is usually between 14 and 28 days, with a range of 9–90 days. The primary lesion or chancre (Fig. 13.4) develops at the site of infection, usually in the genital area. A dull red macule develops, becomes papular and then erodes to form an indurated ulcer (chancre). The draining inguinal lymph nodes may become moderately enlarged, mobile, discrete and rubbery. The chancre and the lymph nodes are both painless and non-tender, unless there is concurrent or secondary infection. Without treatment, the chancre will resolve within 2–6 weeks to leave a thin atrophic scar.

i 13.6 Classification of syphilis

Stage	Acquired	Congenital
Early	Primary Secondary Latent	Clinical and latent
Late	Latent Benign tertiary Cardiovascular Neurosyphilis	Clinical and latent

Fig. 13.4 Primary syphilis. A painless ulcer (chancre) is shown in the coronal sulcus of the penis. This is usually associated with inguinal lymphadenopathy. *Courtesy of Dr P. Hay, St George's Hospital, London.*

Chancres may develop on the vaginal wall and on the cervix. Extragenital chancres are found in about 10% of patients, affecting sites such as the finger, lip, tongue, tonsil, nipple, anus or rectum. Anal chancres often resemble fissures and may be painful.

13

Secondary syphilis

This occurs 6–8 weeks after the development of the chancre, when treponemes disseminate to produce a multisystem disease. Constitutional features, such as mild fever, malaise and headache, are common. Over 75% of patients present with a rash on the trunk and limbs that may later involve the palms and soles; this is initially macular but evolves to maculopapular or papular forms, which are generalised, symmetrical and non-irritable. Scales may form on the papules later. Lesions are red, changing to a 'gun-metal' grey as they resolve. Without treatment, the rash may last for up to 12 weeks. Condylomata lata (papules coalescing to plaques) may develop in warm, moist sites such as the vulva or perianal area. Generalised non-tender lymphadenopathy is present in over 50% of patients. Mucosal lesions, known as mucous patches, may affect the genitalia, mouth, pharynx or larynx and are essentially modified papules, which become eroded. Rarely, confluence produces characteristic 'snail track ulcers' in the mouth.

Other features, such as meningitis, cranial nerve palsies, anterior or posterior uveitis, hepatitis, gastritis, glomerulonephritis or periostitis, are sometimes seen. Neurological involvement may be more common in HIV-positive patients.

The differential diagnosis of secondary syphilis can be extensive, but in the context of a suspected STI, primary HIV infection is the most important alternative condition to consider (Ch. 12). Non-STI conditions that mimic the rash include psoriasis, pityriasis rosea, scabies, allergic drug reaction, erythema multiforme and pityriasis (tinea) versicolor.

The clinical manifestations of secondary syphilis will resolve without treatment but relapse may occur, usually within the first year of infection. Thereafter, the disease enters the phase of latency.

Latent syphilis

This phase is characterised by the presence of positive syphilis serology or the diagnostic cerebrospinal fluid (CSF) abnormalities of neurosyphilis in an untreated patient with no evidence of clinical disease. It is divided into early latency (within 2 years of infection), when syphilis may be transmitted sexually, and late latency, when the patient is no longer sexually infectious.

Transmission of syphilis from a pregnant woman to her fetus, and rarely by blood transfusion, is possible for several years following infection.

Late syphilis

Late latent syphilis

This may persist for many years or for life. Without treatment, over 60% of patients might be expected to suffer little or no ill health. Coincidental prescription of antibiotics for other illnesses, such as respiratory tract or skin infections, may treat latent syphilis serendipitously and make the interpretation of serological test results difficult (see below).

Benign tertiary syphilis

This may develop between 3 and 10 years after infection but is now rarely seen in the UK. Skin, mucous membranes, bone, muscle or viscera can be involved. The characteristic feature is a chronic granulomatous lesion called a gumma, which may be single or multiple. Healing with scar formation may impair the function of the structure affected. Skin lesions may take the form of nodules or ulcers, while subcutaneous lesions may ulcerate with a gummy discharge. Healing occurs slowly, with the formation of characteristic tissue-paper scars. Mucosal lesions may occur in the mouth, pharynx, larynx or nasal septum, appearing as punched-out ulcers. Of particular importance is gummatous involvement of the tongue, healing of which may lead to leucoplakia with the attendant risk of malignant change. Gummas of the tibia, skull, clavicle and sternum have been described, as has involvement of the brain, spinal cord, liver, testis and, rarely, other organs. Resolution of active disease should follow treatment, though some tissue damage may be permanent. Paroxysmal cold haemoglobinuria (p. 950) may be seen.

Cardiovascular syphilis

This may present many years after initial infection. Aortitis, which may involve the aortic valve and/or the coronary ostia, is the key feature. Clinical features include aortic incompetence, angina and aortic aneurysm (p. 505). The condition typically affects the ascending aorta and sometimes the aortic arch; aneurysm of the descending aorta is rare. Treatment with penicillin will not correct anatomical damage and surgical intervention may be required.

Neurosyphilis

This may also take years to develop. Asymptomatic infection is associated with CSF abnormalities in the absence of clinical signs. Meningovascular disease, tabes dorsalis and general paralysis of the insane constitute the symptomatic forms (p. 1125). Neurosyphilis and cardiovascular syphilis may coexist and are sometimes referred to as quaternary syphilis.

Congenital syphilis

Congenital syphilis is rare where antenatal serological screening is practised. Antisyphilitic treatment in pregnancy treats the fetus, if infected, as well as the mother.

Treponemal infection may give rise to a variety of outcomes after 4 months of gestation, when the fetus becomes immunocompetent:

- miscarriage or stillbirth, prematurely or at term
- birth of a syphilitic baby (a very sick baby with hepatosplenomegaly, bullous rash and perhaps pneumonia)
- birth of a baby who develops signs of early congenital syphilis during the first few weeks of life (Box 13.7)
- birth of a baby with latent infection who either remains well or develops congenital syphilis/stigmata later in life (see Box 13.7).

13.7 Clinical features of congenital syphilis

Early congenital syphilis (neonatal period)	
• Maculopapular rash • Condylomata lata • Mucous patches • Fissures around mouth, nose and anus • Rhinitis with nasal discharge (snuffles)	• Hepatosplenomegaly • Osteochondritis/periostitis • Generalised lymphadenopathy • Choroiditis • Meningitis • Anaemia/thrombocytopenia
Late congenital syphilis	
• Benign tertiary syphilis • Periostitis • Paroxysmal cold haemoglobinuria • Neurosyphilis	• 8th nerve deafness • Interstitial keratitis • Clutton's joints (painless effusion into knee joints)
Stigmata	
• Hutchinson's incisors (anterior–posterior thickening with notch on narrowed cutting edge) • Mulberry molars (imperfectly formed cusps/deficient dental enamel) • High arched palate • Maxillary hypoplasia • Saddle nose (following snuffles)	• Rhagades (radiating scars around mouth, nose and anus following rash) • Salt and pepper scars on retina (from choroiditis) • Corneal scars (from interstitial keratitis) • Sabre tibia (from periostitis) • Bossing of frontal and parietal bones (healed periosteal nodes)

Investigations in adult cases

Treponema pallidum may be identified in serum collected from chancres, or from moist or eroded lesions in secondary syphilis using a dark-field microscope, a direct fluorescent antibody test or PCR.

The serological tests for syphilis (STS) are listed in Box 13.8. These are antibody tests that almost always remain positive, even after successful treatment. Prolonged untreated infection results in higher titres that may not decline at all. Interpretation of results requires knowledge of any treatment, which may include antibiotics given coincidentally, e.g. for skin or respiratory tract infections.

Many centres use treponemal enzyme immunoassays (EIAs) for IgG and IgM antibodies to screen for syphilis. EIA for antitreponemal IgM becomes positive at approximately 2 weeks, while non-treponemal tests become positive about 4 weeks after primary syphilis. All positive results in asymptomatic patients must be confirmed by repeat tests.

Biological false-positive reactions occur occasionally; these are most commonly seen with Venereal Diseases Research Laboratory (VDRL) or rapid plasma reagin (RPR) tests (when treponemal tests will be negative). Acute false-positive reactions may be associated with infections, such as infectious mononucleosis, chickenpox and malaria, and may also occur in pregnancy. Chronic false-positive reactions may be associated with autoimmune diseases. False-negative results for non-treponemal tests may be found in secondary syphilis because extremely high antibody levels can

13.8 Serological tests for syphilis

Non-treponemal (non-specific) tests
• Venereal Diseases Research Laboratory (VDRL) test • Rapid plasma reagin (RPR) test
Treponemal (specific) antibody tests
• Treponemal antigen-based enzyme immunoassay (EIA) for IgG and IgM • *Treponema pallidum* haemagglutination assay (TPHA) • *T. pallidum* particle agglutination assay (TPPA) • Fluorescent treponemal antibody-absorbed (FTA-ABS) test

prevent the formation of the antibody–antigen lattice necessary for the visualisation of the flocculation reaction (the prozone phenomenon).

In benign tertiary and cardiovascular syphilis, examination of CSF should be considered because asymptomatic neurological disease may coexist. The CSF should also be examined in patients with clinical signs of neurosyphilis (p. 1125) and in both early and late congenital syphilis. Positive STS may be found in patients who are being investigated for neurological disease, especially dementia. In many instances, the serology reflects previous infection unrelated to the presenting complaint, especially when titres are low. Examination of CSF is occasionally necessary.

Chest X-ray, electrocardiogram (ECG) and echocardiogram are useful in the investigation of cardiovascular syphilis. Biopsy may be required to diagnose gumma.

Endemic treponematoses, such as yaws, endemic (non-venereal) syphilis (bejel) and pinta (pp. 253 and 254), are caused by treponemes that are morphologically indistinguishable from *T. pallidum* and cannot be differentiated by serological tests. A VDRL or RPR test may help to elucidate the correct diagnosis because adults with late yaws usually have low titres.

Investigations in suspected congenital syphilis

Passively transferred maternal antibodies from an adequately treated mother may give rise to positive serological tests in her baby. In this situation, non-treponemal tests should become negative within 3–6 months of birth. A positive EIA test for antitreponemal IgM suggests early congenital syphilis. A diagnosis of congenital syphilis mandates investigation of the mother, her partner and any siblings.

Management

Penicillin is the drug of choice. Currently, a single dose of 2.4 megaunits of intramuscular benzathine benzylpenicillin is recommended for early syphilis (<2 years' duration), with three doses at weekly intervals being recommended in late syphilis. A 14-day course of procaine penicillin is recommended for the treatment of neurosyphilis, supplemented by a 3-day course of prednisolone (see below). Doxycycline is indicated for patients allergic to penicillin, except in pregnancy (see below). Azithromycin is less favoured due to the potential for resistance. All patients must be followed up to ensure cure, and partner notification is of particular importance. Resolution of clinical signs in early syphilis with declining titres for non-treponemal tests, usually to undetectable levels within 6 months for primary syphilis and 12–18 months for secondary syphilis, is an indicator of successful treatment. Specific treponemal antibody tests may remain positive for life. In patients who have had syphilis for many years there may be little serological response following treatment.

Pregnancy

Penicillin is the treatment of choice in pregnancy. Erythromycin stearate can be given if there is penicillin hypersensitivity, but it crosses the placenta poorly; the newborn baby must therefore be treated with a course of penicillin and consideration given to retreating the mother. Some specialists recommend penicillin desensitisation for pregnant mothers so that penicillin can be given during temporary tolerance. A 10-day course of ceftriaxone is a further alternative. Babies should be treated in hospital with the help of a paediatrician.

Treatment reactions

- *Anaphylaxis*. Penicillin is a common cause; on-site facilities should be available for management (p. 75).
- *Jarisch–Herxheimer reaction*. This is an acute febrile reaction that follows treatment and is characterised by headache, malaise and myalgia; it resolves within 24 hours. It is common in early syphilis and rare in late syphilis. Fetal distress or premature labour can occur in pregnancy.
  The reaction may also cause worsening of neurological (cerebral artery occlusion) or ophthalmic (uveitis, optic neuritis) disease, myocardial ischaemia (inflammation of the coronary ostia) and laryngeal stenosis (swelling of a gumma). Prednisolone 40–60 mg daily for 3 days is recommended to prevent the reaction in patients with these forms of the disease; antisyphilitic treatment can be started 24 hours after introducing glucocorticoids. In high-risk situations it is wise to initiate therapy in hospital.
- *Procaine reaction*. Fear of impending death occurs immediately after the accidental intravenous injection of procaine penicillin and may be associated with hallucinations or fits. Symptoms are short-lived, but verbal assurance and sometimes physical restraint are needed. The reaction can be prevented by aspiration before intramuscular injection to ensure the needle is not in a blood vessel.

Gonorrhoea

Gonorrhoea is caused by infection with *Neisseria gonorrhoeae* and may involve columnar epithelium in the lower genital tract, rectum, pharynx and eyes. Transmission is usually the result of vaginal, anal or oral sex. Gonococcal conjunctivitis may be caused by accidental infection from contaminated fingers. Untreated mothers may infect babies during delivery, resulting in ophthalmia neonatorum (Fig. 13.5). Infection of children beyond the neonatal period usually indicates sexual abuse.

Clinical features

The incubation period is usually 2–10 days. In men the anterior urethra is commonly infected, causing urethral discharge and dysuria, but symptoms are absent in about 10% of cases. Examination will usually show a mucopurulent or purulent urethral discharge. Rectal infection in MSM is usually asymptomatic but may present with anal discomfort, discharge or rectal bleeding. Proctoscopy may reveal either no abnormality, or clinical evidence of proctitis (p. 334) such as inflamed rectal mucosa and mucopus.

In women, the urethra, paraurethral glands/ducts, Bartholin's glands/ducts or endocervical canal may be infected. The rectum may also be involved either due to contamination from a urogenital site or as a result of anal sex. Occasionally, the rectum is the

13

Fig. 13.5 Gonococcal ophthalmia neonatorum. *From McMillan A, Scott GR. Sexually transmitted infections: a colour guide. Churchill Livingstone, Elsevier Ltd; 2000.*

only site infected. About 80% of women who have gonorrhoea are asymptomatic. There may be vaginal discharge or dysuria but these symptoms are often due to additional infections, such as chlamydia (see below), trichomoniasis or candidiasis, making full investigation essential (p. 331). Lower abdominal pain, dyspareunia and intermenstrual bleeding may be indicative of PID. Clinical examination may show no abnormality, or pus may be expressed from urethra, paraurethral ducts or Bartholin's ducts. The cervix may be inflamed, with mucopurulent discharge and contact bleeding.

Pharyngeal gonorrhoea is the result of receptive orogenital sex and is usually symptomless. Gonococcal conjunctivitis is an uncommon complication, presenting with purulent discharge from the eye(s), severe inflammation of the conjunctivae and oedema of the eyelids, pain and photophobia. Gonococcal ophthalmia neonatorum presents similarly with purulent conjunctivitis and oedema of the eyelids. Conjunctivitis must be treated urgently to prevent corneal damage.

Disseminated gonococcal infection (DGI) is seen rarely, and typically affects women with asymptomatic genital infection. Symptoms include arthritis of one or more joints, pustular skin lesions, tenosynovitis and fever. Gonococcal endocarditis has been described.

Investigations

Gram-negative diplococci may be seen on microscopy of smears from infected sites (see Fig. 13.1). Pharyngeal smears are difficult to analyse due to the presence of other diplococci, so the diagnosis must be confirmed by culture or NAAT.

Management of adults

Emerging resistance is making it increasingly difficult to cure gonorrhoea with a single oral dose of antimicrobials, and recommended treatment in the UK has changed to intramuscular ceftriaxone 500 mg given with an oral dose of azithromycin 1 g, in the hope that combination therapy will slow down the development of cephalosporin resistance. The alternatives listed in Box 13.9 are less likely to be effective.

Longer courses of antibiotics are required for complicated infection. The partner(s) of patients with gonorrhoea should be seen as soon as possible. Delay in treatment may lead to complications (Box 13.10).

13.9 Treatment of uncomplicated anogenital gonorrhoea

Uncomplicated infection

- Ceftriaxone 500 mg IM plus azithromycin 1 g orally *or*
- Cefixime 400 mg stat *or*
- Ciprofloxacin 500 mg orally stat[1,2] *or*
- Ofloxacin 400 mg orally stat[1,2]

Pregnancy and breastfeeding

- Ceftriaxone 500 mg plus azithromycin 1 g IM stat *or*
- Spectinomycin 2 g IM stat[3]

Pharyngeal gonorrhoea

- Ceftriaxone 500 mg IM plus azithromycin 1 g stat *or*
- Ciprofloxacin 500 mg[1,2] orally stat *or*
- Ofloxacin 400 mg[1,2] orally stat

[1]Contraindicated in pregnancy and breastfeeding. [2]If prevalence of quinolone resistance for *Neisseria gonorrhoeae* is <5%. [3]May be available only in specialist clinics.

13.10 Complications of delayed therapy in gonorrhoea

- Acute prostatitis
- Epididymo-orchitis
- Bartholin's gland abscess
- Pelvic inflammatory disease (may lead to infertility or ectopic pregnancy)
- Disseminated gonococcal infection

Chlamydial infection

Chlamydial infection in men

Chlamydia is transmitted and presents in a similar way to gonorrhoea; however, urethral symptoms are usually milder and may be absent in over 50% of cases. Conjunctivitis is also milder than in gonorrhoea; pharyngitis does not occur. The incubation period varies from 1 week to a few months. Without treatment, symptoms may resolve but the patient remains infectious for several months. Complications, such as epididymo-orchitis and sexually acquired reactive arthritis (SARA, p. 1031), are rare. Sexually transmitted pathogens, such as chlamydia or gonococci, are usually responsible for epididymo-orchitis in men aged less than 35 years, whereas bacteria such as Gram-negative enteric organisms are more commonly implicated in older men.

Treatments for chlamydia are listed in Box 13.11. NSU is treated identically. The partner(s) of men with chlamydia should be treated, even if laboratory tests for chlamydia are negative. Investigation is not mandatory but serves a useful epidemiological purpose; moreover, positive results encourage further attempts at contact-tracing.

Chlamydial infection in women

The cervix and urethra are commonly involved. Infection is asymptomatic in about 80% of patients but may cause intermenstrual and/or post-coital bleeding, dysuria or vaginal discharge. Lower abdominal pain and dyspareunia are features of PID. Examination may reveal mucopurulent cervicitis, contact

13.11 Treatment of chlamydial infection

Standard regimens

- Azithromycin 1 g orally as a single dose[1] *or*
- Doxycycline 100 mg twice daily orally for 7 days[2]

Alternative regimens

- Erythromycin 500 mg four times daily orally for 7 days *or* 500 mg twice daily for 2 weeks *or*
- Ofloxacin 200 mg twice daily orally for 7 days[2]

[1]Safety in pregnancy and breastfeeding has not been fully established.
[2]Contraindicated in pregnancy and breastfeeding.

bleeding from the cervix, evidence of PID or no obvious clinical signs. Treatment options are listed in Box 13.11. The patient's male partner(s) should be investigated and treated.

Many infections clear spontaneously but others persist. PID, with the risk of tubal damage and subsequent infertility or ectopic pregnancy, is a rare but important long-term complication. Other complications include perihepatitis, chronic pelvic pain, conjunctivitis and SARA (p. 1031). Perinatal transmission may lead to ophthalmia neonatorum and/or pneumonia in the neonate.

Other sexually transmitted bacterial infections

Chancroid, granuloma inguinale and LGV as causes of genital ulcers in the tropics are described in Box 13.12. LGV is also a cause of proctitis in MSM (p. 334).

Sexually transmitted viral infections

Genital herpes simplex

Infection with herpes simplex virus type 1 (HSV-1) or type 2 (HSV-2) produces a wide spectrum of clinical problems (p. 247), and may facilitate HIV transmission. Infection is usually acquired sexually (vaginal, anal, orogenital or oroanal), but perinatal transmission to the neonate may also occur. Primary infection at the site of HSV entry, which may be symptomatic or asymptomatic, establishes latency in local sensory ganglia. Recurrences, either symptomatic or asymptomatic viral shedding, are a consequence of HSV reactivation. The first symptomatic episode is usually the most severe. Although HSV-1 is classically associated with orolabial herpes and HSV-2 with anogenital herpes, HSV-1 now accounts for more than 50% of anogenital infections in the UK.

Clinical features

The first symptomatic episode presents with irritable vesicles that soon rupture to form small, tender ulcers on the external genitalia (Fig. 13.6 and see Fig. 13.2). Lesions at other sites (e.g. urethra, vagina, cervix, perianal area, anus or rectum) may cause dysuria, urethral or vaginal discharge, or anal, perianal or rectal pain. Constitutional symptoms, such as fever, headache and malaise, are common. Inguinal lymph nodes become enlarged and tender, and there may be nerve root pain in the 2nd and 3rd sacral dermatomes.

Extragenital lesions may develop at other sites, such as the buttock, finger or eye, due to auto-inoculation. Oropharyngeal infection may result from orogenital sex. Complications, such

13

13.12 Salient features of lymphogranuloma venereum, chancroid and granuloma inguinale (Donovanosis)

Infection and distribution	Organism	Incubation period	Genital lesion	Lymph nodes	Diagnosis	Management
Lymphogranuloma venereum (LGV)						
E/W Africa, India, SE Asia, S America, Caribbean	*Chlamydia trachomatis* types L1, 2, 3	3–30 days	Small, transient, painless ulcer, vesicle, papule; often unnoticed	Tender, usually unilateral, matted, suppurative bubo; inguinal/femoral nodes involved[1]	Serological tests for L1–3 serotypes; swab from ulcer or bubo pus for *Chlamydia*	Doxycycline[2] twice daily orally for 21 days *or* Erythromycin 500 mg four times daily orally
Chancroid						
Africa, Asia, Central and S America	*Haemophilus ducreyi* (short Gram-negative bacillus)	3–10 days	Single or multiple painful ulcers with ragged undermined edges	As above but unilocular, suppurative bubo; inguinal nodes involved in ~50%	Microscopy and culture of scrapings from ulcer or pus from bubo	Azithromycin[3] 1 g orally once *or* Ceftriaxone 250 mg IM once *or* Ciprofloxacin[2] 500 mg twice daily orally for 3 days
Granuloma inguinale						
Australia, India, Caribbean, S Africa, S America, Papua New Guinea	*Klebsiella granulomatis* (Donovan bodies)	3–40 days	Ulcers or hypertrophic granulomatous lesions; usually painless[4]	Initial swelling of inguinal nodes, then spread of infection to form abscess or ulceration through adjacent skin	Microscopy of cellular material for intracellular bipolar-staining Donovan bodies	Azithromycin[3] 1 g weekly orally or 500 mg daily orally *or* Doxycycline[2] 100 mg twice daily orally *or* Ceftriaxone 1 g IM daily

N.B. Partners of patients with LGV, chancroid and granuloma inguinale should be investigated and treated, even if asymptomatic.
[1]The genito-ano-rectal syndrome is a late manifestation of LGV. [2]Doxycycline and ciprofloxacin are contraindicated in pregnancy and breastfeeding. [3]The safety of azithromycin in pregnancy and breastfeeding has not been fully assessed. [4]Mother-to-baby transmission of granuloma inguinale may rarely occur.

Fig. 13.6 Herpetic ulceration of the vulva. *From McMillan A, Scott GR. Sexually transmitted infections: a colour guide. Churchill Livingstone, Elsevier Ltd; 2000.*

as urinary retention due to autonomic neuropathy, and aseptic meningitis, are occasionally seen.

First episodes usually heal within 2–4 weeks without treatment; recurrences are usually milder and of shorter duration than the initial attack. They occur more often in HSV-2 infection and their frequency tends to decrease with time. Prodromal symptoms, such as irritation or burning at the subsequent site of recurrence, or neuralgic pain affecting buttocks, legs or hips are commonly seen. The first symptomatic episode may be a recurrence of a previously undiagnosed primary infection. Recurrent episodes of asymptomatic viral shedding are important in the transmission of HSV.

Diagnosis

Swabs are taken from vesicular fluid or ulcers for detection of DNA by PCR, or tissue culture and typing as either HSV-1 or 2. Electron microscopy of such material will give only a presumptive diagnosis, as herpes group viruses appear similar. Type-specific antibody tests are available but are not sufficiently accurate for general use.

Management

First episode

The following 5-day oral regimens should be started within 5 days of the beginning of the episode, or while lesions are still forming:

- aciclovir 400 mg three times daily
- valaciclovir 500 mg twice daily.

Famciclovir 250 mg three times daily or aciclovir 200 mg five times daily is an alternative.

Analgesia may be required and saline bathing can be soothing. Treatment may be continued for longer than 5 days if new lesions develop. Occasionally, intravenous therapy may be indicated if oral therapy is poorly tolerated or aseptic meningitis occurs.

Catheterisation via the suprapubic route is advisable for urinary retention due to autonomic neuropathy because the transurethral route may introduce HSV into the bladder.

Recurrent genital herpes

Symptomatic recurrences are usually mild and may require no specific treatment other than saline bathing. For more severe episodes, patient-initiated treatment at onset, with one of the following 5-day oral regimens, should reduce the duration of the recurrence:

- aciclovir 200 mg five times daily
- famciclovir 125–250 mg twice daily
- valaciclovir 500 mg twice daily.

In a few patients, treatment started at the onset of prodromal symptoms may abort recurrence.

Suppressive therapy may be required for patients with frequent recurrences, especially if these are experienced at intervals of less than 4 weeks. Treatment should be given for a minimum of 1 year before stopping to assess recurrence rate. About 20% of patients will experience reduced attack rates thereafter, but for those whose recurrences remain unchanged, resumption of suppressive therapy is justified. Aciclovir 400 mg twice daily is most commonly prescribed.

Management in pregnancy

If her partner is known to be infected with HSV, a pregnant woman with no previous anogenital herpes should be advised to protect herself during sexual intercourse because the risk of disseminated infection is increased in pregnancy. Consistent condom use during pregnancy may reduce transmission of HSV. Genital herpes acquired during the first or second trimester of pregnancy is treated with aciclovir as clinically indicated. Although aciclovir is not licensed for use in pregnancy in the UK, there is considerable clinical evidence to support its safety. Third-trimester acquisition of infection has been associated with life-threatening haematogenous dissemination and should be treated with aciclovir.

Vaginal delivery should be routine in women who are symptomless in late pregnancy. Caesarean section is sometimes considered if there is a recurrence at the beginning of labour, although the risk of neonatal herpes through vaginal transmission is very low. Caesarean section is often recommended if primary infection occurs after 34 weeks because the risk of viral shedding is very high in labour.

Human papillomavirus and anogenital warts

Human papillomavirus (HPV) DNA typing has demonstrated over 90 genotypes (p. 1238), of which HPV-6, HPV-11, HPV-16 and HPV-18 most commonly infect the genital tract through sexual transmission. It is important to differentiate between the benign genotypes (HPV-6 and 11) that cause anogenital warts, and genotypes such as 16 and 18 that are associated with dysplastic conditions and cancers of the genital tract but are not a cause of benign warts. All genotypes usually result in subclinical infection of the genital tract rather than clinically obvious lesions affecting penis, vulva, vagina, cervix, perineum or anus.

Clinical features

Anogenital warts caused by HPV may be single or multiple, exophytic, papular or flat. Perianal warts (p. 330), while being more common in MSM, are also found in heterosexual men and in women. Rarely, a giant condyloma (Buschke–Löwenstein tumour) develops, with local tissue destruction. Atypical warts should be biopsied. In pregnancy, warts may dramatically increase in size and number, making treatment difficult. Rarely, they are large enough to obstruct labour and, in this case, delivery by caesarean section will be required. Uncommonly, perinatal transmission of HPV leads to anogenital warts, or possibly laryngeal papillomas, in the neonate.

Management

The use of condoms can help prevent the transmission of HPV to non-infected partners, but HPV may affect parts of the genital area not protected by condoms. Vaccination against HPV infection has been introduced and is in routine use in many countries. There are three types of vaccine:

- *A bivalent vaccine* offers protection against HPV types 16 and 18, which account for approximately 75% of cervical cancers in the UK.
- *A quadrivalent vaccine* offers additional protection against HPV types 6 and 11, which account for over 90% of genital warts.
- *A nonovalent vaccine* protects against five additional high-risk types (31, 33, 45, 52 and 58).

All vaccines have been shown to be highly effective in the prevention of cervical intra-epithelial neoplasia in young women, and the quadrivalent and nonovalent vaccines have also been demonstrated to be highly effective in protecting against HPV-associated genital warts. It is currently recommended that HPV vaccination should be administered prior to the onset of sexual activity, typically at age 11–13, in a course of three injections. In the UK, only girls are offered vaccination, but it is possible that vaccination will be extended to MSM in whom HPV transmission is associated with an increased risk of anal cancer. As no vaccine protects against all oncogenic types of HPV, cervical screening programmes will still be necessary.

A variety of treatments are available for established disease, including the following:

- *Podophyllotoxin, 0.5% solution or 0.15% cream* (contraindicated in pregnancy), applied twice daily for 3 days, followed by 4 days' rest, for up to 4 weeks, is suitable for home treatment of external warts.
- *Imiquimod cream* (contraindicated in pregnancy), applied 3 times weekly (and washed off after 6–10 hours) for up to 16 weeks, is also suitable for home treatment of external warts.
- *Catephen* (an extract of the green tea plant, *Camellia sinensis*) is applied by the patient three times daily for up to 16 weeks.
- *Cryotherapy* using liquid nitrogen to freeze warty tissue is suitable for external and internal warts but often requires repeated clinic visits.
- *Hyfrecation* – electrofulguration that causes superficial charring – is suitable for external and internal warts. Hyfrecation results in smoke plume, which contains HPV DNA and has the potential to cause respiratory infection in the operator/patient. Masks should be worn during the procedure and adequate extraction of fumes should be provided.
- *Surgical removal* may be used to excise refractory warts, especially pedunculated perianal lesions, under local or general anaesthesia.

Molluscum contagiosum

Infection by molluscum contagiosum virus, both sexual and non-sexual, produces flesh-coloured, umbilicated, hemispherical papules usually up to 5 mm in diameter after an incubation period of 3–12 weeks (Fig. 13.7). Larger lesions may be seen in HIV infection (p. 306). Lesions are often multiple and, once established in an individual, may spread by auto-inoculation. They are found on the genitalia, lower abdomen and upper thighs when sexually acquired. Facial lesions are highly suggestive of underlying HIV infection. Diagnosis is made clinically or very rarely by electron microscopy. Typically, lesions persist for several months before spontaneous resolution occurs. Treatment regimens are therefore cosmetic; they include cryotherapy, hyfrecation, topical applications of 0.15% podophyllotoxin cream (contraindicated in pregnancy) or expression of the central core.

Fig. 13.7 Molluscum contagiosum of the shaft of the penis. *From McMillan A, Scott GR. Sexually transmitted infections: a colour guide. Churchill Livingstone, Elsevier Ltd; 2000.*

Viral hepatitis

The hepatitis viruses A–D (p. 871) may be sexually transmitted:

- *Hepatitis A (HAV).* Insertive oroanal sex, insertive digital sex, insertive anal sex and multiple sexual partners have been linked with HAV transmission in MSM. HAV transmission in heterosexual men and women is also possible through oroanal sex.
- *Hepatitis B (HBV).* Insertive oroanal sex, anal sex and multiple sexual partners are linked with HBV infection in MSM. Heterosexual transmission of HBV is well documented and commercial sex workers are at particular risk. Hepatitis D (HDV) may also be sexually transmitted.
- *Hepatitis C (HCV).* Sexual transmission of HCV is well documented in MSM but less so in heterosexuals. Sexual transmission is less efficient than for HBV.

The sexual partner(s) of patients with HAV and HBV should be seen as soon as possible and offered immunisation where appropriate. Patients with HAV should abstain from all forms of unprotected sex until non-infectious. Those with HBV should likewise abstain from unprotected sex until they are non-infectious or until their partners have been vaccinated successfully. No active or passive immunisation is available for protection against HCV but the consistent use of condoms is likely to protect susceptible partners. Active immunisation against HAV and HBV should be offered to susceptible people at risk of infection. Many STI clinics offer HAV immunisation to MSM along with routine HBV immunisation; a combined HAV and HBV vaccine is available.

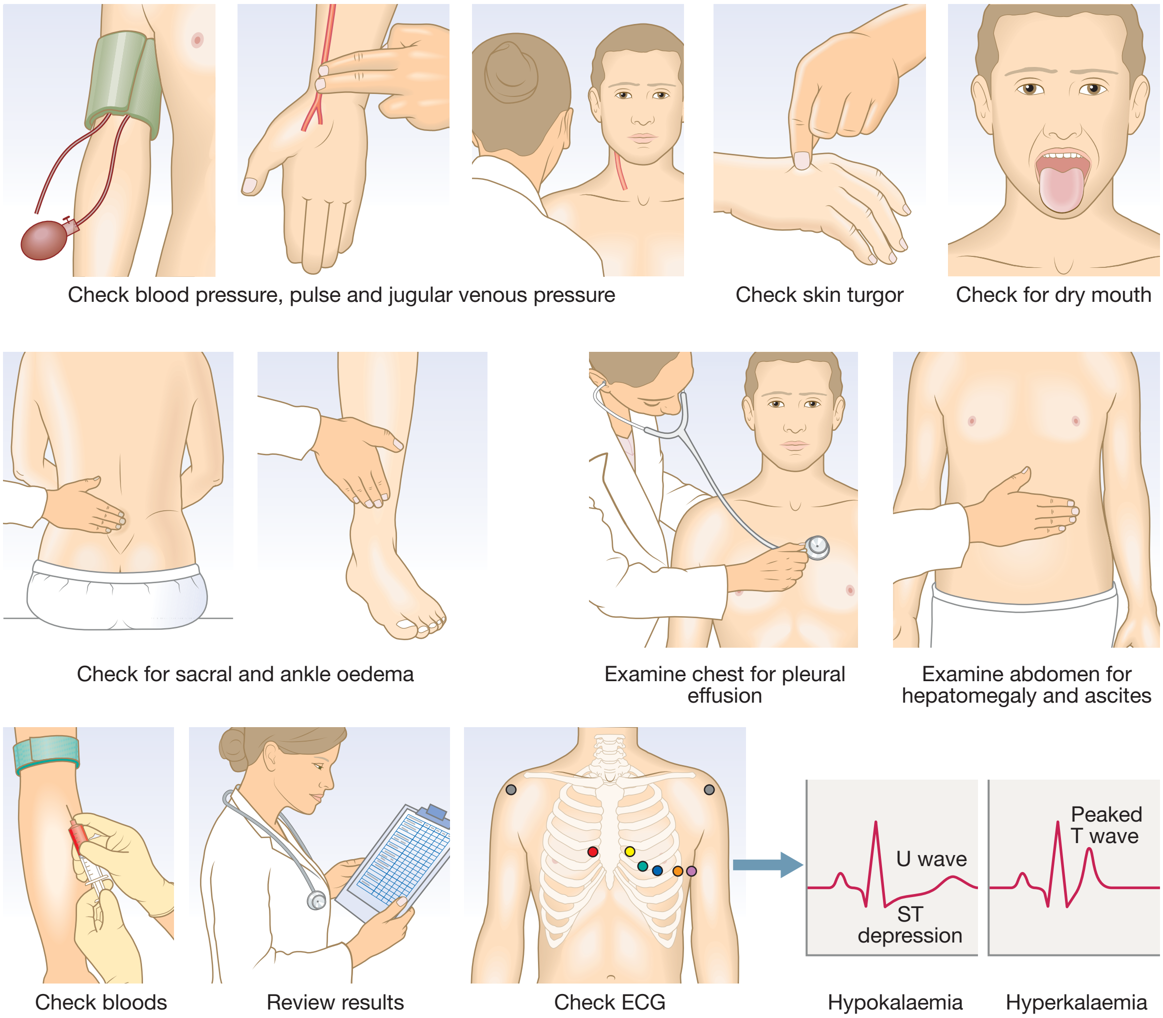
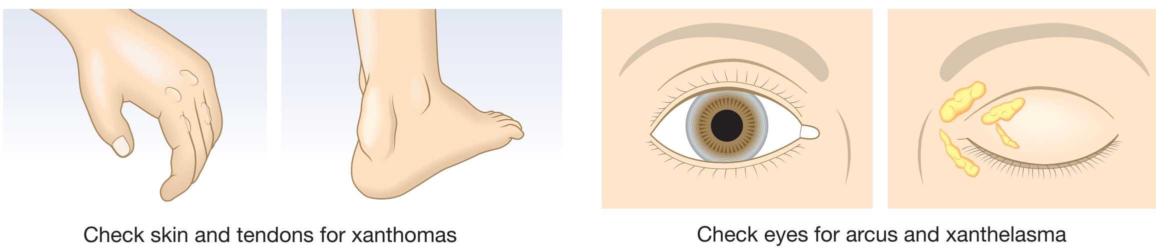
Clinical biochemistry and metabolic medicine



Clinical examination in biochemical and metabolic disorders

Many biochemical and metabolic disorders are clinically silent or present with non-specific manifestations, and are first detected by laboratory testing. Several abnormalities can be picked up by history and physical examination, however, as summarised below.



Insets: (ankle oedema) From Huang H-W, Wong L-S, Lee C-H. Sarcoidosis with bilateral leg lymphedema as the initial presentation: a review of the literature. Assessment of volume status and electrolyte disturbances

Check for signs of hyperlipidaemia

There is a worldwide trend towards increased use of laboratory-based diagnostic investigations, and biochemical investigations in particular. In the health-care systems of developed countries, it has been estimated that 60–70% of all critical decisions taken in regard to patients, and over 90% of data stored in electronic medical records systems, involve a laboratory service or result.

This chapter covers a diverse group of disorders affecting adults that are not considered elsewhere in this book, whose primary manifestation is in abnormalities of biochemistry laboratory results, or whose underlying pathophysiology involves disturbance in specific biochemical pathways.

Biochemical investigations

There are three broad reasons why a clinician may request a biochemical laboratory investigation:

- to screen an asymptomatic subject for the presence of disease
- to assist in diagnosis of a patient's presenting complaint
- to monitor changes in test results, as a marker of disease progression or response to treatment.

Contemporary medical practice has become increasingly reliant on laboratory investigation and, in particular, on biochemical investigation. This has been associated with extraordinary improvements in the analytical capacity and speed of laboratory instrumentation and the following operational trends:

- Large central biochemistry laboratories feature extensive use of automation and information technology. Specimens are transported from clinical areas to the laboratory using high-speed transport systems (such as pneumatic tubes) and identified with machine-readable labels (such as bar codes). Laboratory instruments have been miniaturised and integrated with robot transport systems to enable multiple rapid analyses of a single sample. Statistical process control techniques are used to assure the quality of analytical results, and increasingly to monitor other aspects of the laboratory, such as the time taken to complete the analysis ('turn-around time').
- Point-of-care testing (POCT) brings selected laboratory analytical systems into clinical areas, to the patient's bedside or even connected to an individual patient. These systems allow the clinician to receive results almost instantaneously for immediate treatment of the patient, although often with lesser precision or at greater cost than using a central laboratory.
- The diversity of analyses has widened considerably with the introduction of many techniques borrowed from the chemical or other industries (Box 14.1).

Good medical practice involves the appropriate ordering of laboratory investigations and correct interpretation of test results (Box 14.2). The key principles, including the concepts of sensitivity and specificity, are described on page 4. Reference intervals for laboratory results are provided in Chapter 35. Many laboratory investigations can be subject to variability arising from whether the sample is being taken in the fed or fasted state; the timing of sample collection, in relation to diurnal variation of analytes; dosage intervals for therapeutic drug monitoring; sample type, such as serum plasma; use of anticoagulants, such as EDTA, which can interfere with some assays; or artefacts, such as

14.1 Range of analytical modalities used in the clinical biochemistry laboratory

Analytical modality	Analyte	Typical applications
Ion-selective electrodes	Blood gases, electrolytes (Na, K, Cl)	Point-of-care testing (POCT) High-throughput analysers
Colorimetric chemical reaction or coupled enzymatic reaction	Simple mass or concentration measurement (creatinine, phosphate) Simple enzyme activity	High-throughput analysers
Ligand assay (usually immunoassay)	Specific proteins Hormones Drugs	Increasingly available for POCT or high-throughput analysers
Chromatography: gas chromatography (GC), high-performance liquid chromatography (HPLC), thin-layer chromatography (TLC)	Organic compounds	Therapeutic drug monitoring (TDM)
Mass spectroscopy (MS)		Drug screening (drugs of misuse) Vitamins Biochemical metabolites
Spectrophotometry, turbidimetry, nephelometry, fluorimetry	Haemoglobin derivatives Specific proteins Immunoglobulins	Xanthochromia Lipoproteins Paraproteins

14.2 How to interpret urea and electrolytes results*

Sodium

- Largely reflects changes in sodium and water balance
- See 'Hypernatraemia' and 'Hyponatraemia' (pp. 358 and 357)

Potassium

- May reflect K shifts in and out of cells
- Low levels usually mean excessive losses (gastrointestinal or renal)
- High levels usually mean renal dysfunction
- See 'Hypokalaemia' and 'Hyperkalaemia' (pp. 361 and 362)

Chloride

- Generally changes in parallel with plasma Na
- Low in metabolic alkalosis
- High in some forms of metabolic acidosis

Bicarbonate

- Abnormal in acid–base disorders
- See Box 14.18 (p. 365)

Urea

- Increased with a fall in glomerular filtration rate (GFR), reduced renal perfusion or urine flow rate, and in high protein intake or catabolic states
- See page 386

Creatinine

- Increased with a fall in GFR, in individuals with high muscle mass, and with some drugs
- See Fig. 15.2 (p. 387)

*The term urea and electrolytes (U&Es) refers to urea, electroyles and creatinine. In some countries this is abbreviated to EUC (electrolytes/urea/creatinine).

taking a venous sample proximal to the site of an intravenous infusion. It is therefore important for clinical and laboratory staff to communicate effectively and for clinicians to follow local recommendations concerning collection and transport of samples in the appropriate container and with appropriate labelling.

Water and electrolyte homeostasis

Total body water (TBW) is approximately 60% of body weight in an adult male, although the proportion is somewhat more for infants and less for women. In a 70 kg man TBW is therefore about 40 L. Approximately 25 L is located inside cells (the intracellular fluid or ICF), while the remaining 15 L is in the extracellular fluid (ECF) compartment (Fig. 14.1). Most of the ECF (approximately 12 L) is interstitial fluid, which is within the tissues but outside cells, whereas the remainder (about 3 L) is in the plasma compartment.

The ion composition between the main body fluid compartments intracellularly and extracellularly is illustrated in Figure 14.1. The dominant positively charged ion (cation) within cells is potassium, whereas phosphates and negatively charged proteins constitute the major intracellular negatively charged ions (anions). In the ECF the dominant cation is sodium, while chloride and, to a lesser extent, bicarbonate are the most important ECF anions. An important difference between the intravascular (plasma) and interstitial compartments of the ECF is that only plasma contains significant concentrations of protein.

The major force maintaining the difference in cation concentrations between the ICF and ECF is the sodium–potassium

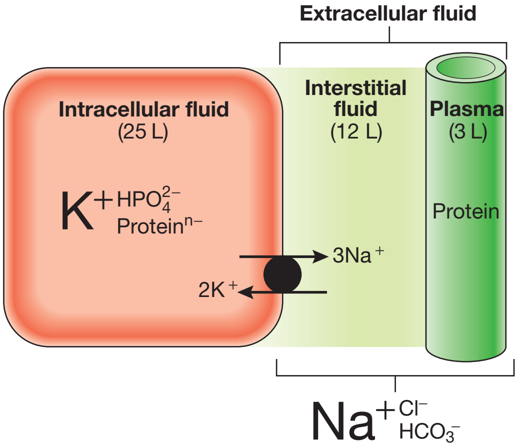

Fig. 14.1 Normal distribution of body water and electrolytes. Schematic representation of volume (L = litres) and composition (dominant ionic species only shown) of the intracellular fluid (ICF) and extracellular fluid (ECF) in a 70 kg male. The main difference in composition between the plasma and interstitial fluid (ISF) is the presence of appreciable concentrations of protein in the plasma but not the ISF. The Na/K differential is maintained by the Na,K-adenosine triphosphatase (ATPase) pump.

pump (Na,K-activated adenosine triphosphatase (ATPase)), which is present in all cell membranes. Maintenance of these gradients is essential for many cell processes, including the excitability of conducting tissues such as nerve and muscle. The difference in protein content between the plasma and the interstitial fluid compartment is maintained by the impermeability of the capillary wall to protein. This protein concentration gradient (the colloid osmotic, or oncotic, pressure of the plasma) contributes to the balance of forces across the capillary wall that favour fluid retention within the plasma compartment.

The concentration of sodium in the ECF plays a pivotal role in determining plasma osmolality and thereby controlling intracellular volume through changes in water balance between the intracellular and extracellular space. In contrast, plasma volume is largely controlled by total body sodium, which determines volume change. Therefore, disturbances in water homeostasis typically present with biochemical abnormalities such as hyponatraemia or hypernatraemia, whereas disturbances in sodium homeostasis present with hypervolaemia or hypovolaemia as the result of expansion or contraction of ECF volume, respectively.

Sodium homeostasis

Most of the body's sodium is located in the ECF, where it is by far the most abundant cation. Accordingly, total body sodium is the principal determinant of ECF volume. Sodium intake varies widely between individuals, ranging between 50 and 250 mmol/24 hrs. The kidneys can compensate for these wide variations in sodium intake by increasing excretion of sodium when there is sodium overload, and retaining sodium in the presence of sodium depletion, to maintain normal ECF volume and plasma volume.

Functional anatomy and physiology

The functional unit for renal excretion is the nephron (Fig. 14.2). Blood undergoes ultrafiltration in the glomerulus, generating a

fluid that is free from cells and protein and which resembles plasma in its electrolyte composition. This is delivered into the renal tubules, where reabsorption of water and various electrolytes occurs. (More detail on the structure and function of the glomerulus is given in Ch. 15.) The glomerular filtration rate (GFR) is approximately 125 mL/min (equivalent to 180 L/24 hrs) in a normal adult. Over 99% of the filtered fluid is reabsorbed into the blood in the peritubular capillaries during its passage through successive segments of the nephron, largely as a result of tubular reabsorption of sodium. The processes mediating sodium reabsorption, and the factors that regulate it, are key to understanding clinical disturbances and pharmacological interventions of sodium and fluid balance.

The nephron can be divided into at least four different functional segments in terms of sodium reabsorption (Fig. 14.3).

Proximal renal tubule

About 65% of the filtered sodium load is reabsorbed in the proximal renal tubule. The cellular mechanisms are complex but some of the key features are shown in Figure 14.3A. Filtered sodium in the luminal fluid enters the proximal tubular cell through transporters in the apical membrane that couple sodium transport to the entry of glucose, amino acid, phosphate and other organic molecules. Entry of sodium into the tubular cells at this site is also linked to secretion of H^+ ions, through the sodium–hydrogen exchanger (NHE-3). Intracellular H^+ ions are generated within tubular cells from the breakdown of carbonic acid, which is produced from carbon dioxide and water under the influence of carbonic anhydrase. Large numbers of Na,K-ATPase pumps are present on the basolateral membrane of tubular cells, which transport sodium from the cells into the blood. In addition, a large component of the transepithelial flux of sodium, water and other dissolved solutes occurs through gaps *between* the cells (the 'shunt' pathway). Overall, fluid and electrolyte reabsorption is almost isotonic in this segment, as water reabsorption is matched very closely to sodium fluxes, such that the osmolality of fluid passing into the loop of Henle is very similar to that of plasma. A component of this water flow also passes *through* the cells, via aquaporin-1 (AQP-1) water channels, which are not sensitive to hormonal regulation.

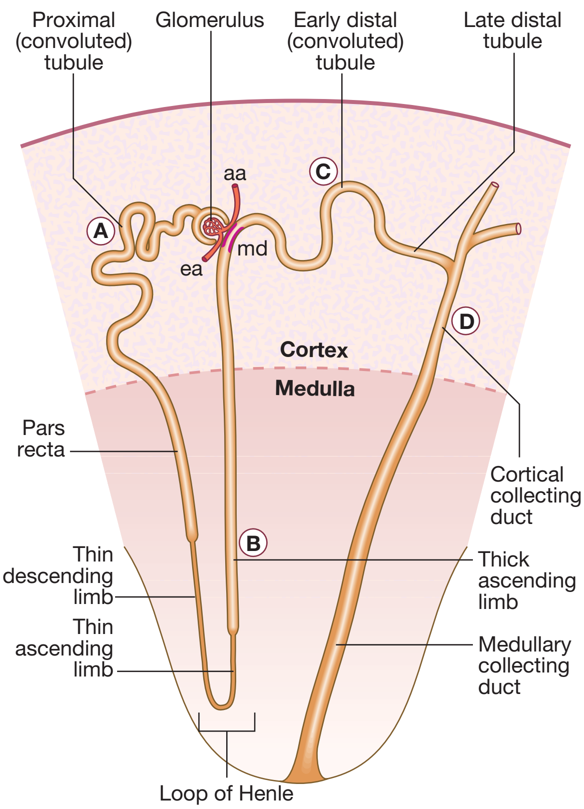

Fig. 14.2 The nephron. Letters A–D refer to tubular segments shown in more detail in Figure 14.3. (aa = afferent arteriole; ea = efferent arteriole; md = macula densa)

Loop of Henle

The thick ascending limb of the loop of Henle (Fig. 14.3B) reabsorbs a further 25% of the filtered sodium but is impermeable to water, resulting in dilution of the luminal fluid. The primary driving force is the Na,K-ATPase on the basolateral cell membrane, but in this segment sodium enters the cell from the lumen through a specific carrier molecule, the Na,K,2Cl co-transporter ('triple co-transporter', or NKCC2), which allows electroneutral entry of these ions into the renal tubular cell by balancing transport of anions (Na^+/K^+) with cations (Cl^-). Some of the potassium accumulated inside the cell recirculates across the apical membrane back into the lumen through a specific potassium channel (ROMK), providing a continuing supply of potassium to match the high concentrations of sodium and chloride in the lumen. A small positive transepithelial potential difference exists in the lumen of this segment relative to the interstitium, and this serves to drive cations such as sodium, potassium, calcium and magnesium between the cells, forming a reabsorptive shunt pathway.

Early distal renal tubule

About 6% of filtered sodium is reabsorbed in the early distal tubule (also called distal convoluted tubule) (Fig. 14.3C), again driven by the activity of the basolateral Na,K-ATPase. In this segment, entry of sodium into the cell from the luminal fluid occurs through a sodium–chloride co-transport carrier (NCCT). This segment is also impermeable to water, resulting in further dilution of the luminal fluid. There is no significant transepithelial flux of potassium in this segment, but calcium is reabsorbed through the mechanism shown in Figure 14.3C: a basolateral sodium–calcium exchanger leads to low intracellular concentrations of calcium, promoting calcium entry from the luminal fluid through a calcium channel.

Late distal renal tubule and collecting ducts

The late distal tubule and cortical collecting duct are anatomically and functionally continuous (Fig. 14.3D). Here, sodium entry from the luminal fluid occurs through the epithelial sodium channel (ENaC), generating a substantial lumen-negative transepithelial potential difference. This sodium flux into the tubular cells is balanced by secretion of potassium and hydrogen ions into the lumen and by reabsorption of chloride ions. Potassium is accumulated in the cell by the basolateral Na,K-ATPase, and passes into the luminal fluid down its electrochemical gradient, through an apical potassium channel (ROMK). Chloride ions pass largely between cells. Hydrogen ion secretion is mediated by an H^+-ATPase located on the luminal membrane of the intercalated cells, which constitute approximately one-third of the epithelial cells in this segment of the nephron. The distal tubule and collecting duct have a variable permeability to water, depending on circulating levels of vasopressin (antidiuretic hormone, ADH).

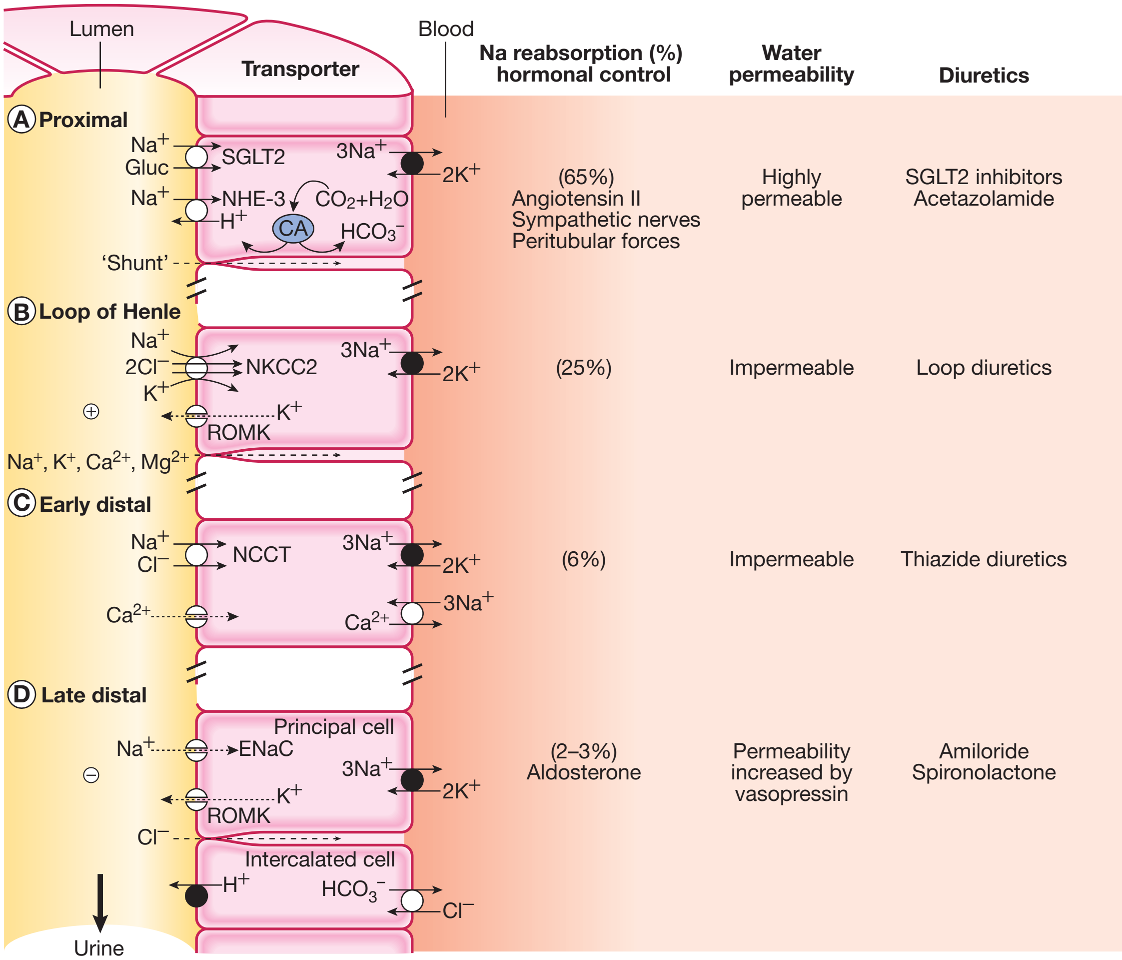

Fig. 14.3 Principal transport mechanisms in segments of the nephron. The apical membrane of tubular cells is the side facing the lumen and the basolateral membrane is the side facing the blood. Black circles indicate active transport pumps linked to ATP hydrolysis and white symbols indicate ion channels and transporter molecules. Details of the proportion of sodium reabsorbed, influence of regulatory factors, water permeability and sites of action for different classes of diuretics are shown. The SGLT2 inhibitors are primarily used for the treatment of diabetes but have diuretic properties by blocking SGLT2 in the proximal tubule. At the same site, acetazolamide inhibits carbonic anhydrase (CA), which, by reducing production of hydrogen ions by proximal tubular cells, inhibits sodium–hydrogen exchange through the NHE-3 transporter. Loop diuretics block the NKCC2 transporter in the loop of Henle, whereas thiazide diuretics block the NCCT channel in the early distal tubule. Amiloride and spironolactone block the ENaC channel in the late distal tubule and collecting ducts. See text for further details and abbreviations.

All ion transport processes in this segment are stimulated by the steroid hormone aldosterone, which can increase sodium reabsorption in this segment to a maximum of 2–3% of the filtered sodium load.

Less than 1% of sodium reabsorption occurs in the medullary collecting duct, where it is inhibited by atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP).

Regulation of sodium transport

The amount of sodium excreted by the kidney is dependent on the filtered load of sodium (which is largely determined by GFR) and the control of tubular sodium reabsorption. A number of interrelated mechanisms serve to maintain whole-body sodium balance, and hence ECF volume, by matching urinary sodium excretion to sodium intake (Fig. 14.4), and controlling those two processes.

Important sensing mechanisms include volume receptors in the cardiac atria and the intrathoracic veins, as well as pressure receptors located in the central arterial tree (aortic arch and carotid sinus) and the afferent arterioles within the kidney. A further afferent signal is generated within the kidney itself: the enzyme renin is released from specialised smooth muscle cells in the walls of the afferent and efferent arterioles, at the point where they make contact with the early distal tubule (at the macula densa; see Fig. 14.2) to form the juxtaglomerular apparatus. Renin release is stimulated by:

- reduced perfusion pressure in the afferent arteriole
- increased sympathetic nerve activity
- decreased sodium chloride concentration in the distal tubular fluid.

Renin acts on the peptide substrate, angiotensinogen (which is produced by the liver), to produce angiotensin I, which is cleaved by angiotensin-converting enzyme (ACE), largely in the pulmonary capillary bed, to produce angiotensin II (see Fig. 18.18, p. 666). Angiotensin II has multiple actions: it stimulates proximal tubular sodium reabsorption and release of aldosterone from the zona glomerulosa of the adrenal cortex, and causes vasoconstriction of small arterioles. Aldosterone amplifies sodium

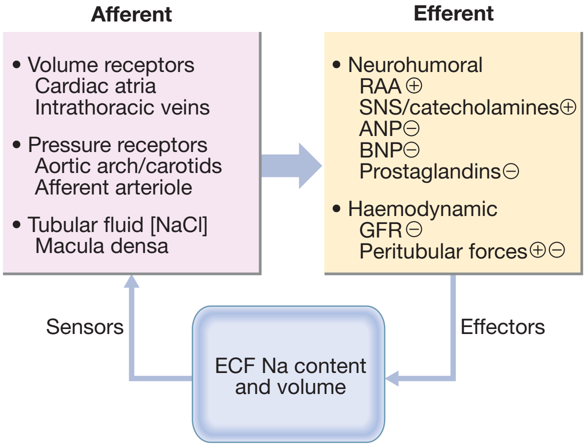

Fig. 14.4 Mechanisms involved in the regulation of sodium transport. (ANP = atrial natriuretic peptide; BNP = brain natriuretic peptide; ECF = extracellular fluid; GFR = glomerular filtration rate; RAA = renin–angiotensin–aldosterone system; SNS = sympathetic nervous system. ⊕ indicates an effect to stimulate Na reabsorption and hence reduce Na excretion, while ⊖ indicates an effect to inhibit Na reabsorption and hence increase Na excretion)

retention by its action on the cortical collecting duct. The net effect of activation of the renin–angiotensin system is to raise blood pressure and cause sodium and water retention, thereby correcting hypovolaemia.

Changes in GFR alter peritubular hydrostatic pressure and oncotic pressure in opposite directions, resulting in a change in sodium reabsorption. In particular, with hypovolaemia, and a reduction in hydrostatic pressure and an increase in oncotic pressure, there is an increase in sodium reabsorption.

The sympathetic nervous system also acts to increase sodium retention, both through haemodynamic mechanisms (afferent arteriolar vasoconstriction and GFR reduction) and by direct stimulation of proximal tubular sodium reabsorption. In contrast, other humoral mediators, such as the natriuretic peptides, which inhibit sodium reabsorption, contribute to natriuresis during periods of sodium and volume excess.

Increases in sodium intake cause hypervolaemia, which increases renal perfusion and GFR and suppresses renin production through increased delivery of sodium into the macula densa. This sets in motion a train of events opposite to those that occur in hypovolaemia, to cause an increase in sodium excretion.

Presenting problems in sodium and water balance

When the balance of sodium intake and excretion is disturbed, any tendency for plasma sodium concentration to change is usually corrected by the osmotic mechanisms controlling water balance (p. 349). As a result, disorders in sodium balance present chiefly as alterations in the ECF volume, resulting in hypovolaemia or hypervolaemia, rather than as an alteration in plasma sodium concentration. Clinical manifestations of altered ECF volume are illustrated in Box 14.3.

Hypovolaemia

Hypovolaemia is defined as a reduction in circulating blood volume. The most common causes are loss or sequestration

14.3 Clinical features of hypovolaemia and hypervolaemia

	Hypovolaemia	Hypervolaemia
Symptoms	Thirst Dizziness on standing Weakness	Ankle swelling Abdominal swelling Breathlessness
Signs	Postural hypotension Tachycardia Dry mouth Reduced skin turgor Reduced urine output Weight loss Delirium, stupor	Peripheral oedema Raised JVP Pulmonary crepitations Pleural effusion Ascites Weight gain Hypertension (sometimes)

(JVP = jugular venous pressure)

14.4 Causes of hypovolaemia

Mechanism	Examples
Inadequate sodium intake	Environmental deprivation, inadequate therapeutic replacement
Gastrointestinal sodium loss	Vomiting, diarrhoea, nasogastric suction, external fistula
Skin sodium loss	Excessive sweating, burns
Renal sodium loss	Diuretic therapy, mineralocorticoid deficiency, tubulointerstitial disease
Internal sequestration*	Bowel obstruction, peritonitis, pancreatitis, crush injury
Reduced blood volume	Acute blood loss

*A cause of circulatory volume depletion, although total body sodium and water may be normal or increased.

of sodium-containing fluids or acute blood loss, as summarised in Box 14.4.

Pathogenesis

Loss of sodium-containing fluid triggers the changes in renal sodium handling and activation of the renin–angiotensin system that were described on page 349. Loss of whole blood, as in acute haemorrhage, is another cause of hypovolaemia, and elicits the same mechanisms for the conservation of sodium and water as loss of sodium-containing fluid.

Clinical features

Hypovolaemia is primarily a clinical diagnosis, based on characteristic symptoms such as thirst, dizziness and weakness along with characteristic clinical signs (see Box 14.3) in the context of a relevant precipitating illness.

Investigations

Serum sodium concentrations are usually normal in hypovolaemia. The GFR is usually maintained unless the hypovolaemia is very severe or prolonged, but urinary flow rate is reduced as a consequence of activation of sodium- and water-retaining mechanisms in the nephron. Serum creatinine, which reflects GFR, is usually normal, but serum urea concentration is typically elevated due to a low urine flow rate, which is accompanied

by increased tubular reabsorption of urea. Similarly, serum uric acid may also rise, reflecting increased reabsorption in the proximal renal tubule. The urine osmolality increases due to increased reabsorption of sodium and water, while the urine sodium concentration falls and sodium excretion may fall to less than 0.1% of the filtered sodium load.

Management

Management of sodium and water depletion has two main components:

- treat the cause where possible, to stop ongoing salt and water losses
- replace the salt and water deficits, and provide ongoing maintenance requirements, usually by intravenous fluid replacement when depletion is severe.

Intravenous fluid therapy

Intravenous fluid therapy can be used to maintain water, sodium and potassium intake when the patient is fasting, such as during an acute illness or post-operatively. If any deficits or continuing pathological losses are identified, additional fluid and electrolytes will be required. In prolonged periods of fasting (more than a few days), attention also needs to be given to providing sufficient caloric and nutritional intake to prevent excessive catabolism of body energy stores (p. 704). The daily maintenance requirements for water and electrolytes in a typical adult are shown in Box 14.5 and the composition of some widely available intravenous fluids are given in Box 14.6. The choice of fluid and the rate of administration depend on the clinical circumstances, as assessed at the bedside and from laboratory data, as described in Box 14.7.

The choice of intravenous fluid therapy in the treatment of significant hypovolaemia relates to the concepts in Figure 14.1. If fluid containing neither sodium nor protein is given, it will distribute in the body fluid compartments in proportion to the normal distribution of total body water. For example, administration of 1 L of 5% dextrose contributes little (approximately 3/40 of the infused volume) towards expansion of the plasma volume, which makes this fluid unsuitable for restoring the circulation and perfusion of vital organs. Intravenous infusion of an isotonic (normal) saline solution, on the other hand, is more effective at expanding the ECF, although only a small proportion (about 3/15) of the infused volume actually contributes to plasma volume.

You would expect that solutions containing plasma proteins (colloids) would be better retained within the vascular space and to be more effective at correcting hypovolaemia than protein-free fluids (crystalloids). However, recent clinical studies have not shown any advantage of giving albumin-containing infusions in the treatment of acute hypovolaemia. Furthermore, synthetic colloids such as dextrans have been shown to be associated with an increased risk of acute kidney injury and mortality in the critically ill. Therefore, crystalloids are the fluid of choice for resuscitation in acute hypovolaemia. More studies, however, are required to clarify the most appropriate crystalloid in this situation, given that normal saline can cause a mild metabolic acidosis, perhaps related to excessive chloride loading, whereas ‘balanced solutions’, such as Hartmann’s, may cause a mild hyponatraemia, as its composition is slightly hypotonic.

Hypervolaemia

Hypervolaemia is the result of sodium and water excess and is rare in patients with normal cardiac and renal function, since

14.5 Basic daily water and electrolyte requirements

	Requirement per kg	Typical 70 kg adult
Water	35–45 mL/kg	2.45–3.15 L/24 hrs
Sodium	1.5–2 mmol/kg	105–140 mmol/24 hrs
Potassium	1.0–1.5 mmol/kg	70–105 mmol/24 hrs

14.7 How to assess fluid and electrolyte balance in hospitalised patients

Step 1: assess clinical volume status
- Examine patient for signs of hypovolaemia or hypervolaemia (see Box 14.3)
- Check daily weight change

Step 2: review fluid balance chart
- Check total volumes IN and OUT on previous day (IN–OUT is positive by ~400 mL in normal balance, reflecting insensible fluid losses of ~800 mL and metabolic water generation of ~400 mL)
- Check cumulative change in daily fluid balance over previous 3–5 days
- Correlate chart figures with weight change and clinical volume status to estimate net fluid balance

Step 3: assess ongoing pathological process
- Check losses from gastrointestinal tract and surgical drains
- Estimate increased insensible losses (e.g. in fever) and internal sequestration (‘third space’)

Step 4: check plasma U&Es (see Box 14.2)
- Check plasma Na as marker of relative water balance
- Check plasma K as a guide to extracellular K balance
- Check HCO_3^- as a clue to acid–base disorder
- Check urea and creatinine to monitor renal function

Step 5: prescribe appropriate intravenous fluid replacement therapy
- Replace basic water and electrolytes each day (see Box 14.5)
- Allow for anticipated oral intake and pathological fluid loss
- Adjust amounts of water (if IV, usually given as isotonic 5% dextrose), sodium and potassium according to plasma electrolyte results

14.6 Composition of some isotonic intravenous fluids

Fluid	D-glucose	Calories	Na^+ (mmol/L)	Cl^- (mmol/L)	Other (mmol/L)
5% dextrose	50 g	200	0	0	0
Normal (0.9%) saline	0	0	154	154	0
Hartmann’s solution	0	0	131	111	K^+ 5 Ca^{2+} 2 Lactate$^-$ 29

the kidney has a large capacity to increase renal excretion of sodium and water via the homeostatic mechanisms described on page 349.

Pathogenesis

The most common systemic disorders responsible for hypervolaemia are outlined in Box 14.8. In cardiac failure, cirrhosis and nephrotic syndrome, sodium retention occurs in response to circulatory insufficiency caused by the primary disorder, as illustrated in Figure 14.5. The pathophysiology is different in renal failure, when the primary cause of volume expansion is the profound reduction in GFR impairing sodium and water excretion, while secondary tubular mechanisms are of lesser importance. In Conn's syndrome (p. 674), the pathophysiology also differs, in that increased secretion of aldosterone directly stimulates sodium reabsorption.

i 14.8 Causes of sodium and water excess

Mechanism	Examples
Impaired renal function	Primary renal disease
Primary hyperaldosteronism*	Conn's syndrome
Secondary hyperaldosteronism (see Fig. 14.5)	Congestive cardiac failure Cirrhotic liver disease Nephrotic syndrome Protein-losing enteropathy Malnutrition Idiopathic/cyclical oedema Renal artery stenosis*

*Conditions in this box *other than* primary hyperaldosteronism and renal artery stenosis are typically associated with generalised oedema.

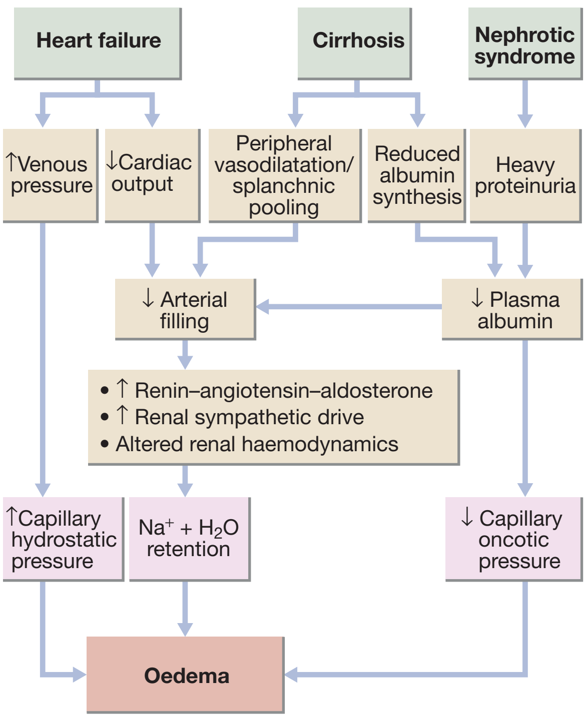

Fig. 14.5 Secondary mechanisms causing sodium excess and oedema in cardiac failure, cirrhosis and nephrotic syndrome. Primary renal retention of Na and water may also contribute to oedema formation when glomerular filtration rate is significantly reduced (see Box 14.8 and p. 395).

Clinical features

Peripheral oedema is the most common physical sign of hypervolaemia since the excess fluid leaks out of the capillaries to expand the interstitial compartment of the ECF. This is particularly the case in nephrotic syndrome and chronic liver disease, in which hypoalbuminaemia is a prominent feature. The main exception is primary hyperaldosteronism (Conn's syndrome), which presents with hypertension and often hypokalaemia, but in which peripheral oedema is not commonly seen.

Investigations

Although hypervolaemia is accompanied by an excess of total body sodium, serum sodium concentrations are normal due to the accompanying water retention. Serum concentrations of potassium are normal except in Conn's syndrome, where there is hypokalaemia due to the increased aldosterone production (p. 674). Creatinine, GFR and urea are usually normal, unless the underlying cause of hypervolaemia is renal failure. General investigations may reveal evidence of cardiac, renal or liver disease.

Management

The management of hypervolaemia involves a number of components:

- specific treatment directed at the underlying cause, such as ACE inhibitors in heart failure and glucocorticoids in minimal change nephropathy
- restriction of dietary sodium (to 50–80 mmol/24 hrs) to match the diminished excretory capacity
- treatment with diuretics.

Diuretic therapy

Diuretics play a pivotal role in the treatment of hypervolaemia due to salt and water retention and in hypertension (p. 513). They act by inhibiting sodium reabsorption at various locations along the nephron (see Fig. 14.3). Their potency and adverse effects relate to their mechanism and site of action.

Carbonic anhydrase inhibitors Acetazolamide is a carbonic anhydrase inhibitor that inhibits intracellular production of H^+ ions in the proximal tubule, reducing the fraction of sodium reabsorption that is exchanged for H^+ by the apical membrane sodium–hydrogen exchanger. It is a weak diuretic but is seldom used clinically for this purpose, since only a small fraction of proximal sodium reabsorption uses this mechanism, and much of the sodium that is not reabsorbed in the proximal tubule can be reabsorbed by downstream segments of the nephron.

Sodium-dependent glucose transporter inhibitors Inhibitors of the sodium-dependent glucose transporter 2 (SGLT2), such as dapagliflozin and canagliflozin, simultaneously block glucose and sodium reabsorption in the proximal tubule. They have mild diuretic properties but are principally used to lower blood glucose in the treatment of diabetes (p. 745).

Loop diuretics Loop diuretics, such as furosemide, inhibit sodium reabsorption in the thick ascending limb of the loop of Henle, by blocking the action of the apical membrane NKCC2 co-transporter. Because this segment reabsorbs a large fraction

of the filtered sodium, these drugs are potent diuretics, and are commonly used in diseases associated with significant oedema. Loop diuretics cause excretion not only of sodium (and with it water) but also of potassium. This occurs largely as a result of delivery of increased amounts of sodium to the late distal tubule and cortical collecting ducts, where sodium reabsorption is associated with excretion of potassium, and is amplified if circulating aldosterone levels are high.

Thiazide diuretics Thiazide diuretics inhibit sodium reabsorption in the early distal tubule, by blocking the NCCT co-transporter in the apical membrane. Since this segment reabsorbs a much smaller fraction of the filtered sodium, these are less potent than loop diuretics, but are widely used in the treatment of hypertension and less severe oedema. Like loop diuretics, thiazides increase excretion of potassium through delivery of increased amounts of sodium to the late distal tubule and collecting duct. They are the diuretics that are most likely to be complicated by the development of hyponatraemia, as outlined on page 357.

Potassium-sparing diuretics Potassium-sparing diuretics act on the late distal renal tubule and cortical collecting duct segment to inhibit sodium reabsorption. Since sodium reabsorption and potassium secretion are linked at this site, the reduced sodium reabsorption is accompanied by reduced potassium secretion. The apical sodium channel (see Fig. 14.3) is blocked by amiloride and triamterene, while spironolactone and eplerenone also act at this site by blocking binding of aldosterone to the mineralocorticoid receptor.

Osmotic diuretics These act independently of a specific transport mechanism. As they are freely filtered at the glomerulus but not reabsorbed by any part of the tubular system, they retain fluid osmotically within the tubular lumen and limit the extent of sodium reabsorption in multiple segments. Mannitol is the most commonly used osmotic diuretic. It is given by intravenous infusion to achieve short-term diuresis in conditions such as cerebral oedema.

Clinical use of diuretics

The following principles should be observed when using diuretics:

- Use the minimum effective dose.
- Use for as short a period of time as necessary.
- Monitor regularly for adverse effects.

The choice of diuretic is determined by the potency required, the presence of coexistent conditions, and the side-effect profile.

Adverse effects encountered with the most frequently used classes of diuretic (loop drugs and thiazide drugs) are summarised in Box 14.9. Volume depletion and electrolyte disorders are the most common, as predicted from their mechanism of action. The metabolic side-effects listed are rarely of clinical significance and may reflect effects on K^+ channels that influence insulin secretion (p. 723). Since most drugs from these classes are sulphonamides, there is a relatively high incidence of hypersensitivity reactions, and occasional idiosyncratic side-effects in a variety of organ systems.

The side-effect profile of the potassium-sparing diuretics differs in a number of important respects from that of other diuretics. The disturbances in potassium, magnesium and acid–base balance are in the opposite direction, so that normal or increased levels of potassium and magnesium are found in the blood, and there is a tendency to metabolic acidosis, especially when renal function is impaired.

i 14.9 Adverse effects of loop-acting and thiazide diuretics

Renal side-effects	
• Hypovolaemia • Hyponatraemia • Hypokalaemia • Metabolic alkalosis	• Hyperuricaemia • Hypomagnesaemia • Hypercalciuria (loop) • Hypocalciuria (thiazide)
Metabolic side-effects	
• Glucose intolerance/ hyperglycaemia	• Hyperlipidaemia
Miscellaneous side-effects	
• Hypersensitivity reactions • Erectile dysfunction	• Acute pancreatitis/cholecystitis (thiazides)

An important feature of the most commonly used diuretic drugs (furosemide, thiazides and amiloride) is that they act on their target molecules from the luminal side of the tubular epithelium. Since they are highly protein-bound in the plasma, very little reaches the urinary fluid by glomerular filtration, but there are active transport mechanisms for secreting organic acids and bases, including these drugs, across the proximal tubular wall into the lumen, resulting in adequate drug concentrations being delivered to later tubular segments. This secretory process may be impaired by certain other drugs, and also by accumulated organic anions as occurs in chronic kidney disease and chronic liver failure, leading to resistance to diuretics.

Diuretic resistance is encountered under a variety of circumstances, including impaired renal function, activation of sodium-retaining mechanisms, impaired oral bioavailability (such as in patients with gastrointestinal disease) and decreased renal blood flow. In these circumstances, short-term intravenous therapy with a loop-acting agent such as furosemide may be useful. Combinations of diuretics administered orally may also increase potency. Either a loop or a thiazide drug can be combined with a potassium-sparing drug, and all three classes can be used together for short periods, with carefully supervised clinical and laboratory monitoring.

Water homeostasis

Daily water intake can vary from about 500 mL to several litres a day. About 800 mL of water is lost daily through the stool, sweat and the respiratory tract (insensible losses) and about 400 mL is generated daily through oxidative metabolism (metabolic water). The kidneys are chiefly responsible for adjusting water excretion to balance intake, endogenous production and losses so as to maintain total body water content and serum osmolality within the reference range of 280–296 mOsmol/kg.

Functional anatomy and physiology

While regulation of total ECF volume is largely achieved through renal control of sodium excretion, mechanisms exist to allow for the excretion of urine that is hypertonic or hypotonic in relation to plasma to maintain constant plasma osmolality.

These functions are largely achieved by the loop of Henle and the collecting ducts (see Fig. 14.2). The countercurrent configuration of flow in adjacent limbs of the loop (Fig. 14.6) involves osmotic movement of water from the descending limbs and reabsorption of

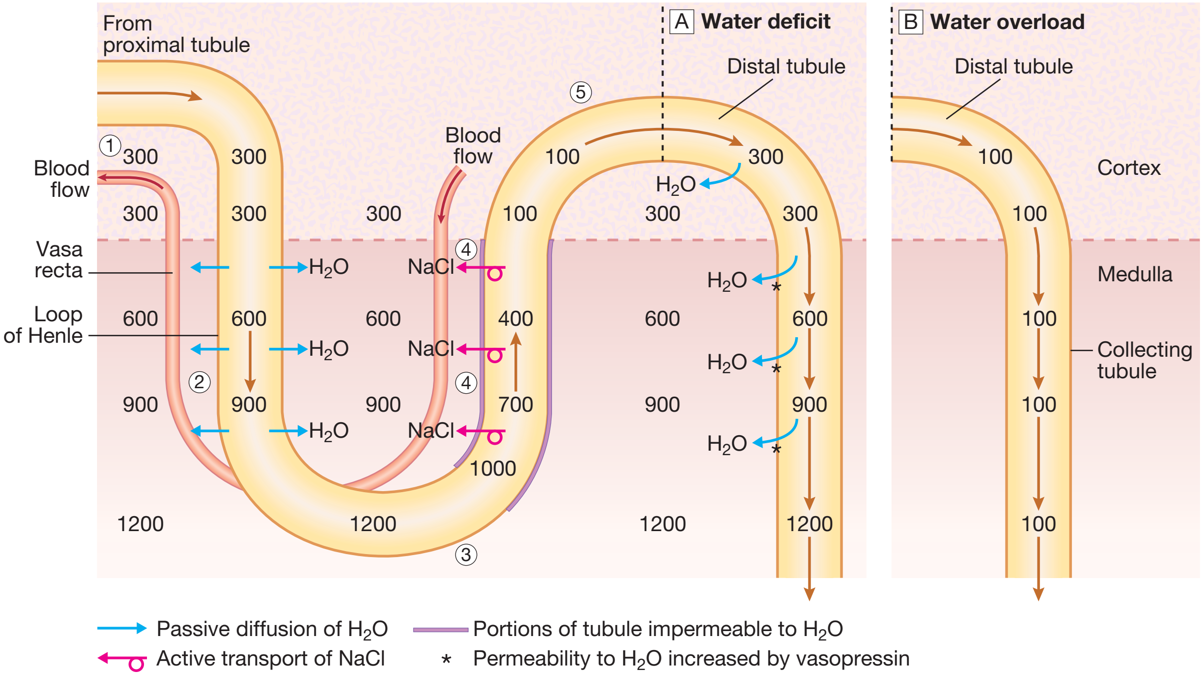

Fig. 14.6 Mechanisms of renal water handling. (1) Filtrate from the proximal tubule is isosmotic to plasma and cortical interstitial fluid. (2) Water moves down its osmotic gradient, concentrating the filtrate but not diluting the interstitium, as the vasa recta carries away the water. (3) The filtrate is at its highest concentration at the bend of the loop and therefore the surrounding medulla is also concentrated. (4) NaCl is pumped out of the filtrate in the thick ascending limb and early distal tubule, increasing the interstitial fluid osmolality. (5) The filtrate has a concentration of 100 mOsmol/kg as it leaves the early distal tubule. **A** In the face of water deficit, vasopressin causes water permeability of the collecting ducts, resulting in osmotic reabsorption of water. **B** In the situation of water overload, vasopressin secretion is suppressed and urine remains dilute.

solute from neighbouring ascending limbs, to set up a gradient of osmolality from isotonic (like plasma) in the renal cortex to hypertonic (around 1200 mOsmol/kg) in the inner part of the medulla. At the same time, the fluid emerging from the thick ascending limb is hypotonic compared to plasma because it has been diluted by the reabsorption of sodium, but not water, from the thick ascending limb and is further diluted in the early distal tubule. As this dilute fluid passes from the cortex through the collecting duct system to the renal pelvis, it traverses the medullary interstitial gradient of osmolality set up by the operation of the loop of Henle, and water is able to be reabsorbed.

Further changes in the urine osmolality on passage through the collecting ducts depend on the circulating level of vasopressin, which is released by the posterior pituitary gland under conditions of increased plasma osmolality or hypovolaemia (p. 688).

- When water intake is high and plasma osmolality is normal or low–normal (Fig. 14.6B), vasopressin levels are suppressed and the collecting ducts remain impermeable to water. The luminal fluid osmolality remains low, resulting in the excretion of a dilute urine (minimum osmolality approximately 50 mOsmol/kg in a healthy young person).
- When water intake is restricted and plasma osmolality is high (Fig. 14.6A), or in the presence of plasma volume depletion, vasopressin levels rise. This causes water permeability of the collecting ducts to increase through binding of vasopressin to the V2 receptor, which enhances collecting duct water permeability through the insertion of AQP-2 channels into the luminal cell membrane. This results in osmotic reabsorption of water along the entire length of the collecting duct, with maximum urine osmolality approaching that in the medullary tip (up to 1200 mOsmol/kg).

Parallel to these changes in vasopressin release are changes in water-seeking behaviour triggered by the sensation of thirst, which also becomes activated as plasma osmolality rises.

In summary, for adequate dilution of the urine there must be:

- adequate solute delivery to the loop of Henle and early distal tubule
- normal function of the loop of Henle and early distal tubule
- absence of vasopressin in the circulation.

If any of these processes is faulty, water retention and hyponatraemia may result.

Conversely, to achieve concentration of the urine there must be:

- adequate solute delivery to the loop of Henle
- normal function of the loop of Henle
- vasopressin release into the circulation
- vasopressin action on the collecting ducts.

Failure of any of these steps may result in inappropriate water loss and hypernatraemia.

Presenting problems in regulation of osmolality

Changes in plasma osmolality are largely determined by changes in serum sodium concentration and its associated anions. Changes in sodium concentration usually occur because of disturbances in water balance either because there is a relative excess of body water compared to total body sodium (hyponatraemia) or

a relative lack of body water compared to total body sodium (hypernatraemia). Abnormalities of water balance can result from disturbances in urinary concentration or dilution.

If extracellular osmolality falls abruptly, water flows rapidly across cell membranes, causing cell swelling, whereas cell shrinkage occurs when osmolality rises. Cerebral function is particularly sensitive to such volume changes, particularly brain swelling during hypo-osmolality, which can lead to an increase in intracerebral pressure and reduced cerebral perfusion.

Hyponatraemia

Hyponatraemia is defined as a serum Na < 135 mmol/L. It is a common electrolyte abnormality with many potential underlying causes, as summarised in Box 14.10.

Pathophysiology

In all cases, hyponatraemia is caused by greater retention of water relative to sodium. The causes are best categorised according to associated changes in the ECF volume (Box 14.10).

Hyponatraemia with hypovolaemia

In this situation there is depletion of sodium and water but the sodium deficit exceeds the water deficit, causing hypovolaemia and hyponatraemia (see Box 14.3). The cause of sodium loss is usually apparent and common examples are shown in Box 14.10.

Hyponatraemia with euvolaemia

In this situation there are no major disturbances of body sodium content and the patient is clinically euvolaemic. Excess body water may be the result of abnormally high intake, either orally (primary polydipsia) or as a result of medically infused fluids (as intravenous dextrose solutions, or by absorption of sodium-free bladder irrigation fluid after prostatectomy).

Water retention also occurs in the syndrome of inappropriate secretion of antidiuretic hormone, or vasopressin (SIADH). In this condition, an endogenous source of vasopressin (either cerebral or tumour-derived) promotes water retention by the kidney in the absence of an appropriate physiological stimulus (Box 14.11). The clinical diagnosis requires the patient to be euvolaemic, with no evidence of cardiac, renal or hepatic disease potentially associated with hyponatraemia. Other non-osmotic stimuli that cause release of vasopressin (pain, stress, nausea) should also be excluded. Supportive laboratory findings are shown in Box 14.11.

Hyponatraemia with hypervolaemia

In this situation, excess water retention is associated with sodium retention and volume expansion, as in heart failure, liver disease or kidney disease.

Clinical features

Hyponatraemia is often asymptomatic but can also be associated with profound disturbances of cerebral function, manifesting as anorexia, nausea, vomiting, delirium, lethargy, seizures and coma. The likelihood of symptoms occurring is related to the speed at which hyponatraemia develops rather than the severity of hyponatraemia. This is because water rapidly flows into cerebral cells when plasma osmolality falls acutely, causing them to become swollen and ischaemic. However, when hyponatraemia develops gradually, cerebral neurons have time to respond by reducing intracellular osmolality, through excreting potassium and reducing synthesis of intracellular organic osmolytes (Fig. 14.7). The osmotic gradient favouring water movement into the cells is thus reduced and symptoms are avoided. This process takes about 24–48 hours and hyponatraemia is therefore classified as acute (<48 hours) and chronic (>48 hours). Hyponatraemia can also be defined as mild (130–135 mmol/L), moderate (125–129 mmol/L) or severe (< 124 mmol/L), based on biochemical findings or on the degree of severity of symptoms (Box 14.12).

Investigations

An algorithm for the clinical assessment of patients with hyponatraemia is shown in Figure 14.8. Artefactual causes of hyponatraemia should be considered in all cases. These include severe hyperlipidaemia or hyperproteinaemia, when the aqueous fraction of the serum specimen is reduced because of the volume occupied by the macromolecules (although this artefact is dependent on the assay technology). Transient hyponatraemia

14.10 Causes of hyponatraemia

Volume status	Examples
Hypovolaemic	Renal sodium losses: Diuretic therapy (especially thiazides) Adrenocortical failure Gastrointestinal sodium losses: Vomiting Diarrhoea Skin sodium losses: Burns
Euvolaemic	Primary polydipsia Excessive electrolyte-free water infusion SIADH Hypothyroidism
Hypervolaemic	Congestive cardiac failure Cirrhosis Nephrotic syndrome Chronic kidney disease (during free water intake)

(SIADH = syndrome of inappropriate antidiuretic hormone (vasopressin) secretion; see Box 14.11).

14.11 Causes and diagnosis of syndrome of inappropriate antidiuretic hormone secretion

Causes

- Tumours
- Central nervous system disorders: stroke, trauma, infection, psychosis, porphyria
- Pulmonary disorders: pneumonia, tuberculosis, obstructive lung disease
- Drugs: anticonvulsants, psychotropics, antidepressants, cytotoxics, oral hypoglycaemic agents, opiates
- Idiopathic

Diagnosis

- Low plasma sodium concentration (typically < 130 mmol/L)
- Low plasma osmolality (< 275 mOsmol/kg)
- Urine osmolality not minimally low (typically > 100 mOsmol/kg)
- Urine sodium concentration not minimally low (> 30 mmol/L)
- Low–normal plasma urea, creatinine, uric acid
- Clinical euvolaemia
- Absence of adrenal, thyroid, pituitary or renal insufficiency
- No recent use of diuretics
- Exclusion of other causes of hyponatraemia (see Box 14.10)
- Appropriate clinical context (above)

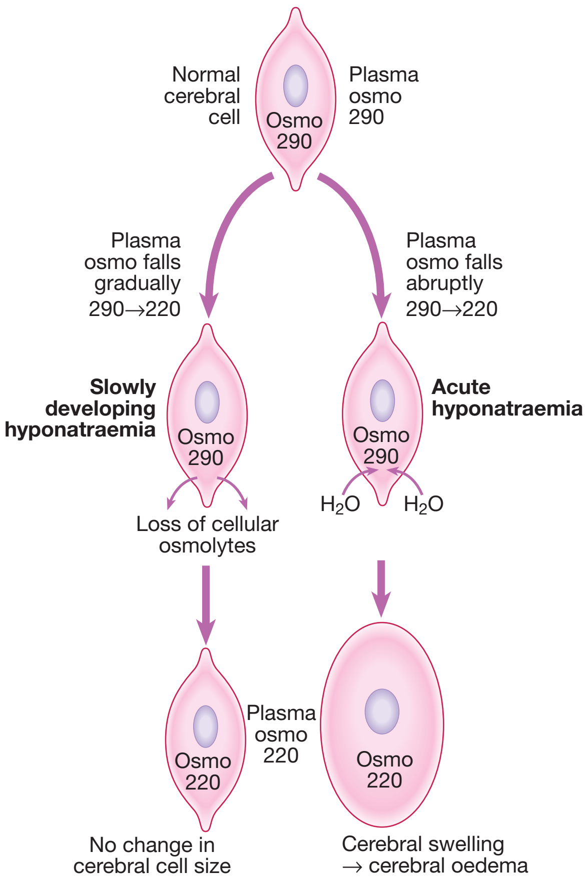

Fig. 14.7 Hyponatraemia and the brain. Numbers represent osmolality (osmo) in mOsmol/kg.

14.12 Symptoms and severity of hyponatraemia

Severity	Serum sodium	Symptoms
Mild	130–135 mmol/L	None
Moderate	125–129 mmol/L	Nausea Delirium Headache
Severe	<124 mmol/L	Vomiting Somnolence Seizures Coma Cardiorespiratory arrest

may also occur due to osmotic shifts of water out of cells during hyperosmolar states caused by acute hyperglycaemia or by mannitol infusion, but in these cases plasma osmolality is normal.

When these conditions have been excluded, serum and urine electrolytes and osmolality (Fig. 14.8) are usually the only tests required to clarify the underlying cause. Hypovolaemic hyponatraemia is characterised by a low urinary sodium concentration (<30 mmol/L) when there are extrarenal causes of sodium loss and high urinary sodium concentration (>30 mmol/L) in patients with excessive renal sodium loss.

Measurement of vasopressin is not generally helpful in distinguishing between different categories of hyponatraemia. This is because concentrations of vasopressin are raised both in hypovolaemic states and in most chronic hypervolaemic states, as the impaired circulation in those disorders activates vasopressin release through non-osmotic mechanisms. Indeed, patients with these disorders may have higher circulating vasopressin (ADH) levels than patients with SIADH. The only disorders listed in Box 14.10 in which vasopressin is suppressed are primary polydipsia and iatrogenic water intoxication, where the hypo-osmolar state inhibits vasopressin release from the pituitary.

Management

The treatment of hyponatraemia is critically dependent on its rate of development, severity, presence of symptoms and underlying cause. If hyponatraemia has developed rapidly (<48 hours) and there are signs of cerebral oedema, such as obtundation or convulsions, sodium levels should be restored rapidly to normal by infusion of hypertonic (3%) sodium chloride. A common approach is to give an initial bolus of 150 mL over 20 minutes, which may be repeated once or twice over the initial hours of observation, depending on the neurological response and rise in plasma sodium.

Rapid correction of hyponatraemia that has developed more slowly (>48 hours) can be hazardous, since brain cells adapt to slowly developing hypo-osmolality by reducing the intracellular osmolality, thus maintaining normal cell volume (see Fig. 14.7). Under these conditions, an abrupt increase in extracellular osmolality can lead to water shifting out of neurons, abruptly reducing their volume and causing them to detach from their myelin sheaths. The resulting 'myelinolysis' can produce permanent structural and functional damage to mid-brain structures, and is generally fatal. The rate of correction of the plasma Na concentration in chronic asymptomatic hyponatraemia should not exceed 10 mmol/L/24 hrs, and an even slower rate is generally safer.

The underlying cause should also be treated. For hypovolaemic patients, this involves controlling the source of sodium loss, and administering intravenous saline if clinically warranted. Patients with euvolaemic hyponatraemia generally respond to fluid restriction in the range of 600–1000 mL/24 hrs, accompanied where possible by withdrawal of the precipitating stimulus (such as drugs causing SIADH). In patients with persistent hyponatraemia due to prolonged SIADH, oral urea therapy (30–45 g/day) can be used, which provides a solute load to promote water excretion. Oral vasopressin receptor antagonists such as tolvaptan may also be used to block the vasopressin-mediated component of water retention in a range of hyponatraemic conditions, but concerns exist with regard to the risk of overly rapid correction of hyponatraemia with these agents. Hypervolaemic patients with hyponatraemia need treatment of the underlying condition, accompanied by cautious use of diuretics in conjunction with strict fluid restriction. Potassium-sparing diuretics may be particularly useful in this context when there is significant secondary hyperaldosteronism.

Hypernatraemia

Hypernatraemia is defined as existing when the serum Na is >145 mmol/L. The causes are summarised in Box 14.13, grouped according to any associated disturbance in total body sodium content.

Pathophysiology

Hypernatraemia occurs due to inadequate concentration of the urine in the face of restricted water intake. This can arise because

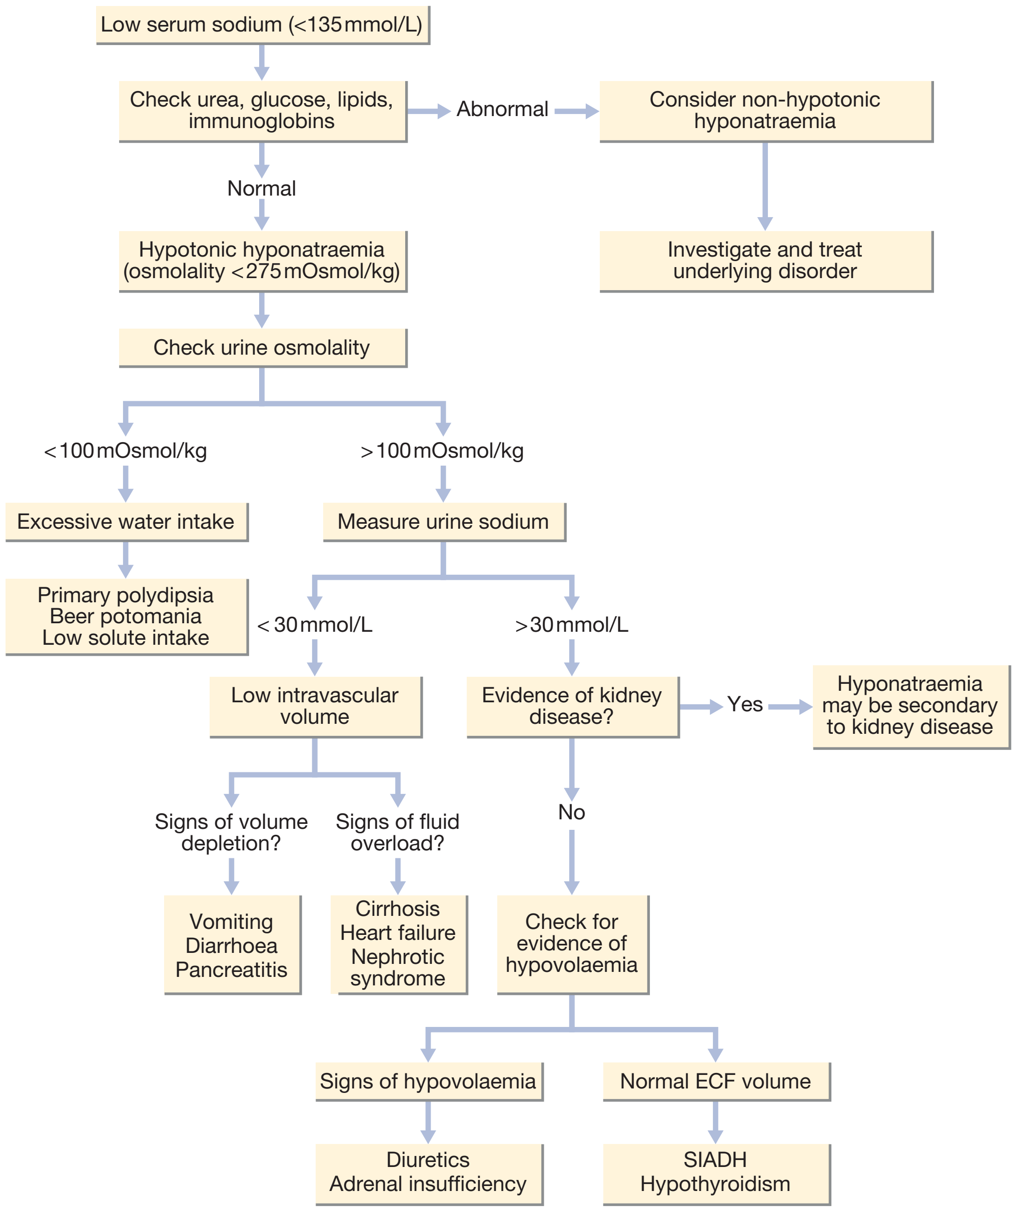

Fig. 14.8 Algorithm for the diagnosis of hyponatraemia. (ECF = extracellular fluid; SIADH = syndrome of inappropriate antidiuretic hormone (vasopressin) secretion)

i 14.13 Causes of hypernatraemia

Volume status	Examples
Hypovolaemic	Renal sodium losses: Diuretic therapy (especially osmotic diuretic, or loop diuretic during water restriction) Glycosuria (hyperglycaemic hyperosmolar state, p. 738) Gastrointestinal sodium losses: Colonic diarrhoea Skin sodium losses: Excessive sweating
Euvolaemic	Diabetes insipidus (central or nephrogenic) (p. 687)
Hypervolaemic	Enteral or parenteral feeding Intravenous or oral salt administration Chronic kidney disease (during water restriction)

of failure to generate an adequate medullary concentration gradient in the kidney due to low GFR or loop diuretic therapy, but more commonly is caused by failure of the vasopressin system. This can occur because of pituitary damage (cranial diabetes insipidus, p. 687) or because the collecting duct cells are unable to respond to circulating vasopressin concentrations in the face of restricted water intake (nephrogenic diabetes insipidus). Whatever the underlying cause, sustained or severe hypernatraemia generally reflects an impaired thirst mechanism or responsiveness to thirst.

Clinical features

Patients with hypernatraemia generally have reduced cerebral function, either as a primary problem or as a consequence of the hypernatraemia itself, which results in dehydration of neurons and brain shrinkage. In the presence of an intact thirst mechanism and preserved capacity to obtain and ingest water,

14.14 Hyponatraemia and hypernatraemia in old age

- **Decline in GFR**: older patients are predisposed to both hyponatraemia and hypernatraemia, mainly because, as glomerular filtration rate declines with age, the capacity of the kidney to dilute or concentrate the urine is impaired.
- **Hyponatraemia**: occurs when free water intake continues in the presence of a low dietary salt intake and/or diuretic drugs (particularly thiazides).
- **Vasopressin release**: water retention is aggravated by any condition that stimulates vasopressin release, especially heart failure. Moreover, the vasopressin response to non-osmotic stimuli may be brisker in older subjects. Appropriate water restriction may be a key part of management.
- **Hypernatraemia**: occurs when water intake is inadequate, due to physical restrictions preventing access to drinks and/or blunted thirst. Both are frequently present in patients with advanced dementia or following a severe stroke.
- **Dietary salt**: hypernatraemia is aggravated if dietary supplements or medications with a high sodium content (especially effervescent preparations) are administered. Appropriate prescription of fluids is a key part of management.

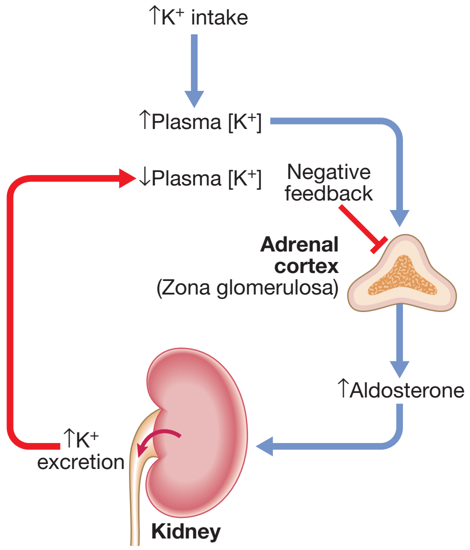

Fig. 14.9 **Feedback control of plasma potassium concentration.**

hypernatraemia may not progress very far. If adequate water is not obtained, dizziness, delirium, weakness and, ultimately, coma and death can result.

Management

Treatment of hypernatraemia depends on both the rate of development and the underlying cause. If there is reason to think that the condition has developed rapidly, neuronal shrinkage may be acute and relatively rapid correction may be attempted. This can be achieved by infusing an appropriate volume of intravenous fluid (isotonic 5% dextrose or hypotonic 0.45% saline) at an initial rate of 50–70 mL/hr. In older, institutionalised patients, however, it is more likely that the disorder has developed slowly, and extreme caution should be exercised in lowering plasma sodium to avoid the risk of cerebral oedema. Where possible, the underlying cause should also be addressed (Box 14.13).

Elderly patients are predisposed, in different circumstances, to both hyponatraemia and hypernatraemia, and a high index of suspicion of these electrolyte disturbances is appropriate in elderly patients with recent alterations in behaviour (Box 14.14).

Potassium homeostasis

Potassium is the major intracellular cation (see Fig. 14.1), and the steep concentration gradient for potassium across the cell membrane of excitable cells plays an important part in generating the resting membrane potential and allowing the propagation of the action potential that is crucial to normal functioning of nerve, muscle and cardiac tissues. Control of body potassium balance is described below.

Functional anatomy and physiology

The kidneys normally excrete some 90% of the daily intake of potassium, typically 80–100 mmol/24 hrs. Potassium is freely filtered at the glomerulus; around 65% is reabsorbed in the proximal tubule and a further 25% in the thick ascending limb of the loop of Henle. Little potassium is transported in the early distal tubule but a significant secretory flux of potassium into the urine occurs in the late distal tubule and cortical collecting duct to ensure that the amount removed from the blood is proportional to the ingested load.

The mechanism for potassium secretion in the distal parts of the nephron is shown in Figure 14.3D. Movement of potassium from blood to lumen is dependent on active uptake across the basal cell membrane by the Na,K-ATPase, followed by diffusion of potassium through the ROMK channel into the tubular fluid. The electrochemical gradient for potassium movement into the lumen is contributed to both by the high intracellular potassium concentration and by the negative luminal potential difference relative to the blood.

A number of factors influence the rate of potassium secretion. Luminal influences include the rate of sodium delivery and fluid flow through the late distal tubule and cortical collecting ducts. This is a major factor responsible for the increased potassium loss that accompanies diuretic treatment. Agents interfering with the generation of the negative luminal potential also impair potassium secretion, and this is the basis of reduced potassium secretion associated with potassium-sparing diuretics such as amiloride. Factors acting on the blood side of this tubular segment include plasma potassium and pH, such that hyperkalaemia and alkalosis both enhance potassium secretion directly. However, the most important factor in the acute and chronic adjustment of potassium secretion to match metabolic potassium load is aldosterone.

As shown in Figure 14.9, a negative feedback relationship exists between the plasma potassium concentration and aldosterone. In addition to its regulation by the renin–angiotensin system (see Fig. 18.18, p. 666), aldosterone is released from the adrenal cortex in direct response to an elevated plasma potassium. Aldosterone then acts on the kidney to enhance potassium secretion, hydrogen secretion and sodium reabsorption, in the late distal tubule and cortical collecting ducts. The resulting increased excretion of potassium maintains plasma potassium within a narrow range (3.6–5.0 mmol/L). Factors that reduce angiotensin II levels may indirectly affect potassium balance by blunting the rise in aldosterone that would otherwise be provoked by hyperkalaemia. This accounts for the increased risk of hyperkalaemia during therapy with ACE inhibitors and related drugs.

Presenting problems in potassium homeostasis

Changes in the distribution of potassium between the ICF and ECF compartments can alter plasma potassium concentration, without any overall change in total body potassium content. Potassium is driven into the cells by extracellular alkalosis and by a number of hormones, including insulin, catecholamines (through the β_2-receptor) and aldosterone. Any of these factors can produce hypokalaemia, whereas extracellular acidosis, lack of insulin, and insufficiency or blockade of catecholamines or aldosterone can cause hyperkalaemia due to efflux of potassium from the intracellular compartment.

Hypokalaemia

Hypokalaemia is a common electrolyte disturbance and is defined as existing when serum K^+ falls below 3.5 mmol/L. The main causes of hypokalaemia are shown in Box 14.15.

14.15 Causes of hypokalaemia

Cause	Other features and comment
Reduced intake	Urine K^+ > 20–30 mmol/24 hrs
Dietary deficiency	
Potassium-free intravenous fluids	
Redistribution into cells	
Alkalosis Insulin Catecholamines β-adrenergic agonists Hypokalaemic periodic paralysis	Caused by flux of K^+ into cells
Increased urinary excretion	Urine K^+ > 20–30 mmol/24 hrs
Activation of mineralocorticoid receptor:	
Conn's syndrome Cushing's syndrome Glucocorticoid excess Carbenoxelone/liquorice	Associated with hypertension and alkalosis
Genetic disorders:	
Liddle's syndrome	Associated with hypertension and alkalosis
Bartter's syndrome Gitelman's syndrome	Associated with hypertension, alkalosis and hypomagnesaemia
Renal tubular acidosis Type 1 (distal) Type 2 (proximal)	Inherited and acquired forms; associated with high serum chloride. Type 2 associated with glycosuria, aminoaciduria and phosphaturia
Acetazolamide	Associated with acidosis
Diuresis:	
Loop diuretics Thiazides Recovery from acute tubular necrosis Recovery from renal obstruction	Increased sodium delivery to distal tubule
Increased gastrointestinal loss	Urine K^+ < 20–30 mmol/L
Upper gastrointestinal tract:	
Vomiting Nasogastric aspiration	Loss of gastric acid Associated with metabolic alkalosis
Lower gastrointestinal tract:	
Diarrhoea Laxative abuse Villous adenoma Bowel obstruction/fistula Ureterosigmoidostomy	Associated with metabolic acidosis

Pathophysiology

Hypokalaemia is generally indicative of abnormal potassium loss from the body, through either the kidney or the gastrointestinal tract. Renal causes of hypokalaemia can be divided into those with and those without hypertension. Hypokalaemia in the presence of hypertension may be due to increased aldosterone secretion in Conn's syndrome (p. 674) or a genetic defect affecting sodium channels in the distal nephron (Liddle's syndrome). Excessive intake of liquorice or treatment with carbenoxolone may result in a similar clinical picture, due to inhibition of the renal 11βHSD2 enzyme, which inactivates cortisol in peripheral tissues.

If blood pressure is normal or low, hypokalaemia can be classified according to the associated change in acid–base balance. Inherited defects in tubular transport should be suspected when hypokalaemia occurs in association with alkalosis, provided that diuretic use has been excluded. One such disease is Bartter's syndrome, in which sodium reabsorption in the thick ascending limb of Henle is defective, usually due to a loss-of-function mutation of the NKCC2 transporter. The clinical and biochemical features are similar to those in chronic treatment with furosemide. In Gitelman's syndrome there is a loss-of-function mutation affecting the NCCT transporter in the early distal tubule. The clinical and biochemical features are similar to chronic thiazide treatment. Note that while both Bartter's and Gitelman's syndromes are characterised by hypokalaemia and hypomagnesaemia, urinary calcium excretion is increased in Bartter's syndrome but decreased in Gitelman's syndrome, analogous to the effects of the loop and thiazide diuretics, respectively, on calcium transport (see Box 14.9).

If hypokalaemia occurs in the presence of a normal blood pressure and metabolic acidosis, renal tubular acidosis (proximal or 'classical' distal) should be suspected (p. 364).

When hypokalaemia is due to potassium wasting through the gastrointestinal tract, the cause is usually obvious clinically. In some cases, when there is occult induction of vomiting, the hypokalaemia is characteristically associated with metabolic alkalosis, due to loss of gastric acid. If, however, potassium loss has occurred through the surreptitious use of aperients, the hypokalaemia is generally associated with metabolic acidosis. In both cases, urinary potassium excretion is low unless there is significant extracellular volume depletion, which can raise urinary potassium levels by stimulating aldosterone production.

Hypokalaemia can also be caused by redistribution of potassium into cells as the result of insulin, β-adrenoceptor agonists and alkalosis, or as the result of K^+ flux into muscle in hypokalaemic periodic paralysis, which is associated with mutations in several genes that regulate transmembrane ion flow into muscle cells. Finally, reduced dietary intake of potassium can contribute to hypokalaemia but is seldom the only cause, except in extreme cases.

Clinical features

Patients with mild hypokalaemia (plasma K^+ 3.0–3.3 mmol/L) are generally asymptomatic, but more profound reductions in plasma potassium often lead to muscular weakness and associated tiredness. Ventricular ectopic beats or more serious arrhythmias may occur and the arrhythmogenic effects of digoxin may be potentiated. Typical electrocardiogram (ECG) changes occur, affecting the T wave in particular (p. 347). Functional bowel obstruction may occur due to paralytic ileus. Long-standing hypokalaemia may cause renal tubular damage (hypokalaemic nephropathy) and can interfere with the tubular response to vasopressin (acquired nephrogenic diabetes insipidus), resulting in polyuria and polydipsia.

Investigations

Measurement of plasma electrolytes, bicarbonate, urine potassium and sometimes of plasma calcium and magnesium is usually sufficient to establish the diagnosis. If the diagnosis remains unclear, plasma renin should be measured. Levels are low in patients with primary hyperaldosteronism (p. 674) and other forms of mineralocorticoid excess, but raised in other causes of hypokalaemia. When there is no obvious clinical clue to which pathway is involved, measurement of urinary potassium may be helpful; if the kidney is the route of potassium loss, the urine potassium is high (>30 mmol/24 hrs), whereas if potassium is being lost through the gastrointestinal tract, the kidney retains potassium, resulting in a lower urinary potassium (generally <20 mmol/24 hrs). It should be noted, however, that if gastrointestinal fluid loss is also associated with hypovolaemia, activation of the renin–angiotensin–aldosterone system may occur, causing increased loss of potassium in the urine.

The cause of hypokalaemia may remain unclear despite the above investigations when urinary potassium measurements are inconclusive and the history is incomplete or unreliable. Many such cases are associated with metabolic alkalosis, and in this setting the measurement of urine chloride concentration can be helpful. A low urine chloride (<30 mmol/L) is characteristic of vomiting (spontaneous or self-induced, in which chloride is lost in HCl in the vomit), while a urine chloride >40 mmol/L suggests diuretic therapy (acute phase) or a tubular disorder such as Bartter's or Gitelman's syndrome. Differentiation between occult diuretic use and primary tubular disorders can be achieved by performing a screen of urine for diuretic drugs.

Management

Treatment of hypokalaemia involves first determining the cause and correcting this where possible. If the problem is mainly one of redistribution of potassium into cells, reversal of the process responsible may be sufficient to restore plasma potassium without providing supplements. In most cases, however, some form of potassium replacement will be required. This can generally be achieved with slow-release potassium chloride tablets, but in more acute circumstances intravenous potassium chloride may be necessary. The rate of administration depends on the severity of hypokalaemia and the presence of cardiac or neuromuscular complications, but should generally not exceed 10 mmol of potassium per hour. In patients with severe, life-threatening hypokalaemia, the concentration of potassium in the infused fluid may be increased to 40 mmol/L if a peripheral vein is used, but higher concentrations must be infused into a large 'central' vein with continuous cardiac monitoring.

In the less common situation where hypokalaemia occurs in the presence of systemic acidosis, alkaline salts of potassium, such as potassium bicarbonate, can be given by mouth. If magnesium depletion is also present, replacement of magnesium may also be required, since low cell magnesium can promote tubular potassium secretion, causing ongoing urinary losses. In some circumstances, potassium-sparing diuretics, such as amiloride, can assist in the correction of hypokalaemia, hypomagnesaemia and metabolic alkalosis, especially when renal loss of potassium is the underlying cause.

Hyperkalaemia

Hyperkalaemia is a common electrolyte disorder, which is defined as existing when serum K^+ is >5 mmol/L. The causes of hyperkalaemia are summarised in Box 14.16.

14.16 Causes of hyperkalaemia

Cause	Other features and comment
Artefactual	
Haemolysis during venepuncture Haemolysis in vitro Thrombocytosis/leucocytosis	Release of intracellular K^+ during sample collection, transit or clotting
Increased intake	
Dietary potassium Potassium-containing intravenous fluids	
Redistribution from cells	
Acidosis	
Insulin deficiency Severe hyperglycaemia β-adrenergic blockers (β-blockers) Hyperkalaemic periodic paralysis Rhabdomyolysis Severe haemolysis Tumour lysis syndrome	Caused by flux of intracellular K^+ into plasma
Reduced urinary excretion	
Reduced glomerular filtration:	
Acute kidney injury Chronic kidney disease	Plasma creatinine typically >500 µmol/L (5.67 mg/dL)
Reduced mineralocorticoid receptor activation:	
Addison's disease Congenital adrenal hyperplasia Isolated aldosterone deficiency	
Angiotensin-converting enzyme (ACE) inhibitors Angiotensin-receptor blockers (ARBs)	ACE inhibitors and ARBs reduce aldosterone levels
Calcineurin inhibitors Spironolactone Eplerenone	All block the mineralocorticoid receptor
Heparin	Heparin inhibits aldosterone production
Inhibitors of renin production:	
Non-steroidal anti-inflammatory drugs (NSAIDs) β-blockers	
Tubulointerstitial disease:	
Interstitial nephritis Diabetic nephropathy Obstructive uropathy	
Other:	
Amiloride	Blocks K^+ exchange in distal tubule
Gordon's syndrome	Direct effect on K^+ transport in renal tubule

Pathophysiology

It is important to remember that hyperkalaemia can be artefactual due to haemolysis of blood specimens during collection or in vitro, or due to release of potassium from platelets in patients with thrombocytosis.

True hyperkalaemia, however, can occur either because of redistribution of potassium between the ICF and ECF, or because potassium intake exceeds excretion. Redistribution

of potassium from the ICF to the ECF may take place in the presence of systemic acidosis, or when the circulating levels of insulin, catecholamines and aldosterone are reduced, or when the effects of these hormones are blocked (p. 361).

High dietary potassium intake may contribute to hyperkalaemia, but is seldom the only explanation unless renal excretion mechanisms are impaired. The mechanism of hyperkalaemia in acute kidney injury and chronic kidney disease is impaired excretion of potassium into the urine as the result of a reduced GFR. In addition, acute kidney injury can be associated with severe hyperkalaemia when there is an increased potassium load, such as in rhabdomyolysis or in sepsis, particularly when acidosis is present. In chronic kidney disease, adaptation to moderately elevated plasma potassium levels commonly occurs. However, acute rises in potassium triggered by excessive dietary intake, hypovolaemia or drugs (see below) may occur and destabilise the situation.

Hyperkalaemia can also develop when tubular potassium secretory processes are impaired, even if the GFR is normal. This can arise in association with low levels of aldosterone, as is found in Addison's disease, hyporeninaemic hypoaldosteronism or inherited disorders such as congenital isolated hypoaldosteronism, in which there is a defect in aldosterone biosynthesis, and pseudohypoaldosteronism type 2 (Gordon's syndrome), caused by mutations in the *WNK2* and *WNK4* genes, which causes decreased potassium secretion in the renal tubules.

Drug-induced causes include ACE inhibitors, angiotensin-receptor blockers (ARBs), non-steroidal anti-inflammatory drugs (NSAIDs) and β-adrenoceptor antagonists (β-blockers).

In another group of conditions, tubular potassium secretion is impaired as the result of aldosterone resistance. This can occur in a variety of diseases in which there is inflammation of the tubulointerstitium, such as systemic lupus erythematosus; following renal transplantation; during treatment with potassium-sparing diuretics; and in a number of inherited disorders of tubular transport.

In aldosterone deficiency or aldosterone resistance, hyperkalaemia may be associated with acid retention, giving rise to the pattern of hyperkalaemic distal ('type 4') renal tubular acidosis (p. 364).

Clinical features

Mild to moderate hyperkalaemia (<6.5 mmol/L) is usually asymptomatic. More severe hyperkalaemia can present with progressive muscular weakness, but sometimes there are no symptoms until cardiac arrest occurs. The typical ECG changes are shown on page 347. Peaking of the T wave is an early ECG sign, but widening of the QRS complex presages a dangerous cardiac arrhythmia. However, these characteristic ECG findings are not always present, even in severe hyperkalaemia.

Investigations

Measurement of electrolytes, creatinine and bicarbonate, when combined with clinical assessment, usually provides the explanation for hyperkalaemia. In aldosterone deficiency, plasma sodium concentration is characteristically low, although this can occur with many causes of hyperkalaemia. Addison's disease should be excluded unless there is an obvious alternative diagnosis, as described on page 671.

Management

Treatment of hyperkalaemia depends on its severity and the rate of development, but opinions vary as to what level of serum potassium constitutes severe hyperkalaemia and requires urgent treatment. Patients who have potassium concentrations <6.5 mmol/L in the absence of neuromuscular symptoms or ECG changes can be treated with a reduction of potassium intake and correction of predisposing factors. However, in acute and/or severe hyperkalaemia (plasma potassium >6.5–7.0 mmol/L), more urgent measures must be taken (Box 14.17). The first step should be infusion of 10 mL 10% calcium gluconate to stabilise conductive tissue membranes (calcium has the opposite effect to potassium on conduction of an action potential). Measures to shift potassium from the ECF to the ICF should also be applied, as they generally have a rapid effect and may avert arrhythmias. Ultimately, a means of removing potassium from the body is generally necessary. When renal function is reasonably preserved, loop diuretics (accompanied by intravenous saline if hypovolaemia is present) may be effective. In renal failure, dialysis may be required. Oral ion exchange resins, such as sodium polystyrene sulfonate (SPS), have traditionally been used to bind and excrete gastrointestinal potassium. There are concerns, however, with regard to SPS's lack of proven efficacy and safety, with a number of reports of intestinal necrosis associated with its use. Alternative cation exchanges have been developed and are currently being trialled, with the aim of providing more effective and safer alternatives for the treatment of hyperkalaemia.

14.17 Treatment of severe hyperkalaemia

Objective	Therapy
Stabilise cell membrane potential[1]	IV calcium gluconate (10 mL of 10% solution)
Shift K^+ into cells	Inhaled β_2-adrenoceptor agonist IV glucose (50 mL of 50% solution) and insulin (5 IU Actrapid) IV sodium bicarbonate[2]
Remove K^+ from body	IV furosemide and normal saline[3] Ion-exchange resin (e.g. Resonium) orally or rectally Dialysis

[1]If severe hyperkalaemia (K^+ typically >6.5 mmol/L). [2]If acidosis present. [3]If adequate residual renal function.

Acid–base homeostasis

The pH of arterial plasma is normally 7.40, corresponding to an H^+ concentration of 40 nmol/L, and under normal circumstances H^+ concentrations do not vary outside the range of 37–45 nmol/L (pH 7.43–7.35). Abnormalities of acid–base balance can occur in a wide range of diseases. Increases in H^+ concentration cause acidosis with a decrease in pH, whereas decreases in H^+ concentration cause alkalosis with a rise in pH.

Functional anatomy and physiology

A variety of physiological mechanisms maintain pH of the ECF within narrow limits. The first is the action of blood and tissue buffers, of which the most important involves reaction of H^+ ions with bicarbonate to form carbonic acid, which, under the

influence of the enzyme carbonic anhydrase (CA), dissociates to form CO_2 and water:

$$CO_2 + H_2O \underset{CA}{\leftrightarrow} H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$$

This buffer system is important because bicarbonate is present at a relatively high concentration in ECF (21–29 mmol/L), and two of its key components are under physiological control: CO_2 by the lungs, and bicarbonate by the kidneys. These relationships are illustrated in Figure 14.10 (a form of the Henderson–Hasselbalch equation).

Respiratory compensation for acid–base disturbances can occur quickly. In response to acid accumulation, pH changes in the brainstem stimulate ventilatory drive, reduce PCO_2 and increase pH (p. 555). Conversely, systemic alkalosis leads to inhibition of ventilation, causing a rise in PCO_2 and reduction in pH, although it should be noted that this mechanism has limited capacity to change pH because hypoxia provides an alternative stimulus to drive ventilation.

The kidneys provide a third line of defence against disturbances of arterial pH. When acid accumulates due to chronic respiratory or metabolic (non-renal) causes, the kidneys have the long-term capacity to enhance urinary excretion of acid, effectively increasing the plasma bicarbonate.

Renal control of acid–base balance

Regulation of acid–base balance occurs at several sites in the kidney. The proximal tubule reabsorbs about 85% of the filtered bicarbonate ions, through the mechanism for H^+ secretion illustrated in Figure 14.3A. This is dependent on the enzyme carbonic anhydrase, both in the cytoplasm of the proximal tubular cells and on the luminal surface of the brush border membranes. The system has a high capacity and is required to rescue filtered bicarbonate, but does not lead to significant acidification of the luminal fluid.

Distal nephron segments also have an important role in acid excretion. Hydrogen ions are secreted into the lumen by an H^+-ATPase in the intercalated cells of the cortical collecting duct and the outer medullary collecting duct cells. The H^+ ions

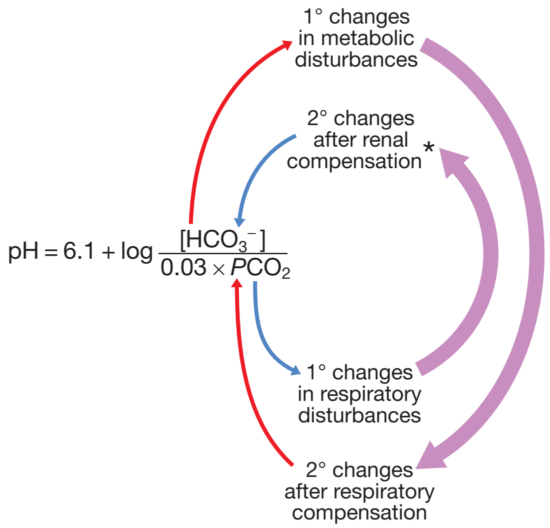

Fig. 14.10 Relationship between pH, PCO_2 (in mmHg) and plasma bicarbonate concentration (in mmol/L). *Note that changes in HCO_3^- concentration are also part of the renal correction for sustained metabolic acid–base disturbances as long as the kidney itself is not the cause of the primary disturbance.

are generated in the tubular cell from the hydration of CO_2 to form carbonic acid, which dissociates into an H^+ ion secreted luminally, and a bicarbonate ion that passes across the basolateral membrane into the blood. The secreted H^+ ions contribute to the reabsorption of any residual bicarbonate present in the luminal fluid, by generating intracellular OH^- that reacts with CO_2 to form HCO_3^-, which exits across the basolateral membrane. However, H^+ secretion also contributes net acid for removal from the body, bound to a variety of urinary buffers, of which phosphate and ammonia are the most important. Urinary buffers are required to prevent a reduction in urinary pH, which would create an unfavourable gradient that would prevent further H^+ secretion. Filtered phosphate (HPO_4^{2-}) combines with H^+ in the distal tubular lumen to form dihydrogen phosphate ($H_2PO_4^-$), which is excreted in the urine with sodium. Ammonia (NH_3) is generated within tubular cells by deamination of the amino acid glutamine by the enzyme glutaminase. The NH_3 then reacts with secreted H^+ in the tubular lumen to form ammonium (NH_4^+), which becomes trapped in the luminal fluid and is excreted with chloride ions.

These two mechanisms remove approximately 1 mmol/kg of hydrogen ions from the body per day, which equates to the non-volatile acid load arising from the metabolism of dietary protein. The slightly alkaline plasma pH of 7.4 (H^+ 40 nmol/L) that is maintained during health can be accounted for by the kidney's ability to generate an acidic urine (typically pH 5–6 (H^+ 1000–10 000 nmol/L), in which the net daily excess of metabolic acid produced by the body can be excreted.

Presenting problems in acid–base balance

Patients with disturbances of acid–base balance may present clinically either with the effects of tissue malfunction due to disturbed pH (such as altered cardiac and central nervous system function), or with secondary changes in respiration that occur as a response to the underlying metabolic change (such as Kussmaul respiration during metabolic acidosis). The clinical picture is often dominated by the underlying cause rather than the acid–base abnormality itself. Frequently, acid–base disturbances only become evident when the venous plasma bicarbonate concentration is measured and found to be abnormal, or when blood gas analysis shows abnormalities in pH, PCO_2 or bicarbonate.

The most common patterns of abnormality in blood gas parameters are shown in Box 14.18. Note that the terms acidosis and alkalosis strictly refer to the underlying direction of the acid–base change, while acidaemia and alkalaemia more correctly refer to the net change present in the blood. Interpretation of arterial blood gases is also described on page 555.

In metabolic disturbances, respiratory compensation is almost immediate, so that the predicted compensatory change in PCO_2 is achieved soon after the onset of the metabolic disturbance. In respiratory disorders, on the other hand, a small initial change in bicarbonate occurs as a result of chemical buffering of CO_2, largely within red blood cells, but over days and weeks the kidney achieves further compensatory changes in bicarbonate concentration as a result of long-term adjustments in acid secretory capacity. When the clinically obtained acid–base parameters do not accord with the predicted compensation shown, a mixed acid–base disturbance should be suspected (p. 367).

Metabolic acidosis

Metabolic acidosis occurs when an acid other than carbonic acid (due to CO_2 retention) accumulates in the body, resulting in a

14.18 Principal patterns of acid–base disturbance

Disturbance	Blood H^+	Primary change	Compensatory response	Predicted compensation
Metabolic acidosis	>40[1]	HCO_3^- <24 mmol/L	PCO_2 <5.33 kPa[2]	PCO_2 fall in kPa = 0.16 × HCO_3^- fall in mmol/L
Metabolic alkalosis	<40[1]	HCO_3^- >24 mmol/L	PCO_2 >5.33 kPa[2,3]	PCO_2 rise in kPa = 0.08 × HCO_3^- rise in mmol/L
Respiratory acidosis	>40[1]	PCO_2 >5.33 kPa[2]	HCO_3^- >24 mmol/L	Acute: HCO_3^- rise in mmol/L = 0.75 × PCO_2 rise in kPa Chronic: HCO_3^- rise in mmol/L = 2.62 × PCO_2 rise in kPa
Respiratory alkalosis	<40[1]	PCO_2 <5.33 kPa[2]	HCO_3^- <24 mmol/L	Acute: HCO_3^- fall in mmol/L = 1.50 × PCO_2 fall in kPa Chronic: HCO_3^- fall in mmol/L = 3.75 × PCO_2 fall in kPa

[1]H^+ of 40 nmol/L = pH of 7.40. [2]PCO_2 of 5.33 kPa = 40 mmHg. [3]PCO_2 does not rise above 7.33 kPa (55 mmHg) because hypoxia then intervenes to drive respiration.

14.19 Causes of metabolic acidosis

Disorder	Mechanism
Normal anion gap	
Ingestion or infusion of inorganic acid	Therapeutic infusion of or poisoning with NH_4Cl, HCl
Gastrointestinal HCO_3^- loss	Loss of HCO_3^- in diarrhoea, small bowel fistula, urinary diversion procedure
Renal tubular acidosis (RTA)	Urinary loss of HCO_3^- in proximal RTA; impaired tubular acid secretion in distal RTA
Increased anion gap	
Endogenous acid load	
Diabetic ketoacidosis	Accumulation of ketones[1] with hyperglycaemia (p. 735)
Starvation ketosis Alcoholic ketoacidosis	Accumulation of ketones without hyperglycaemia (p. 725)
Lactic acidosis	Shock, liver disease, drugs
Kidney disease	Accumulation of organic acids
Exogenous acid load	
Aspirin poisoning	Accumulation of salicylate[2]
Methanol poisoning	Accumulation of formate
Ethylene glycol poisoning	Accumulation of glycolate, oxalate

[1]Ketones include acid anions acetoacetate and β-hydroxybutyrate (p. 725).
[2]Salicylate poisoning is also associated with respiratory alkalosis due to direct ventilatory stimulation.

14.20 Causes of renal tubular acidosis

Proximal renal tubular acidosis (type II RTA)

- Inherited:
  - Fanconi's syndrome
  - Cystinosis
  - Wilson's disease
- Paraproteinaemia:
  - Myeloma
- Amyloidosis
- Hyperparathyroidism
- Heavy metal toxicity:
  - Lead, cadmium and mercury poisoning
- Drugs:
  - Carbonic anhydrase inhibitors
  - Ifosfamide

Classical distal renal tubular acidosis (type I RTA)

- Inherited
- Autoimmune diseases:
  - Systemic lupus erythematosus
  - Sjögren's syndrome
- Hyperglobulinaemia
- Toxins and drugs:
  - Toluene
  - Lithium
  - Amphotericin

Hyperkalaemic distal renal tubular acidosis (type IV RTA)

- Hypoaldosteronism (primary or secondary)
- Obstructive nephropathy
- Renal transplant rejection
- Drugs:
  - Amiloride
  - Spironolactone

fall in the plasma bicarbonate. The causes of metabolic acidosis are summarised in Box 14.19, subdivided into two categories, depending on whether the anion gap is normal or raised.

Pathophysiology

Metabolic acidosis with a normal anion gap occurs when there is a primary loss of bicarbonate from the ECF, or when there is poisoning with or therapeutic infusion of a mineral acid such as hydrochloric acid or ammonium chloride. Renal tubular acidosis (RTA) is an important cause of metabolic acidosis with a normal anion gap. It can be caused by a defect in one of three processes:

- impaired bicarbonate reabsorption in the proximal tubule (proximal RTA)
- impaired acid secretion in the late distal tubule or cortical collecting duct intercalated cells (classical distal RTA)
- impaired sodium reabsorption in the late distal tubule or cortical collecting duct, which is associated with reduced secretion of both potassium and H^+ ions (hyperkalaemic distal RTA).

Various subtypes of RTA are recognised and the most common causes are shown in Box 14.20. The inherited forms of RTA are due to mutations in the genes that regulate acid or bicarbonate transport in the renal tubules (see Fig. 14.3).

Acidosis with an increased anion gap is most commonly seen in ketoacidosis, renal failure and lactic acidosis, where there is endogenous production of anions distinct from Cl^- and HCO_3^-. Ketoacidosis is caused by insulin deficiency and is exacerbated by catecholamine and stress hormone excess, which combine to cause lipolysis and the formation of acidic ketones (acetoacetate, 3-hydroxybutyrate and acetone). The most common cause of ketoacidosis is diabetic ketoacidosis (DKA); its aetiology and management are discussed on page 735. Starvation ketoacidosis occurs when there is reduced food intake in situations of high glucose demand, such as in neonates, and in pregnant or breastfeeding women. In alcoholic ketoacidosis, there is usually a background of chronic malnutrition and a recent alcohol binge. Two subtypes of lactic acidosis have been defined:

- *type 1*, due to tissue hypoxia and peripheral generation of lactate, as in patients with circulatory failure and shock
- *type 2*, due to impaired metabolism of lactate, as in liver disease or by a number of drugs and toxins, including metformin, which inhibit lactate metabolism (p. 746).

Metabolic acidosis with an increased anion gap may also be a consequence of exogenous acid loads from poisoning with aspirin, methanol or ethylene glycol.

Clinical features

Normal anion gap metabolic acidosis is usually due either to bicarbonate loss in diarrhoea, where the clinical diagnosis is generally obvious, or to RTA. Although some forms of RTA are inherited, it may also be an acquired disorder, and in these circumstances the discovery of metabolic acidosis may serve as an early clue to the underlying diagnosis. The presentation of increased anion gap acidosis is usually dominated by clinical features of the underlying disease, such as uncontrolled diabetes mellitus, kidney failure or shock, or may be suggested by the clinical history of starvation, alcoholism or associated symptoms, such as visual complaints in methanol poisoning (p. 147).

Investigations

The different types of metabolic acidosis can be distinguished by blood gas measurements, along with measurements of creatinine, electrolytes and bicarbonate. Under normal circumstances, the anion gap, defined as the numerical difference between the main measured cations ($Na^+ + K^+$) and the anions ($Cl^- + HCO_3^-$) is about 5–11 mmol/L. This gap is normally made up of anions, such as phosphate and sulphate, as well as albumin. RTA should be suspected when there is a hyperchloraemic acidosis with a normal anion gap in the absence of gastrointestinal disturbance. The diagnosis can be confirmed by finding an inappropriately high urine pH (>5.5) in the presence of systemic acidosis. Sometimes, distal RTA may be incomplete, such that the plasma bicarbonate concentration may be normal under resting conditions. In this case, an acid challenge test can be performed by administration of an acid load in the form of ammonium chloride to reduce plasma bicarbonate. The diagnosis of incomplete distal RTA can be confirmed if the urine pH fails to fall below 5.3 in the presence of a low bicarbonate.

The different subtypes of RTA can be differentiated by various biochemical features. Patients with proximal and distal RTA often present with features of profound hypokalaemia, while type IV RTA is associated with hyperkalaemia. Proximal RTA is frequently associated with urinary wasting of amino acids, phosphate and glucose (Fanconi's syndrome), as well as bicarbonate and potassium. Patients with this disorder can lower the urine pH when the acidosis is severe and plasma bicarbonate levels have fallen below 16 mmol/L, since distal H^+ secretion mechanisms are intact. In the classical form of distal RTA, however, acid accumulation is relentless and progressive, resulting in mobilisation of calcium from bone and osteomalacia with hypercalciuria, renal stone formation and nephrocalcinosis. Potassium is also lost in classical distal RTA, while it is retained in hyperkalaemic distal RTA.

Investigations in patients with raised anion gap metabolic acidosis show features of the underlying cause, such as reduced GFR in renal failure and raised urine or blood ketones in ketoacidosis. In DKA, blood glucose is raised, while in starvation and alcoholic acidosis blood glucose is not elevated and may be low. Measurement of plasma lactate is helpful in the diagnosis of lactic acidosis when values are increased over the normal maximal level of 2 mmol/L.

Management

The first step in management of metabolic acidosis is to identify and correct the underlying cause when possible (see Box 14.19). This may involve controlling diarrhoea, treating diabetes mellitus, correcting shock, stopping drugs that might cause the condition, or using dialysis to remove toxins. Since metabolic acidosis is frequently associated with sodium and water depletion, resuscitation with intravenous fluids is often needed. In alcoholism and starvation ketosis, intravenous glucose is indicated. By stimulating endogenous insulin secretion, this will reverse hepatic ketone production. Malnourished patients may also require thiamin, potassium, magnesium and phosphate supplements (p. 706). Use of intravenous bicarbonate in metabolic acidosis is controversial. Because rapid correction of acidosis can induce hypokalaemia or a fall in plasma ionised calcium, the use of bicarbonate infusions is best reserved for situations where the underlying disorder cannot be readily corrected and acidosis is severe (H^+ >100 nmol/L, pH <7.00) or associated with evidence of tissue dysfunction.

The acidosis in RTA can sometimes be controlled by treating the underlying cause (see Box 14.20), but usually supplements of sodium and potassium bicarbonate are also necessary in types I and II RTA to achieve a target plasma bicarbonate level of >18 mmol/L and normokalaemia. In type IV RTA, loop diuretics, thiazides or fludrocortisone (as appropriate to the underlying diagnosis) may be effective in correcting the acidosis and the hyperkalaemia.

Metabolic alkalosis

Metabolic alkalosis is characterised by an increase in the plasma bicarbonate concentration and the plasma pH (see Box 14.18). There is a compensatory rise in PCO_2 due to hypoventilation but this is limited by the need to avoid hypoxia. Classical causes include primary hyperaldosteronism (Conn's syndrome, p. 674), Cushing's syndrome (p. 666) and glucocorticoid therapy (p. 670). Occasionally, overuse of antacid salts for treatment of dyspepsia produces a similar pattern.

Pathophysiology

Metabolic alkalosis is best classified according to the accompanying changes in ECF volume. Hypovolaemic metabolic alkalosis is the most common pattern. This can be caused by sustained vomiting, in which acid-rich fluid is lost directly from the body, or by treatment with loop diuretics or thiazides. In the case of sustained vomiting, loss of gastric acid is the immediate cause of the alkalosis, but several factors act to sustain or amplify this in the context of volume depletion (Fig. 14.11). Loss of sodium and fluid leads to hypovolaemia and secondary hyperaldosteronism, triggering proximal sodium bicarbonate reabsorption and additional acid secretion by the distal tubule. Hypokalaemia occurs due to potassium loss in the vomitus and by the kidney as the result of secondary hyperaldosteronism, and itself is a stimulus to acid secretion. Additionally, the compensatory rise in PCO_2 further enhances tubular acid secretion. The net result is sustained metabolic alkalosis with an inappropriately acid urine, which cannot be corrected until the deficit in circulating volume has been replaced.

Normovolaemic (or hypervolaemic) metabolic alkalosis occurs when bicarbonate retention and volume expansion occur simultaneously.

Clinical features

Clinically, apart from manifestations of the underlying cause, there may be few symptoms or signs related to alkalosis itself. When the rise in systemic pH is abrupt, however, plasma ionised calcium falls and signs of increased neuromuscular irritability, such as tetany, may develop (p. 663).

Investigations

The diagnosis can be confirmed by measurement of electrolytes and arterial blood gases.

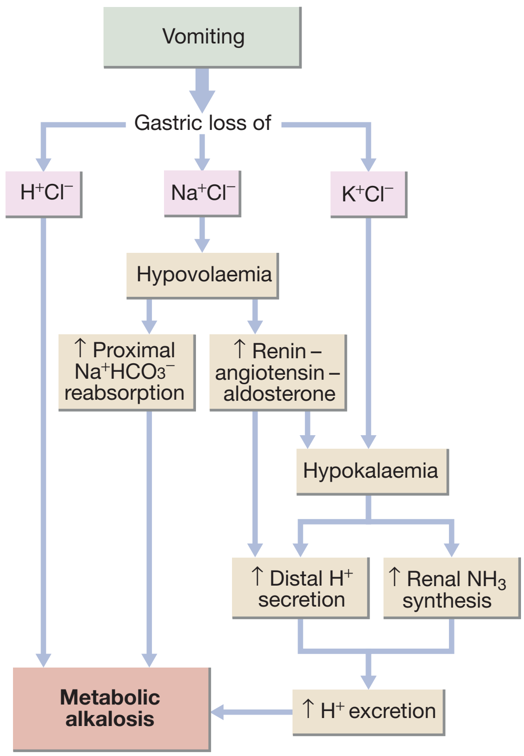

Fig. 14.11 Generation and maintenance of metabolic alkalosis during prolonged vomiting. Loss of H^+Cl^- generates metabolic alkalosis, which is maintained by renal changes.

Management

Metabolic alkalosis with hypovolaemia can be corrected by intravenous infusions of 0.9% saline with potassium supplements. This reverses the secondary hyperaldosteronism and allows the kidney to excrete the excess alkali in the urine. In metabolic alkalosis with normal or increased volume, treatment should focus on management of the underlying endocrine cause (Ch. 18).

Respiratory acidosis

Respiratory acidosis occurs when there is accumulation of CO_2 due to type II respiratory failure (p. 565). This results in a rise in the PCO_2, with a compensatory increase in plasma bicarbonate concentration, particularly when the disorder is of long duration and the kidney has fully developed its capacity for increased acid excretion.

This acid–base disturbance can arise from lesions anywhere along the neuromuscular pathways from the brain to the respiratory muscles that result in impaired ventilation. It can also arise during intrinsic lung disease if there is significant mismatching of ventilation and perfusion.

Clinical features are primarily those of the underlying cause of the respiratory disorder, such as paralysis, chest wall injury or chronic obstructive lung disease, but the CO_2 accumulation may itself lead to drowsiness that further depresses respiratory drive.

Management involves correction of causative factors where possible, but ultimately ventilatory support may be necessary.

Respiratory alkalosis

Respiratory alkalosis develops when there is a period of sustained hyperventilation, resulting in a reduction of PCO_2 and increase in plasma pH. If the condition is sustained, renal compensation occurs, such that tubular acid secretion is reduced and the plasma bicarbonate falls.

Respiratory alkalosis is usually of short duration, occurring in anxiety states or as the result of over-vigorous assisted ventilation. It can be prolonged in the context of pregnancy, pulmonary embolism, chronic liver disease, and ingestion of certain drugs such as salicylates that directly stimulate the respiratory centre in the brainstem.

Clinical features are those of the underlying cause but agitation associated with perioral and digital tingling may also occur, as alkalosis promotes the binding of calcium to albumin, resulting in a reduction in ionised calcium concentrations. In severe cases, Trousseau's sign and Chvostek's sign may be positive, and tetany or seizures may develop (p. 663).

Management involves correction of identifiable causes, reduction of anxiety, and a period of rebreathing into a closed bag to allow CO_2 levels to rise.

Mixed acid–base disorders

It is not uncommon for more than one disturbance of acid–base metabolism to be present at the same time in the same patient: for example, a respiratory acidosis due to narcotic overdose with metabolic alkalosis due to vomiting. In these situations, the arterial pH will represent the net effect of all primary and compensatory changes. Indeed, the pH may be normal, but the presence of underlying acid–base disturbances can be gauged from concomitant abnormalities in the PCO_2 and bicarbonate concentration.

In assessing these disorders, all clinical influences on the patient's acid–base status should be identified, and reference should be made to the table of predicted compensation given in Box 14.18. If the compensatory change is discrepant from the rules of thumb provided, more than one disturbance of acid–base metabolism may be suspected.

Calcium homeostasis

Disorders of calcium homeostasis are discussed in Chapter 18 and bone disease is discussed in Chapter 24.

Magnesium homeostasis

Magnesium is mainly an intracellular cation. It is important to the function of many enzymes, including the Na,K-ATPase, and can regulate both potassium and calcium channels. Its overall effect is to stabilise excitable cell membranes.

Functional anatomy and physiology

Renal handling of magnesium involves filtration of free plasma magnesium at the glomerulus (about 70% of the total), with extensive reabsorption (50–70%) in the loop of Henle and other parts of the proximal and distal renal tubule. Magnesium reabsorption is also enhanced by parathyroid hormone (PTH).

Presenting problems in magnesium homeostasis

Disturbances in magnesium homeostasis usually occur because of increased loss of magnesium through the gut or kidney or

inability to excrete magnesium normally in patients with renal impairment.

Hypomagnesaemia

Hypomagnesaemia is defined as existing when plasma magnesium concentrations are below the reference range of 0.75–1.0 mmol/L (1.5–2.0 mEq/L).

Pathophysiology

Hypomagnesaemia usually is a reflection of magnesium depletion (Box 14.21), which can be caused by excessive magnesium loss from the gastrointestinal tract (notably in chronic diarrhoea) or the kidney (during prolonged use of loop diuretics). Excessive alcohol ingestion can cause magnesium depletion through both gut and renal losses. Some inherited tubular transport disorders, such as Gitelman's and Bartter's syndromes, can also result in urinary magnesium wasting (p. 361). Magnesium depletion has important effects on calcium homeostasis because magnesium is required for the normal secretion of PTH in response to a fall in serum calcium, and because hypomagnesaemia causes end-organ resistance to PTH.

Clinical features

Mild degrees of hypomagnesaemia may be asymptomatic but more severe hypomagnesaemia may be associated with symptoms of hypocalcaemia, such as tetany, cardiac arrhythmias (notably torsades de pointes, p. 476), central nervous excitation and seizures, vasoconstriction and hypertension. Hypomagnesaemia and magnesium depletion are also associated (through uncertain mechanisms) with hyponatraemia and hypokalaemia, which may contribute to some of the clinical manifestations.

14.21 Causes of hypomagnesaemia

Mechanism	Examples
Inadequate intake	Starvation Malnutrition Alcoholism Parenteral alimentation
Excessive losses	
Gastrointestinal	Prolonged vomiting/nasogastric aspiration Chronic diarrhoea/laxative abuse Malabsorption Small bowel bypass surgery Fistulae
Urinary	Diuretic therapy Alcohol Tubulotoxic drugs: Gentamicin Cisplatin Volume expansion Diabetic ketoacidosis Post-obstructive diuresis Recovery from acute tubular necrosis Inherited tubular transport defect: Bartter's syndrome Gitelman's syndrome Primary renal magnesium wasting
Miscellaneous	Acute pancreatitis Foscarnet therapy Proton pump inhibitor therapy Hungry bone syndrome Diabetes mellitus

Management

The underlying cause should be identified and treated where possible. When symptoms are present, the treatment of choice is intravenous magnesium chloride at a rate not exceeding 0.5 mmol/kg in the first 24 hours. If intravenous access is not feasible, magnesium sulphate can be given intramuscularly. Oral magnesium salts have limited effectiveness due to poor absorption and may cause diarrhoea. If hypomagnesaemia is caused by diuretic treatment, adjunctive use of a potassium-sparing agent can also help by reducing magnesium loss into the urine.

Hypermagnesaemia

This is a much less common abnormality than hypomagnesaemia. Predisposing conditions include acute kidney injury, chronic kidney disease and adrenocortical insufficiency. The condition is generally precipitated in patients at risk from an increased intake of magnesium, or from the use of magnesium-containing medications, such as antacids, laxatives and enemas.

Clinical features include bradycardia, hypotension, reduced consciousness and respiratory depression.

Management involves ceasing all magnesium-containing drugs and reducing dietary magnesium intake, improving renal function if possible, and promoting urinary magnesium excretion using a loop diuretic with intravenous hydration, if residual renal function allows. Calcium gluconate may be given intravenously to ameliorate cardiac effects. Dialysis may be necessary in patients with poor renal function.

Phosphate homeostasis

Inorganic phosphate (mainly present as HPO_4^{2-}) is intimately involved in cell energy metabolism, intracellular signalling and bone and mineral homeostasis (Ch. 24). The normal plasma concentration is 0.8–1.4 mmol/L (2.48–4.34 mg/dL).

Functional anatomy and physiology

Phosphate is freely filtered at the glomerulus and approximately 65% is reabsorbed by the proximal tubule, through an apical sodium–phosphate co-transport carrier. A further 10–20% is reabsorbed in the distal tubules, leaving a fractional excretion of some 10% to pass into the urine, usually as $H_2PO_4^-$. Proximal reabsorption is decreased by PTH, fibroblast growth factor 23 (FGF23), volume expansion, osmotic diuretics and glucose infusion.

Presenting problems in phosphate homeostasis

The following section deals primarily with conditions that cause acute disturbances in serum phosphate concentrations. Chronic disorders that are accompanied by phosphate depletion, such as osteomalacia and hypophosphataemic rickets, are discussed in Chapter 24. Acute kidney injury and chronic kidney disease, which are associated with hyperphosphataemia, are discussed below and also in Chapter 15.

Hypophosphataemia

Hypophosphataemia is defined as existing when serum phosphate values fall below 0.8 mmol/L (2.48 mg/dL). The causes are shown in Box 14.22, subdivided into the underlying pathogenic mechanisms.

14.22 Causes of hypophosphataemia

Mechanism	Examples
Redistribution into cells	Refeeding after starvation Respiratory alkalosis Treatment for diabetic ketoacidosis
Inadequate intake or absorption	Malnutrition Malabsorption Chronic diarrhoea Phosphate binders Antacids Vitamin D deficiency or resistance
Increased renal excretion	Hyperparathyroidism Extracellular fluid volume expansion with diuresis Osmotic diuretics Fanconi's syndrome Familial hypophosphataemic rickets Tumour-induced hypophosphataemic rickets

Pathophysiology

Phosphate may redistribute into cells during periods of increased energy utilisation (such as refeeding after a period of starvation) and during systemic alkalosis. However, severe hypophosphataemia usually represents an overall body deficit due to either inadequate intake or absorption through the gut, or excessive renal losses, most notably in primary hyperparathyroidism (p. 663) or as the result of acute plasma volume expansion, osmotic diuresis and diuretics acting on the proximal renal tubule. Less common causes include inherited defects of proximal sodium–phosphate co-transport and tumour-induced osteomalacia due to ectopic production of the hormone FGF23 (p. 1053).

Clinical features

The clinical features of phosphate depletion are wide-ranging, reflecting the involvement of phosphate in many aspects of metabolism. Defects appear in the blood (impaired function and survival of all cell lineages), skeletal muscle (weakness, respiratory failure), cardiac muscle (congestive cardiac failure), smooth muscle (ileus), central nervous system (decreased consciousness, seizures and coma) and bone (osteomalacia in severe prolonged hypophosphataemia, p. 1053).

Investigations

Measurement of creatinine, electrolytes, phosphate, albumin, calcium and alkaline phosphatase should be performed. In selected cases, measurement of PTH and 25(OH)D may be helpful to exclude osteomalacia or hypophosphataemic rickets. The combination of hypophosphataemia and hypercalcaemia suggests primary hyperparathyroidism, which should be further investigated by measurements of PTH, as described on page 663. The presence of hypocalcaemia suggests hypophosphataemic rickets, which should be further investigated as described on page 1053.

Management

Management of hypophosphataemia due to decreased dietary intake or excessive losses involves administering oral phosphate supplements and high-protein/high-dairy dietary supplements that are rich in naturally occurring phosphate. Intravenous treatment with sodium or potassium phosphate salts can be used in critical situations, but there is a risk of precipitating hypocalcaemia and metastatic calcification. Management of primary hyperparathyroidism and hypophosphataemic rickets are described in more detail on pages 664 and 1053.

Hyperphosphataemia

Hyperphosphataemia is most commonly caused by acute kidney injury or chronic kidney disease (pp. 413 and 419).

Pathophysiology

In acute kidney injury and chronic kidney disease, the primary cause is reduced phosphate excretion as the result of a low GFR. In contrast, the hyperphosphataemia in hypoparathyroidism and pseudohypoparathyroidism is due to increased tubular phosphate reabsorption. Redistribution of phosphate from cells into the plasma can also be a contributing factor in the tumour lysis syndromes and other catabolic states. Phosphate accumulation can be aggravated in any of these conditions if the patient takes phosphate-containing preparations or inappropriate vitamin D therapy.

Clinical features

The clinical features relate to hypocalcaemia and metastatic calcification, particularly in chronic kidney disease with tertiary hyperparathyroidism (when a high calcium–phosphate product occurs).

Management

Hyperphosphataemia in patients with kidney disease should be treated with dietary phosphate restriction and the use of oral phosphate binders (p. 418). Hyperphosphataemia in hypoparathyroidism and pseudohypoparathyroidism does not usually require treatment. Hyperphosphataemia associated with tumour lysis syndromes and catabolic states can be treated with intravenous normal saline, which is given to promote phosphate excretion.

Disorders of amino acid metabolism

Congenital disorders of amino acid metabolism usually present in the neonatal period and may involve life-long treatment regimens. However, some disorders, particularly those involved in amino acid transport, may not present until later in life.

Phenylketonuria

Phenylketonuria (PKU) is inherited as an autosomal recessive disorder caused by loss-of-function mutations in the *PAH* gene, which encodes phenylalanine hydroxylase, an enzyme required for degradation of phenylalanine. As a result, phenylalanine accumulates at high levels in the neonate's blood, causing intellectual disability.

The diagnosis of PKU is almost always made by routine neonatal screening (p. 56). Treatment involves life-long adherence to a low-phenylalanine diet. Early and adequate dietary treatment prevents major intellectual disability, although there may still be a slight reduction in IQ.

Homocystinuria

Homocystinuria is an autosomal recessive disorder caused by loss-of-function mutations in the *CBS* gene, which encodes cystathionine β-synthase. The enzyme deficiency causes accumulation of homocysteine and methionine in the blood. Many cases of homocystinuria are diagnosed through newborn screening programmes.

14

Clinical manifestations are wide-ranging and involve the eyes (ectopia lentis – displacement of the lens), central nervous system (intellectual disability, delayed developmental milestones, seizures, psychiatric disturbances), skeleton (resembling Marfan's syndrome, and also with generalised osteoporosis), vascular system (thrombotic lesions of arteries and veins) and skin (hypopigmentation).

Treatment is dietary, involving a methionine-restricted, cystine-supplemented diet, as well as large doses of pyridoxine.

Disorders of carbohydrate metabolism

The most common disorder of carbohydrate metabolism is diabetes mellitus, which is discussed in Chapter 20. There are also some rare inherited defects, discussed below.

Galactosaemia

Galactosaemia is caused by loss-of-function mutations in the *GALT* gene, which encodes galactose-1-phosphate uridyl transferase. It is usually inherited in an autosomal recessive manner. The neonate is unable to metabolise galactose, one of the hexose sugars contained in lactose. Vomiting or diarrhoea usually begins within a few days of ingestion of milk, and the neonate may become jaundiced. Failure to thrive is the most common clinical presentation. The classic form of the disease results in hepatomegaly, cataracts and intellectual disability. Fulminant infection with *Escherichia coli* is a frequent complication. Treatment involves life-long avoidance of galactose- and lactose-containing foods.

The widespread inclusion of galactosaemia in newborn screening programmes has resulted in the identification of a number of milder ('Duarte') variants.

Glycogen storage diseases

Glycogen storage diseases (GSDs, or glycogenoses) result from inherited defects in one of the many enzymes responsible for the formation or breakdown of glycogen, a complex carbohydrate that can be broken down quickly to release glucose during exercise or between meals.

There are several major types of GSD, which are classified by a number, by the name of the defective enzyme, or eponymously after the physician who first described the condition (Box 14.23). Most forms of GSD are inherited in an autosomal recessive manner.

The diagnosis of GSD is made on the basis of the symptoms, physical examination and results of biochemical tests. Occasionally, a muscle or liver biopsy is required to confirm the enzyme defect. Different types of GSD present at different ages, and some may require life-long modifications of diet and lifestyle.

Disorders of complex lipid metabolism

Complex lipids are key components of the cell membrane that are normally catabolised in organelles called lysosomes. The lysosomal storage diseases are a heterogeneous group of disorders caused by loss-of-function mutations in various lysosomal enzymes (Box 14.24), resulting in an inability to break down complex glycolipids or other intracellular macromolecules. These disorders have diverse clinical manifestations, typically including intellectual disability. Some can be treated with enzyme replacement therapy, while others (such as Tay–Sachs disease) can be prevented through community participation in genetic carrier screening programmes.

Lipids and lipoprotein metabolism

The three main biological classes of lipid are:

- cholesterol, which is composed of hydrocarbon rings
- triglycerides (TGs), which are esters composed of glycerol linked to three long-chain fatty acids
- phospholipids, which are composed of a hydrophobic 'tail' consisting of two long-chain fatty acids linked through glycerol to a hydrophilic head containing a phosphate group.

Phospholipids are present in cell membranes and are important signalling molecules.

Despite their poor water solubility, lipids need to be absorbed from the gastrointestinal tract and transported throughout the body. This is achieved by incorporating lipids within lipoproteins. Plasma cholesterol and TGs are clinically important because they are major treatable risk factors for cardiovascular disease, while severe hypertriglyceridaemia also predisposes to acute pancreatitis.

14.23 Glycogen storage diseases

Type	Eponym	Enzyme deficiency	Clinical features and complications
I	Von Gierke	Glucose-6-phosphatase	Childhood presentation, hypoglycaemia, hepatomegaly
II	Pompe	α-glucosidase (acid maltase)	Classical presentation in infancy, muscle weakness (may be severe)
III	Cori	Glycogen debrancher enzyme	Childhood presentation, hepatomegaly, mild hypoglycaemia
IV	Andersen	Brancher enzyme	Presentation in infancy, severe muscle weakness (may affect heart), cirrhosis
V	McArdle	Muscle glycogen phosphorylase	Exercise-induced fatigue and myalgia
VI	Hers	Liver phosphorylase	Mild hepatomegaly
VII	Tarui	Muscle phosphofructokinase	Exercise-induced fatigue and myalgia
IX[1]		Liver phosphorylase kinase	Mild hepatomegaly
0		Hepatic glycogen synthase	Fasting hypoglycaemia, post-prandial hyperglycaemia
X[2]		Muscle phosphoglycerate mutase	Exercise-induced myoglobinuria

[1]Note that type VIII has been merged into type IX and no longer exists as a separate entity. [2]Recent progress in molecular genetics has recognised a number of additional, rarer types of glycogen storage disease. These are not shown in this table, which stops at type X.

i 14.24 Lysosomal storage diseases

Lysosomal storage disease	Enzyme deficiency	Clinical features	Human enzyme replacement therapy
Fabry's disease	α-galactosidase A	Variable age of onset Neurological (pain in extremities) Dermatological (hypohidrosis, angiokeratomas) Cerebrovascular (renal, cardiac, central nervous system)	Available for clinical use
Gaucher's disease (various types)	Glucocerebrosidase	Splenic and liver enlargement, with variable severity of disease Some types also have neurological involvement	Available for clinical use in some types
Mucopolysaccharidosis Hurler's syndrome Hunter's syndrome Sanfilippo's syndrome Morquio's syndrome + several other types	Several enzymes involved in breakdown of glycosaminoglycans	Vary with syndrome: can cause intellectual disability, skeletal and joint abnormalities, abnormal facies, obstructive respiratory diseases and recurrent respiratory infections	Available for clinical use in some types; clinical trials under way for other types
Niemann–Pick disease	Acid sphingomyelinase	Most common presentation is as a progressive neurological disorder, accompanied by organomegaly Some variants do not have neurological symptoms	Clinical trials planned for some types
GM2-gangliosidosis Tay–Sachs disease Hexosaminidase activator deficiency Sandhoff's disease	Hexosaminidase A Hexosaminidase activator Hexosaminidase A and B	Severe progressive neurological disorder Cherry-red spot in macula Organomegaly in Sandhoff's disease	

Functional anatomy and physiology

Lipids are transported and metabolised by apolipoproteins, which combine with lipids to form spherical or disc-shaped lipoproteins, consisting of a hydrophobic core and a less hydrophobic coat (Fig. 14.12). The structure of some apolipoproteins also enables them to act as enzyme co-factors or cell receptor ligands. Variations in lipid and apolipoprotein composition result in distinct classes of lipoprotein that perform specific metabolic functions.

Processing of dietary lipid

The intestinal absorption of dietary lipid is described on page 768 (see also Fig. 14.13). Enterocytes lining the gut extract monoglyceride and free fatty acids from micelles and re-esterify them into TGs, which are combined with a truncated form of apolipoprotein B (Apo B48) as it is synthesised. Intestinal cholesterol derived from dietary and biliary sources is also absorbed through a specific intestinal membrane transporter termed NPC1L1. This produces chylomicrons containing TG and cholesterol ester that are secreted basolaterally into lymphatic lacteals and carried to the circulation through the thoracic duct. On entering the blood stream, nascent chylomicrons are modified by further addition of apolipoproteins. Chylomicron TGs are hydrolysed by lipoprotein lipase located on the endothelium of tissue capillary beds. This releases fatty acids that are used locally for energy production or stored as TG in muscle or fat. The residual 'remnant' chylomicron particle is avidly cleared by low-density lipoprotein receptors (LDLRs) in the liver, which recognise Apo E on the remnant lipoproteins. Complete absorption of dietary lipids takes about 6–10 hours, so chylomicrons are usually undetectable in the plasma after a 12-hour fast.

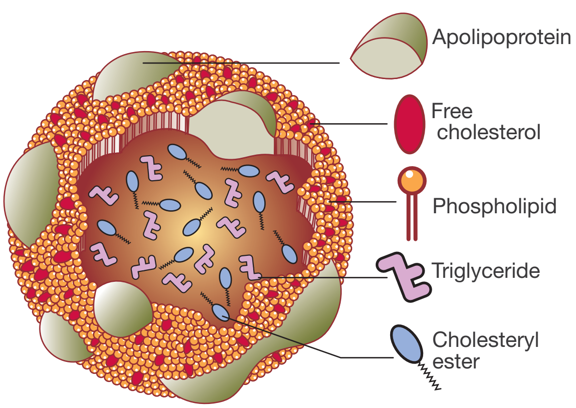

Fig. 14.12 Structure of lipoproteins.

The main dietary determinants of plasma cholesterol concentrations are the intake of saturated and *trans*-unsaturated fatty acids, which reduce LDLR levels (see below), whereas dietary cholesterol has surprisingly little effect on fasting cholesterol levels. Plant sterols and drugs that inhibit cholesterol absorption are effective because they also reduce the re-utilisation of biliary cholesterol. The dietary determinants of plasma TG concentrations are complex since excessive intake of carbohydrate, fat or alcohol may all contribute to increased plasma TG by different mechanisms.

Endogenous lipid synthesis

In the fasting state, the liver is the major source of plasma lipids (Fig. 14.13). The liver may acquire lipids by uptake, synthesis or conversion from other macronutrients. These lipids are transported to other tissues by secretion of very low-density lipoproteins (VLDLs), which are rich in TG but differ from chylomicrons in that they are less massive and contain full-length Apo B100. Following secretion into the circulation, VLDLs undergo metabolic processing similar to that of chylomicrons. Hydrolysis of VLDL TG releases fatty acids to tissues and converts VLDLs into 'remnant' particles, referred to as intermediate-density lipoproteins (IDLs). Most IDLs are rapidly cleared by LDLRs in the liver but some are

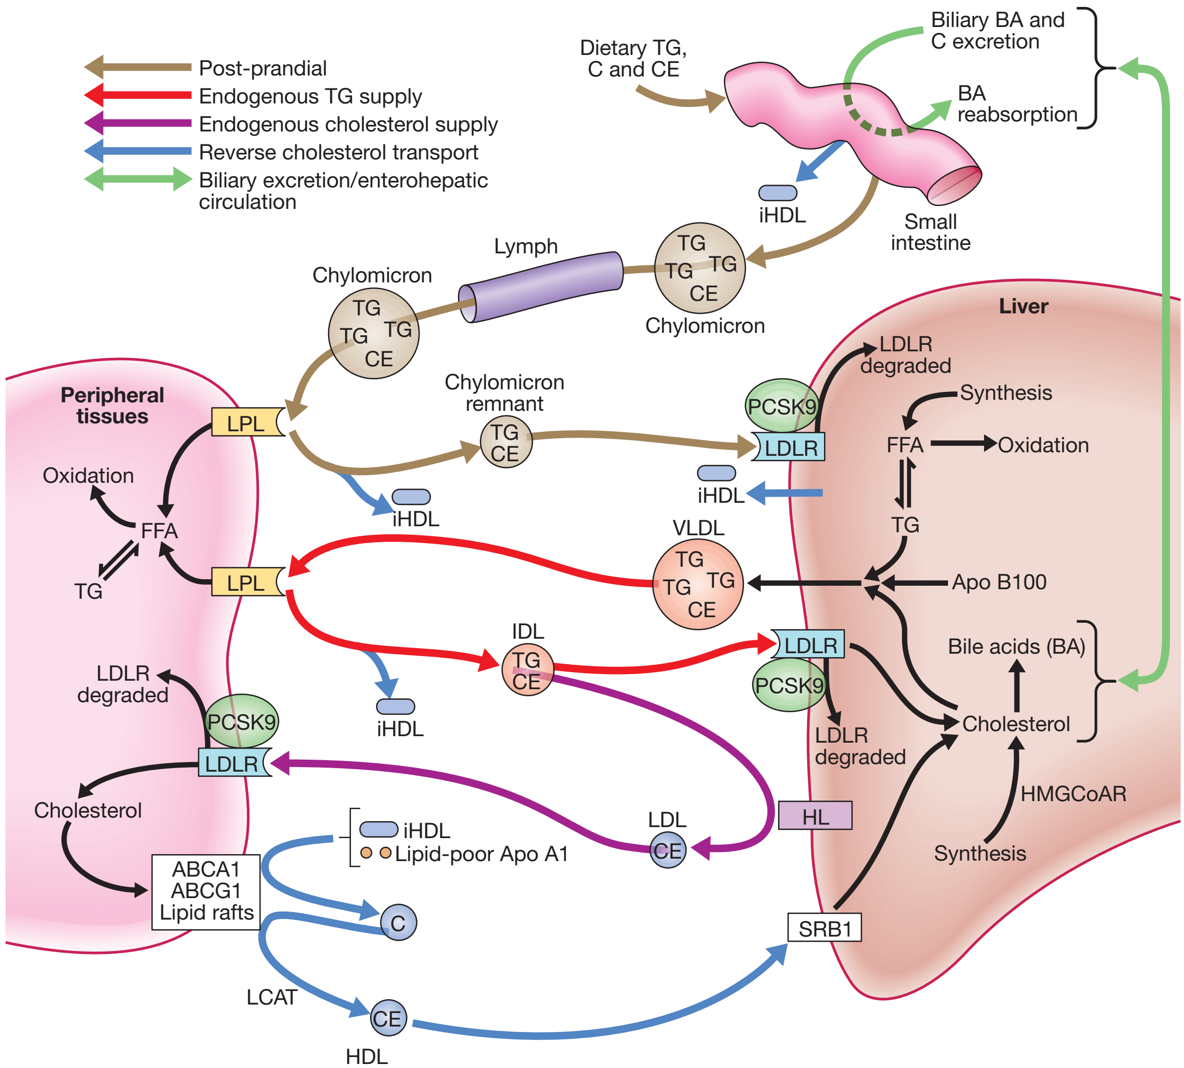

Fig. 14.13 Absorption, transport and storage of lipids. Pathways of lipid transport are shown; in addition, cholesterol ester transfer protein exchanges triglyceride and cholesterol ester between very low-density lipoprotein/chylomicrons and high-/low-density lipoprotein, and free fatty acids released from peripheral lipolysis can be taken up in the liver. (ABCA1/ABCG1 = adenosine triphosphate-binding cassette A1/G1; Apo = apolipoprotein; BA = bile acids; C = cholesterol; CE = cholesterol ester; FFA = free fatty acids; HDL = mature high-density lipoprotein; HL = hepatic lipase; HMGCoAR = hydroxy-methyl-glutaryl-co-enzyme A reductase; IDL = intermediate-density lipoprotein; iHDL = immature high-density lipoprotein; LCAT = lecithin cholesterol acyl transferase; LDL = low-density lipoprotein; LDLR = low-density lipoprotein receptor (Apo B100 receptor); LPL = lipoprotein lipase; PCSK9 = proprotein convertase subtilisin kexin 9; SRB1 = scavenger receptor B1; TG = triglyceride; VLDL = very low-density lipoprotein)

processed by hepatic lipase, which converts the particle to an LDL by removing TG and most materials other than Apo B100, and free and esterified cholesterol. The catabolism of TG-rich chylomicrons and VLDL by lipoprotein lipase is modulated by Apos C2 and C3 on the surface of these particles.

The LDL particles act as a source of cholesterol for cells and tissues (Fig. 14.13). LDL cholesterol is internalised by receptor-mediated endocytosis through the LDLR. Delivery of cholesterol via this pathway down-regulates expression of LDLR and reduces the synthesis and activity of the rate-limiting enzyme for cholesterol synthesis, hydroxy-methyl-glutaryl-co-enzyme A (HMGCoA) reductase. Another important regulator of LDLR levels is the sterol-sensitive protease proprotein convertase subtilisin kexin 9 (PCSK9), which degrades the LDLR. Intracellular free cholesterol concentrations are maintained within a narrow range by the inhibitory effects of LDL on expression of LRLR, fine-tuning of the half-life of LDLR through PCSK9, and modulation of cholesterol esterification.

Cholesterol transport

Peripheral tissues are further guarded against excessive cholesterol accumulation by high-density lipoproteins (HDLs; Fig. 14.13). Lipid-poor Apo A1 (derived from the liver, intestine and th e outer layer of chylomicrons and VLDL) accepts cellular cholesterol and phospholipid from a specific membrane transporter known as the ATP-binding cassette A1 (ABCA1). This produces small HDLs that are able to accept more free cholesterol from cholesterol-rich regions of the cell membrane known as ‘rafts’ via another membrane transporter (ABCG1). The cholesterol that has been accepted by these small HDLs is esterified by lecithin cholesterol acyl transferase (LCAT), thus maintaining an uptake gradient and

remodelling the particle into a mature spherical HDL. These HDLs release their cholesterol to the liver and other cholesterol-requiring tissues via the scavenger receptor B1 (SRB1).

The cholesterol ester transfer protein (CETP) in plasma allows transfer of cholesterol from HDLs or LDLs to VLDLs or chylomicrons in exchange for TG. When TG is elevated, the action of CETP may reduce HDL cholesterol and remodel LDLs into 'small, dense' LDL particles that may be more atherogenic in the blood-vessel wall. Animal species that lack CETP are resistant to atherosclerosis.

Lipids and cardiovascular disease

Plasma lipoprotein levels are major modifiable risk factors for cardiovascular disease. Increased levels of atherogenic lipoproteins (especially LDL, but also IDL, and possibly chylomicron remnants) contribute to the development of atherosclerosis (p. 484). A sub-population of LDL particles bears an additional protein known as apolipoprotein (a), which shares homology with plasminogen. The combination of LDL and apolipoprotein (a) is known as lipoprotein (a) (Lp(a)). It transports oxidised phospholipid and is regarded as atherogenic because its plasma concentration is an independent risk factor for cardiovascular disease. Following chemical modifications such as oxidation, Apo B-containing lipoproteins are no longer cleared by normal mechanisms. They trigger a self-perpetuating inflammatory response, during which they are taken up by macrophages to form foam cells, a hallmark of atherosclerotic lesions. These processes also have an adverse effect on endothelial function.

Conversely, HDL removes cholesterol from the tissues to the liver, where it is metabolised and excreted in bile. HDL may also counteract some components of the inflammatory response, such as the expression of vascular adhesion molecules by the endothelium. Consequently, low HDL cholesterol levels, which are often associated with TG elevation, are also associated with atherosclerosis.

Investigations

Lipid measurements are usually performed for the following reasons:

- screening for primary or secondary prevention of cardiovascular disease
- investigation of patients with clinical features of lipid disorders (p. 347) and their relatives
- monitoring of response to diet, weight control and medication.

Abnormalities of lipid metabolism most commonly come to light following these tests. Non-fasting measurements of total cholesterol (TC) and HDL cholesterol (HDL-C) allow estimation of non-HDL cholesterol (non-HDLC, calculated as TC – HDL-C), but a 12-hour fasting sample is required to standardise TG measurement and allow calculation of LDL cholesterol (LDL-C) according to the Friedewald formula:

$$\text{LDL-C} = \text{TC} - \text{HDL-C} - (\text{TG}/2.2)\ \text{mmol/L}$$

or

$$\text{LDL-C} = \text{TC} - \text{HDL-C} - (\text{TG}/5)\ \text{mg/dL}$$

The formula becomes unreliable when TG levels exceed 4 mmol/L (350 mg/dL). Measurements of non-HDLC or Apo B100 may assess risk of cardiovascular disease more accurately than LDL-C, particularly when TG levels are increased. The use of non-fasting samples is increasing because non-fasting TG is a more sensitive marker of the risk of cardiovascular disease. Nevertheless, a 12-hour fast is required for formal diagnosis of the presence of hypertriglyceridaemia or use of the Friedewald equation. Consideration must be given to confounding factors, such as recent illness, after which cholesterol, LDL and HDL levels temporarily decrease in proportion to severity. Results that will affect major decisions, such as initiation of drug therapy, should be confirmed with a repeat measurement.

Elevated levels of TG are common in obesity, diabetes and insulin resistance (Chs 19 and 20), and are frequently associated with low HDL and increased 'small, dense' LDL. Under these circumstances, LDL-C may under-estimate risk. This is one situation in which measurement of non-HDLC or Apo B may provide more accurate risk assessment.

Presenting problems in lipid metabolism

Hyperlipidaemia can occur in association with various diseases and drugs, as summarised in Box 14.25. Overt or subclinical hypothyroidism (p. 639) may cause hypercholesterolaemia, and so measurement of thyroid function is warranted in most cases, even in the absence of typical symptoms and signs.

14

Once secondary causes are excluded, primary lipid abnormalities may be diagnosed. Primary lipid abnormalities can be classified according to the predominant lipid problem: hypercholesterolaemia, hypertriglyceridaemia or mixed hyperlipidaemia (Box 14.26). Although single-gene disorders are encountered in all three categories, most cases are due to multiple-gene (polygenic) loci interacting with environmental factors. Clinical consequences of dyslipidaemia vary somewhat between these causes (pp. 346–347).

Hypercholesterolaemia

Hypercholesterolaemia is a polygenic disorder that is the most common cause of a mild to moderate increase in

i 14.25 Causes of secondary hyperlipidaemia

Secondary hypercholesterolaemia	
Moderately common	
• Drugs: Diuretics, Ciclosporin, Glucocorticoids, Androgens, Antiretroviral agents	• Hypothyroidism • Pregnancy • Cholestatic liver disease
Less common	
• Nephrotic syndrome • Anorexia nervosa	• Porphyria • Hyperparathyroidism
Secondary hypertriglyceridaemia	
Common	
• Type 2 diabetes mellitus • Chronic renal disease • Abdominal obesity • Excess alcohol • Hepatocellular disease	• Drugs: β-blockers, Retinoids, Glucocorticoids, Antiretroviral agents

14.26 Classification of hyperlipidaemia

Disease	Elevated lipid results	Elevated lipoprotein	CHD risk	Pancreatitis risk
Predominant hypercholesterolaemia				
Polygenic (majority)	TC ± TG	LDL ± VLDL	+	–
Familial hypercholesterolaemia (LDLR defect, defective Apo B100, increased function of *PCSK9*)	TC ± TG	LDL ± VLDL	+++	–
Hyperalphalipoproteinaemia	TC ± TG	HDL	–	–
Predominant hypertriglyceridaemia				
Polygenic (majority)	TG	VLDL ± LDL	Variable	+
Lipoprotein lipase deficiency	TG ≫ TC	Chylo	?	+++
Familial hypertriglyceridaemia	TG > TC	VLDL ± Chylo	?	++
Mixed hyperlipidaemia				
Polygenic (majority)	TC + TG	VLDL + LDL	Variable	+
Familial combined hyperlipidaemia*	TC and/or TG	LDL and/or VLDL	++	+
Dysbetalipoproteinaemia*	TC and/or TG	IDL	+++	+

+ = slightly increased risk; ++ = increased risk; +++ = greatly increased risk; ? = risk unclear
*Familial combined hyperlipidaemia and dysbetalipoproteinaemia may also present as predominant hypercholesterolaemia or predominant hypertriglyceridaemia.
(Apo B100 = apolipoprotein B100; CHD = coronary heart disease; Chylo = chylomicrons; HDL = high-density lipoprotein; IDL = intermediate-density lipoprotein; LDL = low-density lipoprotein; LDLR = low-density lipoprotein receptor; TC = total cholesterol; TG = triglycerides; VLDL = very low-density lipoprotein)

14.27 Familial hypercholesterolaemia in adolescence

- **Statin treatment**: may be required from the age of about 10. It does not compromise normal growth and maturation.
- **Smoking**: patients should be strongly advised not to smoke.
- **Adherence to medication:** critically important to the success of treatment. Simple regimens should be used and education and support provided.

LDL-C (Box 14.26). Physical signs, such as corneal arcus and xanthelasma, may be found in this as well as other forms of lipid disturbance (p. 346). The risk of cardiovascular disease is proportional to the degree of LDL-C (or Apo B) elevation, but is modified by other major risk factors, including low HDL-C and high Lp(a).

Familial hypercholesterolaemia (FH) is a more severe disorder with a prevalence of at least 0.4% in most populations. It is usually caused by loss-of-function mutations affecting the *LDLR* gene, which results in an autosomal dominant pattern of inheritance. A similar syndrome can arise with loss-of-function mutations in the ligand-binding domain of Apo B100 or gain-of-function mutations in *PCSK9*, which promote LDLR degradation. Causative mutations can be detected in one of these three genes by genetic testing in about 70% of patients with FH. Most patients with these types of FH have LDL-C levels that are approximately twice as high as in normal subjects of the same age and gender. Affected patients suffer from severe hypercholesterolaemia and premature cardiovascular disease. FH may be accompanied by xanthomas of the Achilles or extensor digitorum tendons (p. 346), which are strongly suggestive of FH. The onset of corneal arcus before age 40 is also suggestive of this condition. Identification of an index case of FH (the first case of FH in a family) should trigger genetic and biochemical screening of other family members, which is a cost-effective method for case detection. Affected individuals should be managed from childhood (Box 14.27).

Homozygous FH may occur sporadically, especially in populations in which there is a 'founder' gene effect or consanguineous marriage. Homozygosity results in more extensive xanthomas and precocious cardiovascular disease, often in childhood. Hyperalphalipoproteinaemia refers to increased levels of HDL-C. In the absence of an increase in LDL-C, this condition rarely causes cardiovascular disease, but exceptions can occur so it should not be regarded as universally benign.

Familial combined hyperlipidaemia, and dysbetalipoproteinaemia, may present with the pattern of predominant hypercholesterolaemia (see 'Mixed hyperlipidaemia' below).

Hypertriglyceridaemia

Hypertriglyceridaemia also usually involves polygenic factors (see Box 14.26). Other common causes include excess alcohol intake, medications (such as β-blockers and retinoids), type 2 diabetes, impaired glucose tolerance, central obesity or other manifestations of insulin resistance (p. 728) and impaired absorption of bile acids. It is often accompanied by post-prandial hyperlipidaemia and reduced HDL-C, both of which may contribute to cardiovascular risk. Excessive intake of alcohol or dietary fat, or other exacerbating factors, may precipitate a massive increase in TG levels, which, if they exceed 10 mmol/L (880 mg/dL), may pose a risk of acute pancreatitis.

Monogenic forms of hypertriglyceridaemia also occur due to loss-of-function mutations in the genes encoding lipoprotein lipase, Apo C2 or *ANGPTL4*, which coordinate the lipolytic breakdown of TG-rich lipoproteins. These cause recessively inherited forms of severe hypertriglyceridaemia that is not readily amenable to drug treatment. They can present in childhood and may be associated with episodes of acute abdominal pain and pancreatitis. In common with other causes of severe hypertriglyceridaemia, hepatomegaly, lipaemia retinalis and eruptive xanthomas may occur (p. 346). Familial hypertriglyceridaemia may also be inherited in a dominant manner due to mutations in the *APOA5* gene, which encodes Apo A5 – a co-factor that is essential for lipoprotein lipase activity. These disorders may also be associated with increased risk of cardiovascular disease.

Familial combined hyperlipidaemia, and dysbetalipoproteinaemia, may present with the pattern of predominant hypertriglyceridaemia (see 'Mixed hyperlipidaemia', below).

Mixed hyperlipidaemia

It is difficult to define quantitatively the distinction between predominant hyperlipidaemias and mixed hyperlipidaemia. The term 'mixed' usually implies the presence of hypertriglyceridaemia, as well as an increase in LDL-C or IDL. Treatment of massive hypertriglyceridaemia may improve TG faster than cholesterol, thus temporarily mimicking mixed hyperlipidaemia.

Primary mixed hyperlipidaemia is usually polygenic and, like predominant hypertriglyceridaemia, often occurs in association with type 2 diabetes, impaired glucose tolerance, central obesity or other manifestations of insulin resistance (p. 728). Both components of mixed hyperlipidaemia may contribute to the risk of cardiovascular disease.

Familial combined hyperlipidaemia is a term used to identify an inherited tendency towards the over-production of atherogenic Apo B-containing lipoproteins. It results in elevation of cholesterol, TG or both in different family members at different times. It is associated with an increased risk of cardiovascular disease but it does not produce any pathognomonic physical signs. In practice, this relatively common condition is substantially modified by factors such as age and weight. It may not be a monogenic condition, but rather one end of a heterogeneous spectrum that overlaps insulin resistance.

Dysbetalipoproteinaemia (also referred to as type 3 hyperlipidaemia, broad-beta dyslipoproteinaemia or remnant hyperlipidaemia) involves accumulation of roughly equimolar levels of cholesterol and TG. It is caused by homozygous inheritance of the Apo E2 allele, which is the isoform least avidly recognised by the LDLR. In conjunction with other exacerbating factors, such as obesity or diabetes, it leads to accumulation of atherogenic IDL and chylomicron remnants. Premature cardiovascular disease is common, as is peripheral vascular disease. It may also result in the formation of palmar xanthomas, tuberous xanthomas or tendon xanthomas.

Rare dyslipidaemias

Several rare disturbances of lipid metabolism have been described (Box 14.28). They provide important insights into lipid metabolism and its impact on risk of cardiovascular disease.

14.28 Miscellaneous and rare forms of hyperlipidaemia

Condition	Lipoprotein pattern	CVD risk
Tangier disease	Very low HDL, low TC	+
Apo A1 deficiency	Very low HDL	++
Apo A1 Milano	Very low HDL	–
Fish eye disease	Very low HDL, high TG	–
LCAT deficiency	Very low HDL, high TG	?
Autosomal recessive FH	Very high LDL	++
Sitosterolaemia	High plant sterols including sitosterol	+
Cerebrotendinous xanthomatosis	Bile acid defect (cholestanol accumulation)	+

+ = slightly increased risk; ++ = increased risk.
(CVD = cardiovascular disease; FH = familial hypercholesterolaemia; HDL = high-density lipoprotein; LCAT = lecithin cholesterol acyl transferase; LDL = low-density lipoprotein; TC = total cholesterol; TG = triglycerides)

Fish eye disease, Apo A1 Milano and lecithin cholesterol acyl transferase (LCAT) deficiency demonstrate that very low HDL-C levels do not necessarily cause cardiovascular disease, but Apo A1 deficiency, and possibly Tangier disease, demonstrate that low HDL-C can be atherogenic under some circumstances. Autosomal recessive *FH* and *PCSK9* gain-of-function mutations reveal the importance of proteins that chaperone the LDLR. Sitosterolaemia and cerebrotendinous xanthomatosis demonstrate that sterols other than cholesterol can cause xanthomas and cardiovascular disease, while *PCSK9* loss-of-function mutations, abetalipoproteinaemia and hypobetalipoproteinaemia suggest that low levels of Apo B-containing lipoproteins reduce the risk of cardiovascular disease. The only adverse health outcomes associated with extremely low plasma lipid levels in the latter two conditions are attributable to fat-soluble vitamin deficiency, or impaired transport of lipid from intestine or liver.

Principles of management

Lipid-lowering therapies have a key role in the secondary and primary prevention of cardiovascular diseases (p. 487). Assessment of absolute risk of cardiovascular disease, treatment of all modifiable risk factors and optimisation of lifestyle, especially diet and exercise, are central to management in all cases. Patients with the greatest absolute risk of cardiovascular disease derive the greatest absolute benefit from treatment. Public health organisations recommend thresholds for the introduction of lipid-lowering therapy based on the identification of patients in very high-risk categories, or those calculated to be at high absolute risk according to algorithms or tables such as the Joint British Societies Coronary Risk Prediction Chart (see Fig. 16.77, p. 511). These tables, which are based on large epidemiological studies, should be recalibrated for the local population, if possible. In general, patients who have cardiovascular disease, diabetes mellitus, chronic renal impairment, familial hypercholesterolaemia or an absolute risk of cardiovascular disease of more than 20% in the ensuing 10 years are arbitrarily regarded as having sufficient risk to justify drug treatment. Age is such an overwhelming determinant of absolute cardiovascular risk that some recent recommendations consider 'lifetime' risk. This diminishes the pressure to treat very elderly patients and supports earlier intervention in non-elderly patients.

Public health organisations also recommend target levels for patients receiving drug treatment. High-risk patients should aim for HDL-C >1 mmol/L (38 mg/dL) and fasting TG <2 mmol/L (approximately 180 mg/dL), while target levels for LDL-C have been reduced to 1.8 mmol/L (76 mg/dL) or less. In general, total cholesterol should be <5 mmol/L (190 mg/dL) during treatment, and <4 mmol/L (approximately 150 mg/dL) in high-risk patients and in secondary prevention of cardiovascular disease. Recent trials have demonstrated continuous benefit of LDL-C reduction to a level of 1.4 mmol/L (54 mg/dL), so further reduction in treatment targets may be anticipated.

Non-pharmacological management

Patients with lipid abnormalities should receive medical advice and, if necessary, dietary counselling to:

- reduce intake of saturated and *trans*-unsaturated fat to less than 7–10% of total energy
- reduce intake of cholesterol to <250 mg/day
- replace sources of saturated fat and cholesterol with alternative foods, such as lean meat, low-fat dairy

14

products, polyunsaturated spreads and low-glycaemic-index carbohydrates
- reduce energy-dense foods such as fats and soft drinks, while increasing activity and exercise to maintain or lose weight
- increase consumption of cardioprotective and nutrient-dense foods, such as vegetables, unrefined carbohydrates, fish, pulses, nuts, legumes, and fruit
- adjust alcohol consumption, reducing intake if excessive or if associated with hypertension, hypertriglyceridaemia or central obesity
- achieve additional benefits with preferential intake of foods containing lipid-lowering nutrients such as n-3 fatty acids, dietary fibre and plant sterols.

The response to diet is usually apparent within 3–4 weeks but dietary adjustment may need to be introduced gradually. Although hyperlipidaemia in general, and hypertriglyceridaemia in particular, can be very responsive to these measures, LDL-C reductions are often only modest in routine clinical practice. Explanation, encouragement and persistence are often required to assist patient adherence. Even minor weight loss can substantially reduce cardiovascular risk, especially in centrally obese patients (p. 700).

All other modifiable cardiovascular risk factors should be assessed and treated. If possible, intercurrent drug treatments that adversely affect the lipid profile should be replaced.

Pharmacological management

The main diagnostic categories provide a useful framework for management and the selection of first-line pharmacological treatment (Fig. 14.14).

Hypercholesterolaemia

Hypercholesterolaemia can be treated with one or more of the cholesterol-lowering drugs as described below.

Statins

These reduce cholesterol synthesis by inhibiting the HMGCoA reductase enzyme. The reduction in cholesterol synthesis up-regulates production of the LDLR, which increases clearance of LDL and its precursor, IDL, resulting in a secondary reduction in LDL synthesis. Statins reduce LDL-C by up to 60%, reduce TG by up to 40% and increase HDL-C by up to 10%. They also reduce the concentration of intermediate metabolites such as isoprenes, which may lead to other effects such as suppression of the inflammatory response. There is clear evidence of protection against total and coronary mortality, stroke and cardiovascular events across the spectrum of cardiovascular disease risk.

Statins are generally well tolerated and serious side-effects are rare (well below 2%). Liver function test abnormalities and muscle problems, such as myalgia, asymptomatic increase in creatine kinase (CK), myositis and, infrequently, rhabdomyolysis, are the most common. Side-effects are more likely in patients who are elderly, debilitated or receiving other drugs that interfere with statin degradation, which usually involves cytochrome P450 3A4 or glucuronidation.

Ezetimibe

Ezetimibe inhibits activity of the intestinal mucosal transporter NPC1L1, which is responsible for absorption of dietary and biliary cholesterol. The resulting depletion of hepatic cholesterol up-regulates hepatic LDLR production. This mechanism of action is synergistic with the effect of statins. Monotherapy in a 10 mg/day dose reduces LDL-C by 15–20%. Slightly greater (17–25%) incremental LDL-C reduction occurs when ezetimibe is added to statins. Ezetimibe is well tolerated, and evidence of a beneficial effect on cardiovascular disease endpoints is now available. Plant sterol-supplemented foods, which also reduce cholesterol absorption, lower LDL-C by 7–15%.

Bile acid-sequestering resins

Drugs in this class include colestyramine, colestipol and colesevelam. These prevent the reabsorption of bile acids, thereby increasing de novo bile acid synthesis from hepatic cholesterol. As with ezetimibe, the resultant depletion of hepatic cholesterol up-regulates LDL receptor activity and reduces LDL-C in a manner that is synergistic with the action of statins. Resins reduce LDL-C and modestly increase HDL-C, but may increase TG. They are safe but may interfere with bioavailability of other drugs. Colesevelam has fewer gastrointestinal effects than older

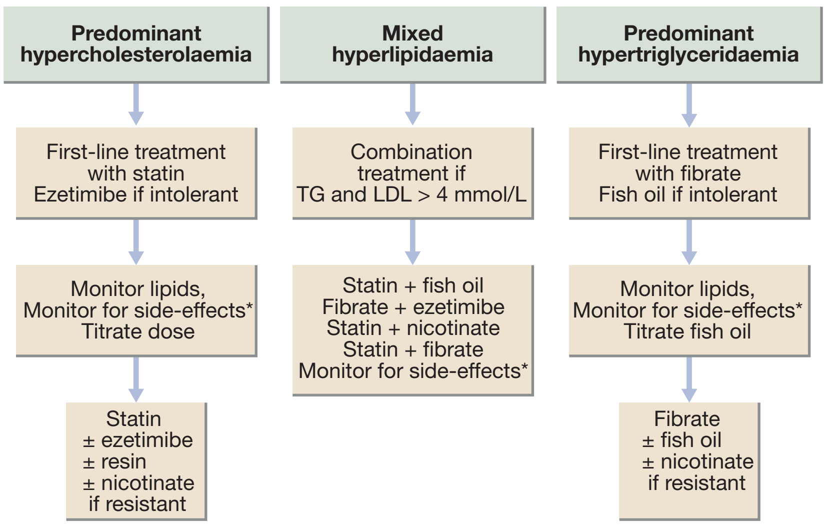

Fig. 14.14 Flow chart for the drug treatment of hyperlipidaemia. *Interrupt treatment if creatine kinase is more than 5–10 times the upper limit of normal, or if elevated with muscle symptoms, or if alanine aminotransferase is more than 2–3 times the upper limit. To convert triglyceride (TG) in mmol/L to mg/dL, multiply by 88. To convert low-density lipoprotein (LDL)-C in mmol/L to mg/dL, multiply by 38.

preparations that are less well tolerated. The depletion of bile acids is sensed via the farnesyl X receptor and the response may also improve glucose metabolism.

PCSK9 inhibitors

Monoclonal antibodies have been developed that neutralise PCSK9, an enzyme that degrades the LDLR. This causes levels of LDLR to increase, which markedly reduces LDL-C. The PCSK9 inhibitors currently available are evolocumab and alirocumab, which are administered by subcutaneous injection every 2–4 weeks. These drugs are well tolerated and highly effective. Reductions in LDL-C of about 50–60% have been observed in patients who have not responded adequately to standard lipid-lowering therapy and this has been accompanied by a reduction in the risk of cardiovascular events of about 15%. The PCSK9 inhibitors do not deplete intracellular concentrations and, because of that, do not trigger compensatory mechanisms that blunt the effect of other cholesterol-lowering medications.

Nicotinic acid

Pharmacological doses reduce peripheral fatty acid release, with the result that VLDL and LDL decline while HDL-C increases. Recent randomised clinical trials have been disappointing regarding effects on atherosclerosis and cardiovascular events. The same may be said of novel agents that inhibit cholesterol ester transfer protein. Neither of these HDL-C-raising drugs is indicated in current lipid management.

Combination therapy

In many patients, treatment of predominant hypercholesterolaemia can be achieved by diet plus the use of a statin in sufficient doses to achieve target LDL-C levels. Patients who do not reach LDL targets on the highest tolerated statin dose, or who are intolerant of statins, may receive ezetimibe, plant sterols, or resins. Ezetimibe and resins are safe and effective in combination with a statin because the mechanisms of action of individual therapies complement each other while blunting each other's compensatory mechanisms.

Hypertriglyceridaemia

Predominant hypertriglyceridaemia can be treated with one of the TG-lowering drugs described below (see Fig. 14.14).

Fibrates

These stimulate peroxisome proliferator-activated receptor (PPAR) alpha, which controls the expression of gene products that mediate the metabolism of TG and HDL. As a result, synthesis of fatty acids, TG and VLDL is reduced, while that of lipoprotein lipase, which catabolises TG, is enhanced. In addition, production of Apo A1 and ABC A1 is up-regulated, leading to increased reverse cholesterol transport via HDL. Consequently, fibrates reduce TG by up to 50% and increase HDL-C by up to 20%, but LDL-C changes are variable.

Fewer large-scale trials have been conducted with fibrates than with statins. The results are less conclusive, but reduced rates of cardiovascular disease have been reported with fibrate therapy in the subgroup of patients with low HDL-C levels and elevated TG (TG >2.3 mmol/L (200 mg/dL)). Fibrates are usually well tolerated but share a similar side-effect profile to statins. In addition, they may increase the risk of cholelithiasis and prolong the action of anticoagulants. Accumulating evidence suggests that they may also have a protective effect against diabetic microvascular complications.

Highly polyunsaturated long-chain n-3 fatty acids

These include eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), which comprise approximately 30% of the fatty acids in fish oil. EPA and DHA are potent inhibitors of VLDL TG formation. Intakes of more than 2 g n-3 fatty acid (equivalent to 6 g of most forms of fish oil) per day lower TG in a dose-dependent fashion. Up to 50% reduction in TG may be achieved with 15 g fish oil per day. Changes in HDL-C are variable but fish oils do not routinely reduce LDL-C. Fish oil fatty acids have also been shown to inhibit platelet aggregation and improve cardiac arrhythmia in animal models. Dietary and pharmacological trials suggested that n-3 fatty acids may reduce mortality from coronary heart disease, but the benefit of fish oil supplements has been less conclusive in recent trials. Fish oils appear to be safe and well tolerated but dietary fish consumption is the preferred source.

Patients with predominant hypertriglyceridaemia who do not respond to lifestyle intervention can be treated with fibrates or fish oil, depending on individual response and tolerance. If target levels are not achieved, the fibrates, fish oil and possibly nicotinic acid can be combined. Massive hypertriglyceridaemia may require more aggressive limitation of dietary fat intake (<10–20% energy as fat). Any degree of insulin deficiency should be corrected because insulin is required for optimal activity of lipoprotein lipase. The initial target for patients with massive hypertriglyceridaemia is TG <10 mmol/L (880 mg/dL), to reduce the risk of acute pancreatitis.

Mixed hyperlipidaemia

Mixed hyperlipidaemia can be difficult to treat. First-line therapy with statins alone is unlikely to achieve target levels once fasting TGs exceed approximately 4 mmol/L (350 mg/dL). Fibrates

14.29 Management of hyperlipidaemia in old age

- **Prevalence of atherosclerotic cardiovascular disease**: greatest in old age.
- **Associated cardiovascular risk**: lipid levels become less predictive, as do other risk factors apart from age itself.
- **Benefit of statin therapy**: maintained up to the age of 80 years but evidence is lacking beyond this.
- **Life expectancy and statin therapy**: lives saved by intervention are associated with shorter life expectancy than in younger patients, and so the impact of statins on quality-adjusted life years is smaller in old age.

14.30 Dyslipidaemia in pregnancy

- **Lipid metabolism**: lipid and lipoprotein levels increase during pregnancy. This includes an increase in low-density lipoprotein cholesterol, which resolves post-partum. Remnant dyslipidaemia and hypertriglyceridaemia may be exacerbated during pregnancy.
- **Treatment**: dyslipidaemia is rarely thought to warrant urgent treatment so pharmacological therapy is usually contraindicated when conception or pregnancy is anticipated. Teratogenicity has been reported with systemically absorbed agents, and non-absorbed agents may interfere with nutrient bioavailability.
- **Monitoring**: while still uncommon among women of child-bearing age, cardiovascular disease is increasing in prevalence. Pre-conception cardiovascular review should be considered for women at high risk to optimise medications for pregnancy and to ensure that the patient will be able to withstand the demands of pregnancy and labour.

are first-line therapy for dysbetalipoproteinaemia, but they may not control the cholesterol component in other forms of mixed hyperlipidaemia. Combination therapy is often required. Effective combinations include:

- statin plus fenofibrate (recognising that the risk of myopathy is increased with gemfibrozil, but fenofibrate is relatively safe in this regard)
- statin plus fish oil when TG is not too high
- fibrate plus ezetimibe when cholesterol is not too high.

Monitoring of therapy

The effects of lipid-lowering therapy should be assessed after 6 weeks (12 weeks for fibrates). At this point, it is prudent to review side-effects, lipid response (see target levels above), CK and liver function tests. During longer-term follow-up, adherence to treatment, diet and exercise should be assessed, with monitoring of weight, blood pressure and lipid levels. The presence of cardiovascular symptoms or signs should be noted and absolute cardiovascular risk assessed periodically. Effective statin therapy may be associated with a paradoxical and as yet unexplained increase in coronary calcium score.

It is not necessary to perform routine checks of CK and liver function unless symptoms occur, or if statins are used in combination with fibrates, or other drugs that may interfere with their clearance. If myalgia or weakness occurs in association with CK elevation over 5–10 times the upper limit of normal, or if sustained alanine aminotransferase (ALT) elevation more than 2–3 times the upper limit of normal occurs that is not accounted for by fatty liver (p. 882), treatment should be discontinued and alternative therapy sought.

The principles of the management of dyslipidaemia can be applied broadly, but the objectives of treatment in the elderly (Box 14.29) and the safety of pharmacological therapy in pregnancy (Box 14.30) warrant special consideration.

The porphyrias

This group of disorders is caused by inherited abnormalities in the haem biosynthetic pathway (Fig. 14.15). Most of the described forms are due to partial enzyme deficiencies with a dominant mode of inheritance. They are commonly classified as hepatic or erythropoietic, depending on whether the major site of excess porphyrin production is in the liver or red cell.

The porphyrias have a penetrance in the order of 25%, emphasising the importance of environmental factors in disease expression. In porphyria cutanea tarda (PCT), which is the most

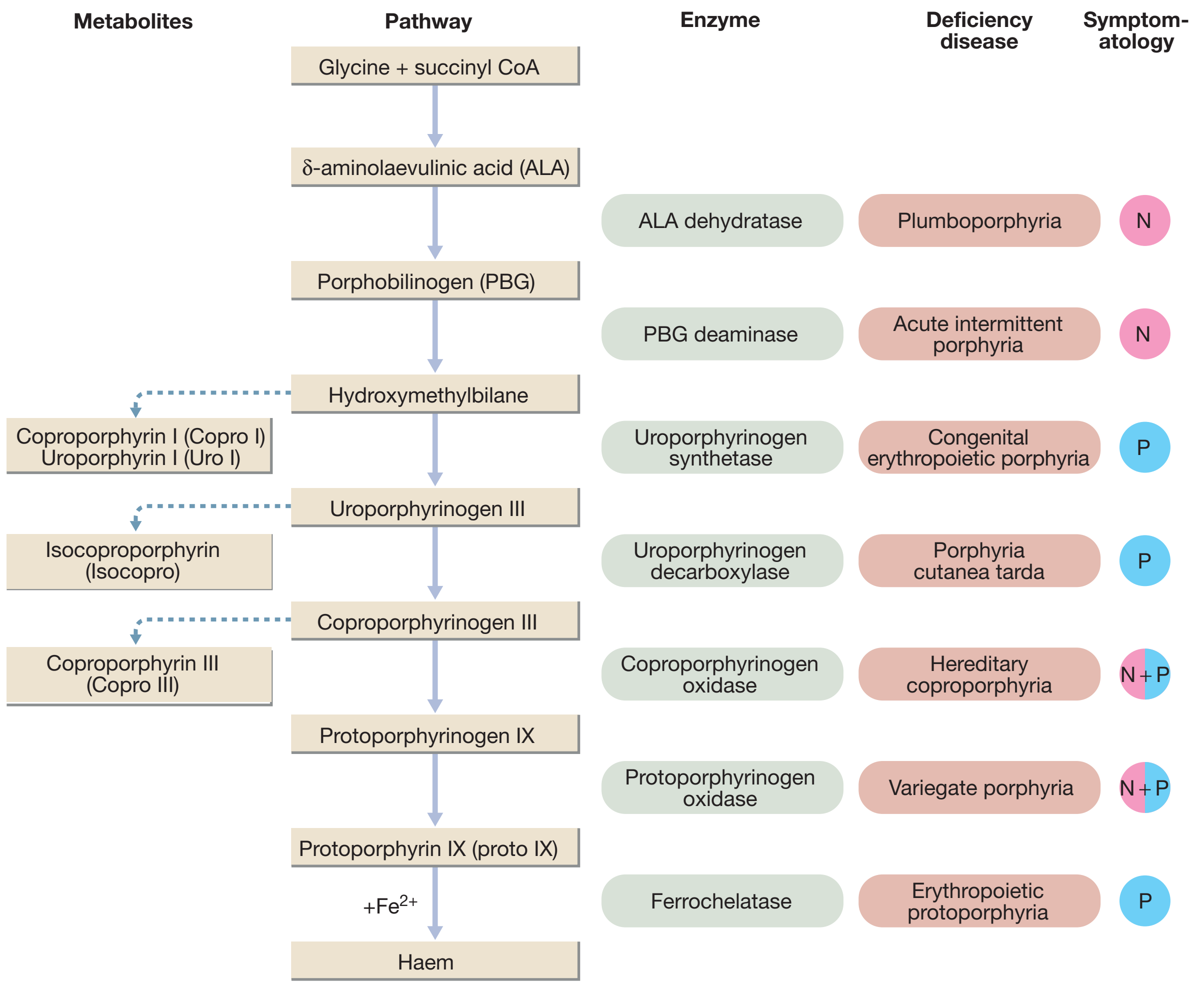

Fig. 14.15 Haem biosynthetic pathway and enzyme defects responsible for the porphyrias. (ALA = δ-aminolaevulinic acid; CoA = co-enzyme A; N = neurovisceral; P = photosensitive; PBG = porphobilinogen)

14.31 Diagnostic biochemical findings in the porphyrias[1]

	Elevated porphyrins and precursors		
Condition	Blood	Urine	Faeces
ALA dehydratase deficiency (plumboporphyria)	Proto IX[2]	ALA, Copro III[2]	
Acute intermittent porphyria (AIP)		ALA, PBG	
Congenital erythropoietic porphyria (CEP)	Uro I	Uro I	Copro I
Porphyria cutanea tarda (PCT)		Uro I	Isocopro
Hereditary coproporphyria (HCP)		ALA, PBG, Copro III	Copro III
Variegate porphyria (VP)		ALA, PBG, Copro III	Proto IX
Erythropoietic protoporphyria (EPP)	Proto IX		Proto IX

[1]Refer to Figure 14.15 for metabolic pathways. [2]The paradoxical rise in coproporphyrin III (Copro III) and protoporphyrin (Proto) in this very rare condition is poorly understood.
(ALA = δ-aminolaevulinic acid; Isocopro = isocoproporphyrin; PBG = porphobilinogen; Uro = uroporphyrin)

common cause of porphyria, environmental triggers include alcohol, iron accumulation, exogenous oestrogens and exposure to various chemicals. Many cases are associated with hepatitis C infection and this should always be screened for on presentation.

Clinical features

The clinical features of porphyria fall into two broad categories: photosensitivity and acute neurovisceral syndrome. The enzyme defects responsible for the diseases are shown in Figure 14.15.

Photosensitive skin manifestations, attributable to excess production and accumulation of porphyrins in the skin, cause pain, erythema, bullae, skin erosions, hirsutism and hyperpigmentation, and occur predominantly on areas of the skin that are exposed to sunlight (p. 1220). The skin also becomes sensitised to damage from minimal trauma.

The other pattern of presentation is with an acute neurological syndrome. This almost always presents with acute abdominal pain together with features of autonomic dysfunction, such as tachycardia, hypertension and constipation. Neuropsychiatric manifestations, hyponatraemia due to inappropriate ADH release (p. 357), and an acute neuropathy may also occur (p. 1138). The neuropathy is predominantly motor and may, in severe cases, progress to respiratory failure.

There is no proven explanation for the episodic nature of the attacks in porphyria, which can relapse and remit or follow a prolonged and unremitting course. Sometimes, specific triggers can be identified, such as alcohol, fasting, or drugs such as anticonvulsants, sulphonamides, oestrogen and progesterone. The oral contraceptive pill is a common precipitating factor. In a significant number, no precipitant can be identified.

Investigations

The diagnosis of porphyria and classification into the various forms have traditionally relied on measurements of porphyrins and porphyrin precursors found in blood, urine and faeces (Box 14.31). The diagnosis is straightforward when the metabolites are significantly elevated, but this is not always the case in asymptomatic individuals who may have normal porphyrin studies.

More recently, measurement of the enzymes that are deficient in the various porphyrias has provided further diagnostic information. An example is measurement of porphobilinogen deaminase activity in red blood cells to diagnose acute intermittent porphyria. There is often considerable overlap between enzyme activities in affected and normal subjects, however. Furthermore, some of the enzymes occur in the mitochondria, for which it is more difficult to obtain suitable specimens for analysis. All the genes of the haem biosynthetic pathway have now been characterised. This has made it possible to identify affected individuals in families by genetic testing, a significant advance considering that penetrance of porphyria is low.

Metabolite excretory patterns are always grossly abnormal during an acute attack or with cutaneous manifestations of porphyria, and are diagnostic of the particular porphyria. A normal metabolite profile under these circumstances effectively excludes porphyria. Metabolites usually remain abnormal for long periods after an acute attack, and in some individuals never return to normal. The diagnosis is not so straightforward in patients who are in remission, or in asymptomatic individuals with a positive family history. Neurological porphyria rarely manifests before puberty, nor can it be readily diagnosed after the menopause as porphyrin excretion may be normal. Genetic testing for disease-specific mutations can clarify the situation.

Management

For patients predisposed to neurovisceral attacks, general management includes avoidance of any agents known to precipitate acute porphyria. Specific management includes intravenous glucose, as provision of 5000 kilojoules per day can, in some cases, terminate acute attacks through a reduction in δ-aminolaevulinic acid (ALA) synthetase activity, leading to reduced ALA and porphyrin synthesis. More recently, administration of haem (in various forms such as haematin or haem arginate) has been shown to reduce metabolite excretory rates, relieve pain and accelerate recovery. Cyclical acute attacks in women sometimes respond to suppression of the menstrual cycle using gonadotrophin-releasing hormone analogues. In rare cases with frequent prolonged attacks or attacks intractable to treatment, liver transplantation has been effective.

There are few specific or effective measures to treat the photosensitive manifestations. The primary goal is to avoid sun exposure and skin trauma. Barrier sun creams containing zinc or titanium oxide are the most effective products. New colourless creams containing nanoparticle formulations have improved patient acceptance. Beta-carotene is used in some patients with erythropoietic porphyria with some efficacy. Afamelanotide, a synthetic analogue of alpha-melanocyte stimulating hormone (α-MSH), has also been shown to provide protection in erythropoietic protoporphyria, and is now undergoing approval in many countries. In porphyria cutanea tarda, a course of venesections to remove iron can result in long-lasting clinical and biochemical remission,

especially if exposure to identified precipitants, such as alcohol or oestrogens, is reduced. Alternatively, a prolonged course of low-dose chloroquine therapy is effective.

Clinical examination of the kidney and urinary tract

Many diseases of the kidney and urinary tract are clinically silent, at least in the early stages. Accordingly, it is common for these conditions to be detected first by routine blood tests or on dipstick testing of the urine. Several important abnormalities can also be picked up on physical examination, however, and these are summarised below.

5 Fundoscopy

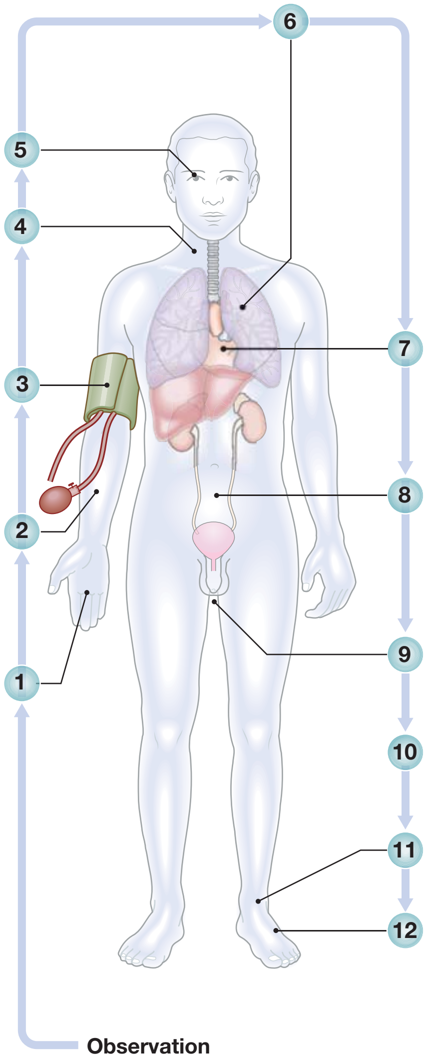
▲ Hypertensive changes

4 Jugular venous pressure
Elevated in fluid overload

3 Blood pressure
Often elevated

2 Skin
Yellow complexion*
Bruising*
Excoriation of pruritus*
Reduced skin turgor in fluid depletion

1 Hands



▲ Splinter haemorrhages

▲ 'Brown line' pigmentation of nails

6 Lungs
Crepitations in fluid overload

Observation
- Tiredness
- Respiratory rate and depth increased in metabolic acidosis
- Pallor*

*Features of advanced chronic kidney disease (see also Fig. 15.22)

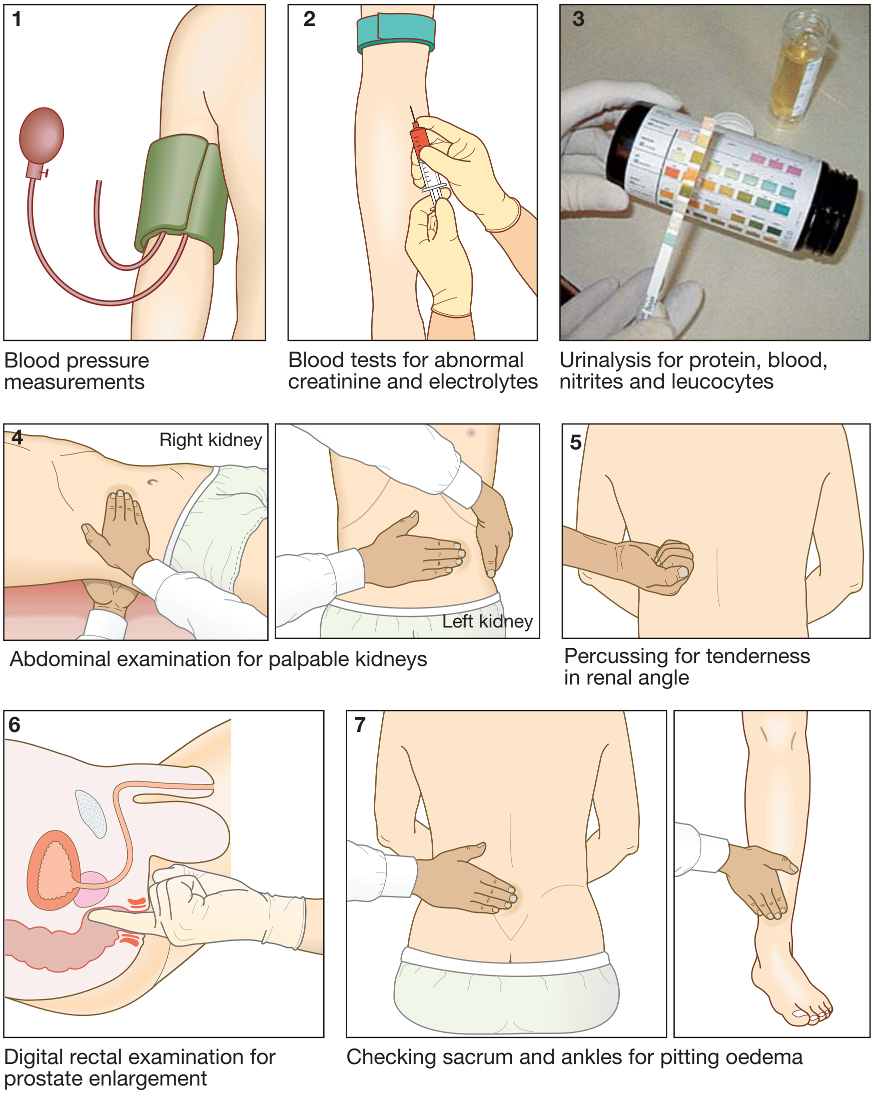
7 Heart
Extra heart sounds in fluid overload
Pericardial friction rub*

8 Abdomen
Renal mass
Local tenderness
Renal or other arterial bruits in renal vascular disease
Rectal examination — prostate

9 Genitalia
Scrotal swellings

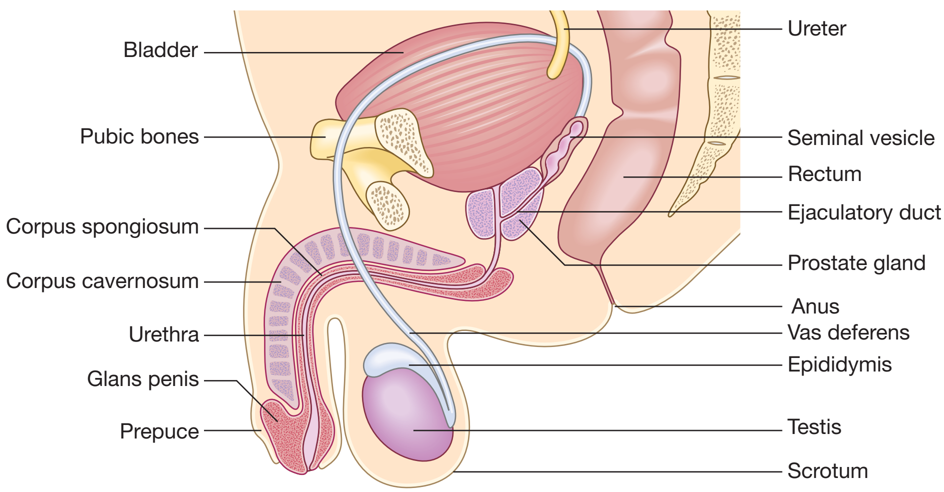
▲ Phimosis

10 Sacral oedema



11 Ankle oedema

12 Peripheral neuropathy*



13 Urinalysis for blood and protein

14 Urine microscopy

Clinical examination techniques to evaluate urological and renal abnormalities. *Inset (Dipstick): From Pitkin J, Peattie AB, Magowan BA. Obstetrics and gynaecology: An illustrated colour text. Edinburgh: Churchill Livingstone, Elsevier Ltd; 2003.*

Male lower urinary tract demonstrating the relationship of the bladder, urethra, vas deferens and testes.

This chapter describes the disorders of the kidneys and urinary tract that are commonly encountered in routine practice, as well as giving an overview of the highly specialised field of renal replacement therapy. Disorders of renal tubular function, which may cause alterations in electrolyte and acid–base balance, are described in Chapter 14.

Functional anatomy and physiology

The kidneys

The kidneys play a central role in excretion of many metabolic breakdown products, including ammonia and urea from protein, creatinine from muscle, uric acid from nucleic acids, drugs and toxins. They achieve this by making large volumes of an ultrafiltrate of plasma (120 mL/min, 170 L/24 hrs) at the glomerulus, and selectively reabsorbing components of this ultrafiltrate at points along the nephron. The rates of filtration and reabsorption are controlled by many hormonal and haemodynamic signals to regulate fluid and electrolyte balance (p. 349), blood pressure (p. 447), and acid–base (p. 363) and calcium–phosphate homeostasis (pp. 367 and 368). In addition, the kidneys activate vitamin D and control the synthesis of red blood cells by producing erythropoietin. Strategies to replace each of these important functions are required when managing patients with kidney failure.

Each kidney is approximately 11–14 cm in length in healthy adults; they are located retroperitoneally on either side of the aorta and inferior vena cava between the 12th thoracic and 3rd lumbar vertebrae (Fig. 15.1A). The right kidney is usually a few centimetres lower because the liver lies above it. Both kidneys rise and descend several centimetres with respiration.

The kidneys have a rich blood supply and receive approximately 20–25% of cardiac output through the renal arteries, which arise from the abdominal aorta. The renal arteries undergo various subdivisions within the kidney, eventually forming interlobular arteries that run through the renal cortex. These eventually give rise to afferent glomerular arterioles that supply the glomeruli. The efferent arteriole, leading from the glomerulus, supplies the distal nephron and medulla in a 'portal' circulation (Fig. 15.1B). This highly unusual arrangement of two serial capillary beds reflects the role of the afferent and efferent arterioles in autoregulation of glomerular filtration.

The nephron

Each kidney contains approximately 1 million individual functional units, called nephrons. Each nephron consists of a glomerulus, which is responsible for ultrafiltration of blood, a proximal renal tubule, a loop of Henle, a distal renal tubule and a collecting duct, which together are responsible for selective reabsorption of water and electrolytes that have been filtered at the glomerulus (see Fig. 14.2, p. 350, and Fig. 15.1B). Under normal circumstances, more than 99% of the 170 L of glomerular filtrate that is produced each day is reabsorbed in the tubules. The remainder passes through the collecting ducts of multiple nephrons and drains into the renal pelvis and ureters.

The glomerulus

The glomerulus comprises a tightly packed loop of capillaries supplied by an afferent arteriole and drained by an efferent arteriole. It is surrounded by a cup-shaped extension of the proximal tubule termed Bowman's capsule, which is composed of epithelial cells. The glomerular capillary endothelial cells contain pores (fenestrae), through which circulating molecules can pass to reach the underlying glomerular basement membrane (GBM), which is formed by fusion of the basement membranes of tubular epithelial and vascular endothelial cells (Fig. 15.1C and D). Glomerular epithelial cells (podocytes) have multiple long foot processes that interdigitate with those of the adjacent epithelial cells, thereby maintaining a selective barrier to filtration (Fig. 15.1E). Mesangial cells lie in the central region of the glomerulus. They have contractile properties similar to those of vascular smooth muscle cells and play a role in regulating glomerular filtration rate.

Under normal circumstances, the glomerulus is impermeable to proteins the size of albumin (67 kDa) or larger, while proteins of 20 kDa or smaller are filtered freely. The ability of molecules between 20 and 67 kDa to pass through the GBM is variable and depends on the size (smaller molecules are filtered more easily) and charge (positively charged molecules are filtered more easily). Very little lipid is filtered by the glomerulus.

Filtration pressure at the glomerulus is normally maintained at a constant level, in the face of wide variations in systemic blood pressure and cardiac output, by alterations in muscle tone within the afferent and efferent arterioles and mesangial cells. This is known as autoregulation. Reduced renal perfusion pressure increases local production of prostaglandins that mediate vasodilatation of the afferent arteriole, thereby increasing the intraglomerular pressure (Fig. 15.1D). In addition, renin is released by specialised smooth muscle cells in the juxtaglomerular apparatus in response to reduced perfusion pressure, stimulation of sympathetic nerves or low sodium concentration of fluid in the distal convoluted tubule at the macula densa. Renin cleaves angiotensinogen to release angiotensin I, which is further cleaved by angiotensin-converting enzyme (ACE) to produce angiotensin II. This restores glomerular perfusion pressure in the short term by causing vasoconstriction of the efferent arterioles within the kidney to raise intraglomerular pressure selectively (Fig. 15.1D), and by inducing systemic vasoconstriction to increase blood pressure and thus renal perfusion pressure. In the longer term, angiotensin II increases plasma volume by stimulating aldosterone release, which enhances sodium reabsorption by the renal tubules (see Fig. 18.18, p. 666). Consumption of non-steroidal anti-inflammatory preparations and renin–angiotensin system inhibitors in the context of volume depletion may impair the ability of the kidney to maintain glomerular filtration and exacerbate pre-renal failure (see Fig. 15.19, p. 413).

Renal tubules, loop of Henle and collecting ducts

The proximal renal tubule, loop of Henle, distal renal tubule and collecting ducts are responsible for reabsorption of water, electrolytes and other solutes, as well as regulating acid–base balance, as described in detail on page 350 and in Figure 14.3. They also play a key role in regulating calcium homeostasis by converting 25-hydroxyvitamin D to the active metabolite 1,25-dihydroxyvitamin D (p. 1049). Failure of this process contributes to the pathogenesis of hypocalcaemia and bone disease that occurs in chronic kidney disease (CKD, p. 415). Fibroblast-like cells that lie in the interstitium of the renal cortex are responsible for production of erythropoietin, which in turn is required for production of red blood cells. Erythropoietin synthesis is regulated by oxygen tension; anaemia and hypoxia increase production, whereas polycythaemia and hyperoxia inhibit it.

15

Failure of erythropoietin production plays an important role in the pathogenesis of anaemia in CKD.

The ureters and bladder

The ureters drain urine from the renal pelvis (Fig. 15.1A) and deliver it to the bladder, a muscular organ that lies anteriorly in the lower part of the pelvis, just behind the pubic bone. The function of the bladder is to store and then release urine during micturition. The bladder is richly innervated. Sympathetic nerves arising from T10–L2 relay in the pelvic ganglia to cause relaxation of the detrusor muscle and contraction of the bladder neck (both via α-adrenoceptors), thereby preventing release of urine from the bladder. The distal sphincter mechanism is innervated by somatic motor fibres from sacral segments S2–4, which reach the sphincter either by the pelvic plexus or via the pudendal nerves. Afferent sensory impulses pass to the cerebral cortex, from where reflex-increased sphincter tone and suppression of detrusor contraction inhibit micturition until it is appropriate. Conversely, parasympathetic nerves arising from S2–4 stimulate detrusor contraction, promoting micturition.

The micturition cycle has a storage (filling) phase and a voiding (micturition) phase. During the filling phase, the high compliance of the detrusor muscle allows the bladder to fill steadily without a rise in intravesical pressure. As bladder volume increases, stretch receptors in its wall cause reflex bladder relaxation and increased sphincter tone. The act of micturition is initiated first by voluntary and then by reflex relaxation of the pelvic floor and distal sphincter mechanism, followed by reflex detrusor contraction. These actions are coordinated by the pontine micturition centre. Intravesical pressure remains greater than urethral pressure until the bladder is empty.

The prostate gland

The prostate gland is situated at the base of the bladder, surrounding the proximal urethra (p. 383). Exocrine glands within the prostate produce fluid, which comprises about 20% of the volume of ejaculated seminal fluid and is rich in zinc and proteolytic enzymes. The remainder of the ejaculate is formed in the seminal vesicles and bulbo-urethral glands, with spermatozoa arising from the testes.

Smooth muscle fibres within the prostate, which are under sympathetic control, play a role in controlling urine flow through the bulbar urethra, and also contract at orgasm to move seminal fluid through ejaculatory ducts into the bulbar urethra (emission). Contraction of the bulbocavernosus muscle (via a spinal muscle reflex) then ejaculates the semen out of the urethra.

The penis

Blood flow into the corpus cavernosum of the penis is controlled by sympathetic nerves from the thoracolumbar plexus, which maintain smooth muscle contraction (p. 383). In response to afferent input from the glans penis and from higher centres, pelvic splanchnic parasympathetic nerves actively relax the cavernosal smooth muscle via neurotransmitters such as nitric oxide, acetylcholine, vasoactive intestinal polypeptide (VIP) and prostacyclin, with consequent dilatation of the lacunar space. At the same time, draining venules are compressed, trapping blood in the lacunar space with consequent elevation of pressure and erection (tumescence) of the penis.

Investigation of renal and urinary tract disease

Glomerular filtration rate

The glomerular filtration rate (GFR) is the sum of the ultrafiltration rates from plasma into the Bowman's space in each nephron and is a measure of renal excretory function. It is proportionate to body size and the reference value is usually expressed after correction for body surface area as 120±25 mL/min/1.73 m^2. The GFR may be measured directly by injecting and measuring the clearance of compounds such as inulin or radiolabelled ethylenediamine-tetra-acetic acid (EDTA), which are completely filtered at the glomerulus and are not secreted or reabsorbed by the renal tubules (Box 15.1). This is not performed routinely, however, and is usually reserved for special circumstances, such as the assessment of renal function in potential live kidney donors. Instead, GFR is usually assessed indirectly in clinical

15.1 How to estimate glomerular filtration rate (GFR)

Measuring GFR

- Direct measurement using labelled ethylenediamine-tetra-acetic acid (EDTA) or inulin
- Creatinine clearance (CrCl):
  - Minor tubular secretion of creatinine causes CrCl to exaggerate GFR when renal function is poor; can be affected by drugs (e.g. trimethoprim, cimetidine)
  - Needs 24-hr urine collection (inconvenient and often unreliable)

$$\text{CrCl (mL/min)} = \frac{\text{urine creatinine concentration } (\mu\text{mol/L}) \times \text{volume (mL)}}{\text{plasma creatinine concentration } (\mu\text{mol/L}) \times \text{time (min)}}$$

Estimating GFR with equations

- The Modification of Diet in Renal Disease (MDRD) study equation (see www.renal.org/eGFR):
  - Requires knowledge of age and sex only; it can therefore be reported automatically by laboratories
  - For limitations, see Box 15.2

$$\text{eGFR} = 175^{*} \times (\text{creatinine in } \mu\text{mol/L}/88.4)^{-1.154} \times (\text{age in yrs})^{-0.203} \times (0.742 \text{ if female}) \times (1.21 \text{ if black})$$

- The Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation:
  - More accurately estimates the actual GFR than the MDRD eGFR in those with relatively preserved renal function

$$\text{eGFR} = 141 \times \min(\text{SCr}/\kappa,\ 1)^{\alpha} \times \max(\text{SCr}/\kappa,\ 1)^{-1.209} \times 0.993^{\text{Age}} \times 1.018 \text{ (if female)} \times 1.159 \text{ (if black)}$$

Where SCr = serum creatinine in μmol/L
κ = 61.9 if female and 79.6 if male
α = −0.329 if female and −0.411 if male
min = whichever is the minimum of serum creatinine/κ or 1
max = whichever is the maximum of serum creatinine/κ or 1

- No equations perform well in unusual circumstances, such as extremes of body (and muscle) mass or in acutely unwell patients (see Box 15.2)

*A correction factor of 175 is used for isotope dilution mass spectrometry traceable creatinine measurements. To convert creatinine in mg/dL to μmol/L, multiply by 88.4.

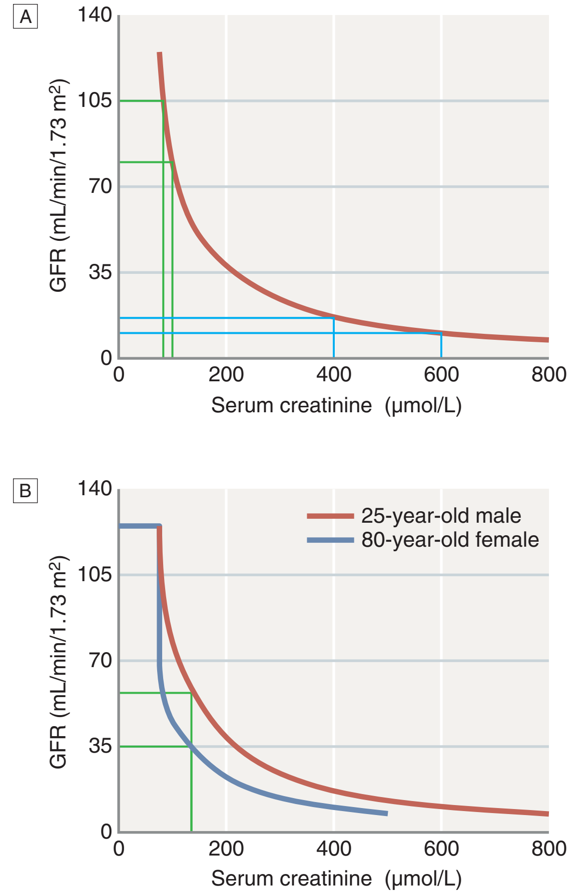

Fig. 15.2 Serum creatinine and the glomerular filtration rate (GFR). **A** The relationship between serum creatinine and estimated GFR (eGFR) is non-linear; small increases above the normal range (e.g. 80–100 μmol/L; green lines) can therefore indicate a substantial decline in renal function (e.g. 105–80 mL/min/1.73 m^2; conversely, in the high range, large changes in creatinine (e.g. 400–600 μmol/L; blue lines) can occur with only small declines in renal function (e.g. 20–15 mL/min/1.73m^2). **B** Creatinine is dependent on muscle mass; the same creatinine value may therefore reflect very different levels of renal function depending on the age and sex of the individual. To convert creatinine in mg/dL to μmol/L, multiply by 88.4.

practice by measuring serum levels of endogenously produced compounds that are excreted by the kidney. The most widely used is serum creatinine, which is produced by muscle at a constant rate, is almost completely filtered at the glomerulus, and is not reabsorbed. Although creatinine is secreted to a small degree by the proximal tubule, this is only usually significant in terms of GFR estimation in severe renal impairment, where it accounts for a larger proportion of the creatinine excreted. Accordingly, provided muscle mass remains constant, changes in serum creatinine concentrations closely reflect changes in GFR. The relationship between serum creatinine and GFR is not linear, however, and a modest elevation in serum creatinine above the normal range may therefore reflect a substantial decline in GFR (Fig. 15.2). For this reason, several methods have been developed to estimate GFR from serum creatinine measurements (see Box 15.1) but the most widely used is the Modification of Diet in Renal Disease (MDRD) equation. Routine reporting by laboratories of estimated GFR (eGFR) has increased recognition of moderate kidney damage and encouraged early deployment

i 15.2 Limitations of estimated glomerular filtration rate (eGFR)

- It is only an estimate, with wide confidence intervals (90% of patients will have eGFR within 30% of their measured GFR, and 98% within 50%)
- It is based on serum creatinine, and so may over-estimate actual GFR in patients with low muscle mass (e.g. those with cachexia, amputees) and under-estimate actual GFR in individuals taking creatine supplements (creatinine is a metabolite of creatine) or trimethoprim (inhibits secretion of creatinine)
- Creatinine level must be stable over days; eGFR is not valid in assessing acute kidney injury
- It tends to under-estimate normal or near-normal function, so slightly low values should not be over-interpreted
- In the elderly, who constitute the majority of those with low eGFR, there is controversy about categorising people as having chronic kidney disease (Box 15.3) on the basis of eGFR alone, particularly at stage 3A, since there is little evidence of adverse outcomes when eGFR is >45 mL/min/1.73 m^2 unless there is also proteinuria
- eGFR is not valid in under-18s or during pregnancy
- Ethnicity is not taken into account in routine laboratory reporting; the laboratory eGFR value should therefore be multiplied by 1.21 for black people
- Few patients will understand eGFR in terms of mL/min/1.73 m^2; it may therefore be helpful to assume that a GFR of 100 mL/min/1.73 m^2 is approximately normal and to discuss eGFR values in terms of a percentage of normal, e.g. 25 mL/min/1.73 m^2 = 25% of normal kidney function

15

of protective therapies; however, some limitations remain (Boxes 15.2 and 15.3). In particular, the MDRD formula is based on the serum creatinine value and so is heavily influenced by muscle mass; eGFR may therefore be misleading in individuals whose muscle bulk is outside the normal range for their sex and age. Measurement of other endogenous metabolites, such as cystatin C, may provide a more accurate estimate of GFR in this setting; this test, however, is not yet widely available in routine clinical practice.

Direct measurement of creatinine clearance by collecting a 24-hour urine sample and relating serum creatinine levels to urinary creatinine excretion (see Box 15.1) is now less commonly performed due to the difficulty in obtaining accurate 24-hour urine collections. It may still have a role in assessing renal function in patients at extremes of muscle mass, where the creatinine-based equations perform poorly.

Urine investigations

Screening for the presence of blood (p. 391), protein (p. 392), glucose, ketones, nitrates and leucocytes, and assessment of urinary pH and osmolality can be achieved by dipstick testing. The presence of leucocytes and nitrites in urine is indicative of renal tract infection. Urine pH can provide diagnostic information in the assessment of renal tubular acidosis (p. 365).

Urine microscopy (Fig. 15.3) may detect dysmorphic erythrocytes, which suggest the presence of nephritis or red cell casts, indicative of glomerular disease. White cell casts are strongly suggestive of pyelonephritis. Microscopy may also detect the presence of bacteria in those with urinary infection and crystals in patients with renal stone disease. It should be noted that calcium oxalate and urate crystals can sometimes be found in normal urine that has been left to stand, due to crystal formation ex vivo.

15.3 Stages of chronic kidney disease (CKD)

Stage[1]	Definition[2]	Description	Prevalence[4]	Clinical presentation[5]
1	Kidney damage[3] with normal or high GFR (>90)	Normal function	3.5%	Asymptomatic
2	Kidney damage and GFR 60–89	Mild CKD	3.9%	Asymptomatic
3A 3B	GFR 45–59 GFR 30–44	Mild to moderate CKD Moderate to severe CKD	7.6% (3A and 3B combined)	Usually asymptomatic Anaemia in some patients at 3B Most are non-progressive or progress very slowly
4	GFR 15–29	Severe CKD	0.4%	First symptoms often at GFR <20 Electrolyte problems likely as GFR falls
5	GFR <15 or on dialysis	Kidney failure	0.1%	Significant symptoms and complications usually present Dialysis initiation varies but usually at GFR <10

[1]Stages of CKD 1–5 were originally defined by the US National Kidney Foundation Kidney Disease Quality Outcomes Initiative 2002. In the 2013 Kidney Disease Outcomes Quality Initiative (K/DOQI) CKD guideline update, the suffices A1, A2 and A3 are recommended, indicating the presence of albuminuria of <30, 30–300 and >300 mg/24 hrs respectively, in view of the prognostic importance of albuminuria. [2]Two GFR values 3 months apart are required to assign a stage. All GFR values are in mL/min/1.73 m^2. [3]Kidney damage means pathological abnormalities or markers of damage, including abnormalities in urine tests or imaging studies. [4]From Hill NR, Fatoba ST, Oke JL et al. Global prevalence of chronic kidney disease – a systematic review and meta-analysis. PLoS One 2016; 11:e0158765. [5]For further information, see page 415.

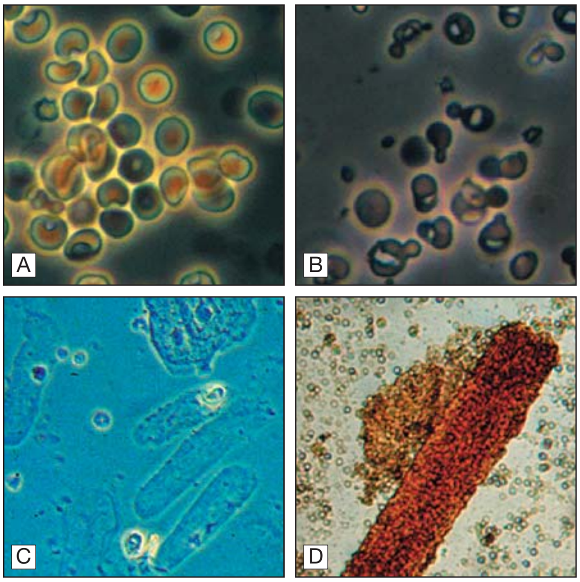

Fig. 15.3 Urine microscopy. A Erythrocytes due to bleeding from lower in the urinary tract (×400). B Dysmorphic erythrocytes due to glomerular inflammation (×400). C Hyaline casts in normal urine. D Erythrocytes and a red cell cast in glomerulonephritis (×100). Panels A–C are phase contrast images; D is a bright field image. *(A, B) Courtesy of Dr G.M. Iadorola and Dr F. Quarello, B. Bosco Hospital, Turin (from www.sin-italia.org/imago/sediment/sed.htm).*

Urine collection over a 24-hour period may be performed to measure excretion of solutes, such as calcium, oxalate and urate, in patients with recurrent renal stone disease (p. 431). Proteinuria can also be measured on 24-hour collections but is usually now quantified by protein/creatinine ratio on spot urine samples.

Other dynamic tests of tubular function, including concentrating ability (p. 688), ability to excrete a water load (p. 357) and ability to excrete acid (p. 415), and calculation of fractional calcium, phosphate or sodium excretion, are valuable in some circumstances but are usually performed in very specific contexts.

The fractional excretion of these ions can be calculated by the general formula: 100×(urine concentration of analyte×serum creatinine) / (serum concentration of analyte×urinary creatinine). Calculation of fractional excretion of sodium (FENa) can help in the setting of acute kidney injury (AKI) to differentiate volume depletion, when the tubules are avidly conserving sodium (FENa typically <1.0%), from acute tubular necrosis, when the tubules are damaged and are less able to conserve sodium (FENa typically >1.0%). In clinical practice this is seldom required.

Blood tests

Haematology

A normochromic normocytic anaemia is common in CKD and is due in part to deficiency of erythropoietin and bone marrow suppression secondary to toxins retained in CKD. Other causes of anaemia include iron deficiency from urinary tract bleeding, and haemolytic anaemia secondary to disorders such as haemolytic uraemic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP). Other abnormalities may be observed that reflect underlying disease processes, such as neutrophilia and raised erythrocyte sedimentation rate (ESR) in vasculitis or sepsis, and lymphopenia and raised ESR in systemic lupus erythematosus (SLE). Fragmented red cells on blood film and low platelets may be observed in thrombotic microangiopathies such as HUS/TTP and malignant hypertension. Pancytopenia may occur in SLE or bone marrow suppression due to myeloma.

Biochemistry

Abnormalities of routine biochemistry are common in renal disease. Serum levels of creatinine may be raised, reflecting reduced GFR (see above), as may serum potassium. Serum levels of urea are often increased in kidney disease but this analyte has limited value as a measure of GFR since levels increase with protein intake, following gastrointestinal haemorrhage and in catabolic states. Conversely, urea levels may be reduced in patients with chronic liver disease or anorexia and in malnourished patients, independently of changes in renal function. In the absence of the other causes mentioned above, an elevated urea:creatinine

ratio is indicative of volume depletion and pre-renal failure. Serum calcium tends to be reduced and phosphate increased in CKD, in association with high parathyroid hormone (PTH) levels caused by reduced production of 1,25-dihydroxyvitamin D (1,25(OH)$_2$D) by the kidney (secondary hyperparathyroidism). In some patients, this may be accompanied by raised serum alkaline phosphatase levels, which are indicative of renal osteodystrophy. Serum bicarbonate may be low in renal failure and in renal tubular acidosis. Serum albumin may be low in liver disease, as a negative acute phase response or due to malnutrition/malabsorption, but if it is a new finding it should prompt urinalysis to exclude nephrotic syndrome. Other biochemical abnormalities may be observed that reflect underlying disease processes, such as raised glucose and HbA$_{1c}$ levels in diabetes mellitus (p. 726) and raised levels of C-reactive protein (CRP) in sepsis and vasculitis.

Immunology

Antinuclear antibodies, antibodies to extractable nuclear antigens and anti-double-stranded DNA antibodies may be detected in patients with renal disease secondary to SLE (p. 1034). Antineutrophil cytoplasmic antibodies (ANCAs) may be detected in patients with glomerulonephritis secondary to systemic vasculitis (p. 1040), as may antibodies to GBM in patients with Goodpasture's syndrome (p. 401), and low levels of complement may be observed in a number of kidney diseases (see Box 15.17, p. 401).

Imaging

Ultrasound

Renal ultrasound is a valuable non-invasive technique that may be performed to assess renal size and to investigate patients who are suspected of having obstruction of the urinary tract (Fig. 15.4), renal tumours, cysts or stones. Ultrasound can also be used to provide images of the prostate gland and bladder, and to estimate the completeness of emptying in patients with suspected bladder outflow obstruction. In addition, it can reveal other abdominal, pelvic and retroperitoneal pathology. Ultrasonography may show increased signal in the renal cortex with loss of distinction between cortex and medulla, which is characteristic of CKD. Doppler imaging can be used to study blood flow in extrarenal and larger intrarenal vessels, and to assess the resistivity index (peak systolic velocity – end-diastolic velocity/peak systolic velocity in the intrarenal arteries), which may be elevated (>0.7) in various diseases, including acute tubular necrosis and rejection of a renal transplant. However, renal ultrasound is operator-dependent and the results are often less clear in obese patients.

Computed tomography

Computed tomography urography (CTU) is used to evaluate cysts and mass lesions in the kidney or filling defects within the collecting systems. It usually entails an initial scan without contrast medium, and subsequent scans following injection of contrast to obtain a nephrogram image and images during the excretory phases. CTU has largely replaced the previous gold-standard investigation of intravenous urography (IVU) for investigation of the upper urinary tract, having the advantage of providing complete staging information and details of surrounding organs. Contrast enhancement is particularly useful for characterising mass lesions within the kidney and differentiating benign from malignant lesions (see Fig. 15.32A, p. 435). CT without contrast gives clear definition of retroperitoneal anatomy regardless of obesity and is superior to ultrasound in this respect. Non-contrast CT of kidneys, ureters and bladder (CTKUB) is the method of choice for demonstrating stones within the kidney or ureter (see Fig. 15.29, p. 432). For investigation of patients with renal trauma, a triple-phase CT scan with a delayed phase, to assess the integrity of the collecting system, is performed. Drawbacks of contrast-enhanced CT scans include the fact that relatively large doses of contrast medium are required, which can cause renal dysfunction, and that the radiation dose is significant (Box 15.4).

Magnetic resonance imaging

Magnetic resonance imaging (MRI) offers excellent resolution and gives good distinction between different tissue types (see Fig. 15.15, p. 406). It is very useful for local staging of prostate, bladder and penile cancers. Magnetic resonance angiography (MRA) provides an alternative to CT for imaging renal vessels but involves administration of gadolinium-based contrast media, which may carry risks for patients with impaired renal function (Box 15.4). Whilst MRA gives good images of the main renal vessels, stenosis of small branch arteries may be missed.

Renal arteriography

Renal arteriography involves taking X-rays following an injection of contrast medium directly into the renal artery. The main indication is to investigate renal artery stenosis (p. 406) or haemorrhage following renal trauma. Renal angiography can often be combined with therapeutic balloon dilatation or stenting of the renal artery. It can be used to occlude bleeding vessels and arteriovenous fistulae by the insertion of thin platinum wires (coils). These curl up within the vessel and promote thrombosis, thereby securing haemostasis.

i 15.4 Renal complications of radiological investigations

Contrast nephrotoxicity

- Acute deterioration in renal function commencing <48 hrs after administration of IV radiographic contrast media

Risk factors
- Pre-existing renal impairment
- Use of high-osmolality, ionic contrast media and repetitive dosing in short time periods
- Diabetes mellitus
- Myeloma

Prevention
- Provide hydration with free oral fluids plus IV isotonic saline 500 mL, then 250 mL/hr during procedure
- Avoid nephrotoxic drugs; withhold non-steroidal anti-inflammatory drugs (NSAIDs). Omit metformin for 48 hrs after the procedure, in case renal impairment occurs
- *N*-acetylcysteine may provide some protection but data are conflicting
- If the risks are high, consider alternative methods of imaging

Cholesterol atheroembolism

- Typically follows days to weeks after intra-arterial investigations or interventions (p. 409)

Nephrogenic sclerosing fibrosis after MRI contrast agents

- Chronic progressive sclerosis of skin, deeper tissues and other organs, associated with gadolinium-based contrast agents
- Only reported in patients with renal impairment, typically on dialysis or with GFR <15 mL/min/1.73 m^2, but caution is advised in patients with GFR <30 mL/min/1.73 m^2

Pyelography

Pyelography involves direct injection of contrast medium into the collecting system from above (antegrade) or below (retrograde). It offers the best views of the collecting system and upper tract, and is often used to identify the cause of urinary tract obstruction (p. 391). Antegrade pyelography requires the insertion of a fine needle into the pelvicalyceal system under ultrasound or radiographic control. In addition to visualising the cause of obstruction, percutaneous nephrostomy drainage can be established and often stents can be passed through any obstruction. Retrograde pyelography can be performed by inserting a ureteric catheter into the ureteric orifice at cystoscopy (Fig. 15.5) and again a stent can be inserted to bypass any obstruction.

Radionuclide studies

These are functional studies requiring the injection of gamma ray-emitting radiopharmaceuticals that are taken up and excreted by the kidney, a process that can be monitored by an external gamma camera.

Dynamic radionuclide studies are performed with mercaptoacetyltriglycine labelled with technetium (^{99m}Tc-MAG3), which is filtered by the glomerulus and excreted into the urine. Imaging following ^{99m}Tc-MAG3 injection can provide valuable information about the perfusion of each kidney but is not a reliable method for identifying renal artery stenosis. In patients with significant obstruction of the outflow tract, ^{99m}Tc-MAG3 persists in the renal pelvis and a loop diuretic fails to accelerate its disappearance. This can be useful in determining the functional significance of an equivocally obstructed collecting system without undertaking pyelography.

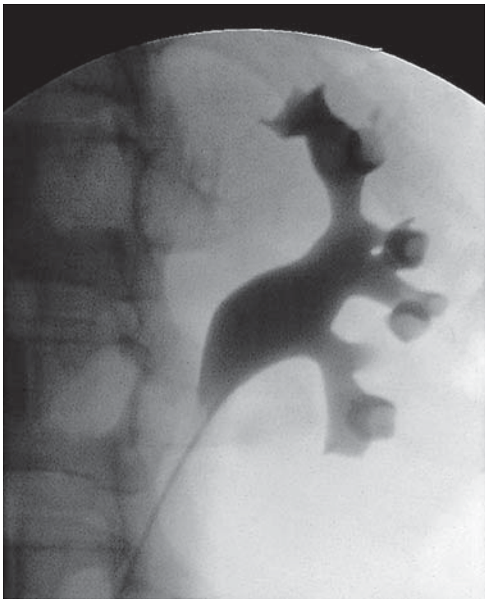

Fig. 15.5 Retrograde pyelography. The best views of the normal collecting system are shown by pyelography. A catheter has been passed into the left renal pelvis at cystoscopy. The anemone-like calyces are sharp-edged and normal. *Courtesy of Dr A.P. Bayliss and Dr P. Thorpe, Aberdeen Royal Infirmary.*

Formal measurements of GFR can be made by radionuclide studies following the injection of diethylenetriamine penta-acetic acid (^{99m}Tc-DPTA).

Static radionuclide studies are performed with dimercaptosuccinic acid labelled with technetium (^{99m}Tc-DMSA), which is taken up by proximal tubular cells. Following intravenous injection, images of the renal cortex are obtained that show the shape, size and relative function of each kidney (Fig. 15.6). This is a sensitive method for demonstrating cortical scarring in reflux nephropathy and a way of assessing the individual function of each kidney.

Radionuclide bone scanning following the injection of methylene diphosphonate (^{99m}Tc-MDP) is indicated to assess the presence and extent of bone metastases in men with advanced prostate cancer (p. 438).

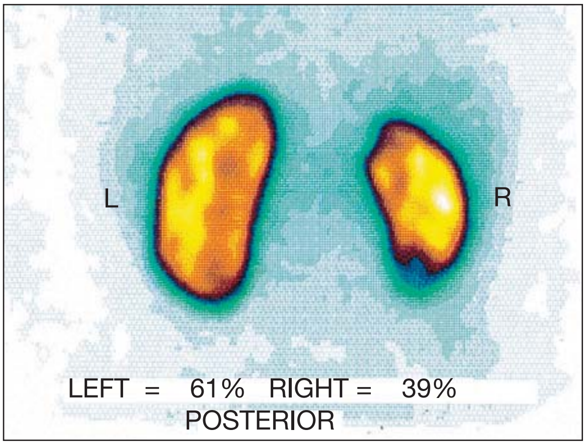

Fig. 15.6 DMSA radionuclide scan. A posterior view is shown of a normal left kidney and a small right kidney (with evidence of cortical scarring at upper and lower poles) that contributes only 39% of total renal function.

i 15.5 Renal biopsy

Indications

- Acute kidney injury and chronic kidney disease of uncertain aetiology
- Nephrotic syndrome or glomerular proteinuria (protein:creatinine ratio > 100 mg/mol) in adults
- Nephrotic syndrome in children that has atypical features or is not responding to treatment
- Nephritic syndrome
- Renal transplant dysfunction
- Rarely performed for isolated haematuria or isolated low-grade proteinuria in the absence of impaired renal function or evidence of a multisystem disorder

Contraindications

- Disordered coagulation or thrombocytopenia. Aspirin and other antiplatelet agents increase bleeding risk
- Uncontrolled hypertension
- Kidneys < 60% predicted size
- Solitary kidney* (except transplants)

Complications

- Pain, usually mild
- Bleeding into urine, usually minor but may produce clot colic and obstruction
- Bleeding around the kidney, occasionally massive and requiring angiography with intervention, or surgery
- Arteriovenous fistula, rarely significant clinically

*Relative contraindication.

Renal biopsy

Renal biopsy is used to establish the diagnosis and severity of renal disease in order to judge the prognosis and need for treatment (Box 15.5). The procedure is performed transcutaneously under local anaesthetic with ultrasound or contrast radiography guidance to ensure accurate needle placement into a renal pole. Light microscopy, electron microscopy and immunohistological assessment of the specimen may all be required.

Presenting problems in renal and urinary tract disease

Oliguria/anuria

Oliguria is defined as being present when less than 400 mL of urine is passed per day, whereas anuria is deemed to exist when less than 100 mL of urine is passed per day.

The volume of urine produced represents a balance between the amount of fluid that is filtered at the glomerulus and that reabsorbed by the renal tubules. When GFR is low, urine volumes may still be normal if tubular reabsorption is also reduced; hence urine volume alone is a poor indicator of the severity of kidney disease. Oliguria and anuria may be caused by a reduction in urine production, as in pre-renal AKI, when GFR is reduced and tubular homeostatic mechanisms increase reabsorption to conserve salt and water. A high solute load or associated tubular dysfunction may, however, produce normal or high urine volumes in such cases until the pre-renal insult becomes severe and GFR is markedly reduced, such as occurs in diabetic ketoacidosis with marked glycosuria. Urine volumes are variable in AKI due to intrinsic renal disease, but a rapid decline in urine volume may be observed. Anuria should prompt a differential including complete urinary obstruction, severe vascular compromise or rapidly progressive glomerulonephritis (Box 15.6).

i 15.6 Causes of anuria (< 100 mL urine output per day)

Condition	Examples
Urinary obstruction (complete)	Urinary retention due to prostatic enlargement, urethral stenosis, bladder tumour Bilateral ureteric obstruction due to retroperitoneal fibrosis, cancer, radiation injury Bilateral renal stones (usually staghorn calculi) Massive crystalluria obstruction of tubules (rare)
Lack of renal perfusion (bilateral)	Aortic dissection involving renal arteries Severe acute tubular necrosis Severe functional hypoperfusion (cardiorenal, hepatorenal)
Rapidly progressive glomerulonephritis	Anti-glomerular basement membrane disease, severe antineutrophil cytoplasmic antibody (ANCA) vasculitis (100% glomerular crescents on biopsy)

Obstruction of the renal tract can produce oliguria and anuria, but to do so, obstruction must be complete and occur distal to the bladder neck, be bilateral, or be unilateral on the side of a single functioning kidney. Unilateral ureteric obstruction may not lead to any noticeable reduction in urine output. The presence of pain that is exacerbated by a fluid load suggests an acute obstruction of the renal tract, and its characteristics may be of value in reaching a diagnosis. Obstruction at the bladder neck is associated with lower midline abdominal discomfort, whereas ureteric obstruction typically presents as loin pain radiating to the groin and at the level of the renal pelvis may present as flank pain. Chronic obstruction rarely produces pain but may give rise to a dull ache. Urethral strictures should be considered as a possible cause, especially in patients with a history of instrumentation of the renal tract.

The presence of bladder enlargement in a middle-aged or elderly man suggests benign or malignant enlargement of the prostate gland as a potential cause of oliguria or anuria (pp. 437 and 438). It is important to note that many cases of acute urinary retention are observed after general anaesthesia, particularly in patients with pre-existing prostatic enlargement. Partial obstruction can be associated with a normal or even high urine volume due to chronic tubular injury, which causes loss of tubular concentrating ability. Management of oliguria and anuria should be directed at the underlying cause and is outlined later in the chapter (p. 413).

Haematuria

Healthy individuals may have occasional red blood cells in the urine (up to 12 500 cells/mL), but the presence of visible (macroscopic) haematuria or non-visible haematuria (microscopic, only detectable on dipstick testing) is indicative of significant bleeding from somewhere in the urinary tract (Fig. 15.7). Once infection, menstruation and causes of a positive urinary dipstick in the absence of red cells (haemoglobinuria/myoglobinuria) have

15

15.7 Interpretation of non-visible haematuria

Dipstick test positive	Urine microscopy	Suggested cause
Haematuria	White blood cells	Infection
	Abnormal epithelial cells	Tumour
	Red cell casts Dysmorphic erythrocytes (phase contrast microscopy)	Glomerular bleeding*
Haemoglobinuria	No red cells	Intravascular haemolysis
Myoglobinuria (brown urine)	No red cells	Rhabdomyolysis

*Glomerular bleeding implies that the GBM is ruptured. It can occur physiologically following very strenuous exertion but usually indicates intrinsic renal disease and is an important feature of the nephritic syndrome.

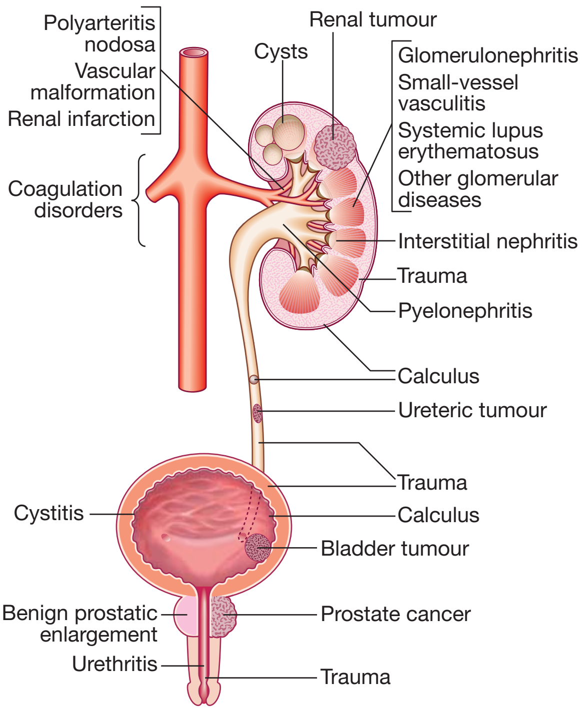

Fig. 15.7 Causes of haematuria.

been excluded (Box 15.7), both visible and persistent non-visible haematuria require investigation, as they may be caused by malignancy or indicate glomerulonephritis.

Visible haematuria is most likely to be caused by tumour, which can affect any part of the urogenital tract (Fig. 15.7), and patients with visible haematuria must therefore be referred to urology for imaging (ultrasound or CT scan) and cystoscopy (Fig. 15.8). Other common causes of visible haematuria are urine infection and stones. Visible haematuria may also be encountered in patients with IgA nephropathy, typically following an upper respiratory tract infection.

Non-visible haematuria may also indicate an underlying tumour, and all patients over 40 years old with persistent (detected on at least 2 of 3 consecutive dipstick tests) non-visible haematuria should therefore undergo imaging and cystoscopy. In younger patients, an underlying tumour is much less likely, and if a

15.8 Investigation of nephritic syndrome

Cause	Investigations
Rapidly progressive glomerulonephritis (RPGN)	
Post-infectious glomerulonephritis	ASOT, C3, C4
Anti-GBM disease	Anti-GBM antibody
Small-vessel vasculitis	p-ANCA, c-ANCA
Lupus nephritis	ANA, dsDNA, C3, C4
Mild glomerulonephritic presentation	
IgA nephropathy	Serum IgA (polyclonal rise in 50% of patients)
Mesangioproliferative glomerulonephritis	C3, C4, hepatitis B,C + HIV serology, ANA, dsDNA, immunoglobulins, PPE
Alport's syndrome*	Genetic screening, hearing test

*Not a glomerulonephritis but may present in a similar manner with haematuria, variable proteinuria, hypertension and slowly declining renal function.
(ANA = antinuclear antibody; ANCA = antineutrophil cytoplasmic antibody; ASOT = anti-streptolysin O titre; C3, C4 = complement proteins 3, 4; dsDNA = double-stranded DNA; GBM = glomerular basement membrane; HIV = human immunodeficiency virus; IgA = immunoglobulin A; PPE = plasma protein electrophoresis)

glomerular cause is not suspected (see below), it may be appropriate to manage them by periodic observation in primary care, although occasionally these individuals develop significant overt renal disease during follow-up.

Glomerular bleeding occurs when inflammatory, destructive or degenerative processes disrupt the GBM, permitting passage of red blood cells into the urine. A characteristic feature of glomerular bleeding is an 'active urinary sediment' (the presence of dysmorphic red blood cells or red cell casts on microscopy); this is not always present, however. Patients with visible and non-visible haematuria should also be assessed for hypertension, proteinuria, reduced/declining renal function, family history of renal disease or features of systemic disease (Fig. 15.8). The presence of any of these features raises the possibility of intrinsic renal pathology and warrants referral to nephrology for further investigation, including consideration of renal biopsy.

Nephritic syndrome

The nephritic syndrome is characterised by the presence of haematuria in association with hypertension, oliguria, fluid retention and reduced/declining renal function. Many patients with glomerulonephritis, particularly those with milder disease, do not exhibit all of these features; their combined presence, however, is typical of a rapidly progressive glomerulonephritis and warrants urgent investigation. In many cases, investigation will include a renal biopsy to confirm diagnosis and guide management, but less invasive investigations may also be useful (Box 15.8).

Patients with nephritic syndrome may also exhibit varying degrees of proteinuria, including nephrotic-range proteinuria; the prominence of haematuria on dipstick should, however, alert the physician to the possibility of a glomerulonephritis. Indeed, it is important to recognise that the characteristic features of nephritic syndrome and nephrotic syndrome do not always present in isolation, but should be considered to be the extreme phenotypes at either end of a spectrum of presentations (Fig. 15.9).

Proteinuria

While very small amounts of high-molecular-weight proteins and moderate amounts of low-molecular-weight proteins pass

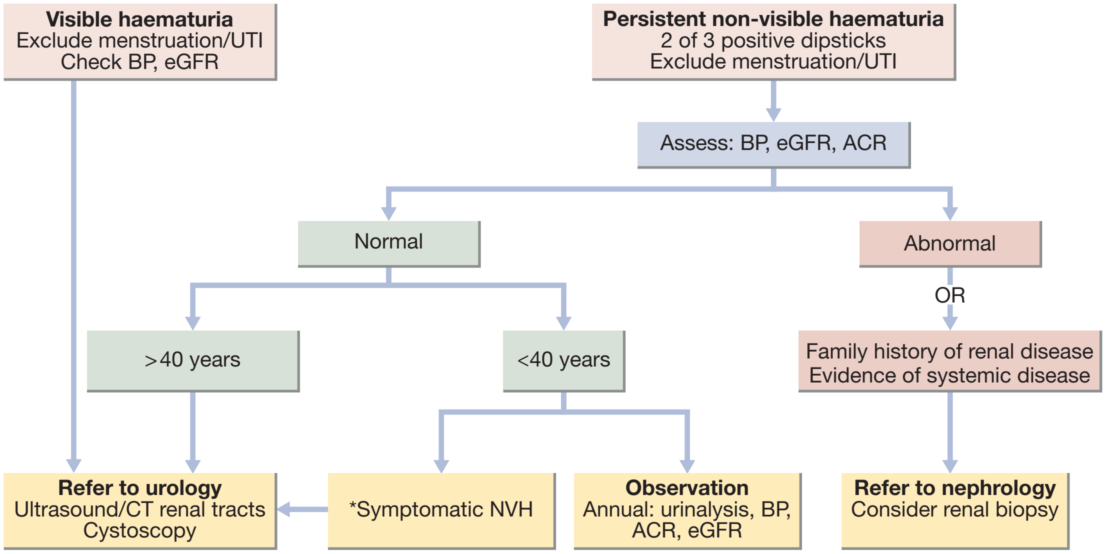

Fig. 15.8 Investigation of haematuria. *Symptomatic: lower urinary tract voiding symptoms such as hesitancy, frequency, urgency and dysuria. (ACR = albumin:creatinine ratio; BP = blood pressure; CT = computed tomography; eGFR = estimated glomerular filtration rate; NVH = non-visible haematuria; UTI = urinary tract infection)

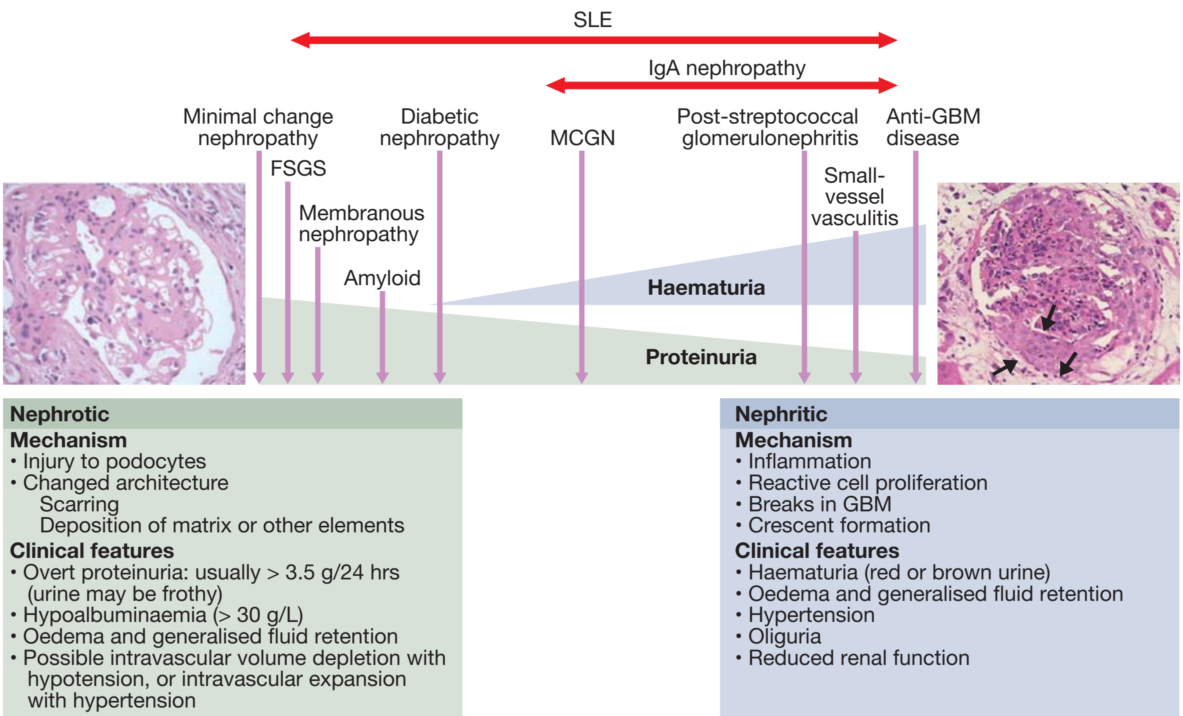

Fig. 15.9 Nephritic and nephrotic syndrome. At one extreme, specific injury to podocytes causes proteinuria and nephrotic syndrome. The histology to the left shows diabetic nephropathy. At the other end of the spectrum, inflammation leads to cell damage and proliferation, breaks form in the glomerular basement membrane (GBM) and blood leaks into urine. In its extreme form, with acute sodium retention and hypertension, such disease is labelled nephritic syndrome. The histology to the right shows a glomerulus with many extra nuclei from proliferating intrinsic cells, and influx of inflammatory cells leading to crescent formation (arrows) in response to severe post-infectious glomerulonephritis. (FSGS = focal and segmental glomerulosclerosis; IgA = immunoglobulin A; MCGN = mesangiocapillary glomerulonephritis; SLE = systemic lupus erythematosus)

through the healthy GBM, these proteins normally are completely reabsorbed by receptors on tubular cells. Hence, in healthy individuals, less than 150 mg of protein is excreted in the urine each day, much of which is derived from tubular cells. This includes Tamm–Horsfall protein (uromodulin), encoded by the *UMOD* gene that has recently been linked to tubulo-interstitial disease (see Box 15.20, p. 405). The presence of larger amounts of protein is usually indicative of significant renal disease.

Proteinuria is usually asymptomatic and is often picked up by urinalysis, although large amounts of protein may make the urine frothy. Transient proteinuria can occur after vigorous exercise, during fever, in heart failure and in people with urinary

15.9 Quantifying proteinuria in random urine samples

ACR[1]	PCR[2]	Typical dipstick results[3]	Significance
<3.5 (female) <2.5 (male)	<25	–	Normal
3.5–30	25–50	–	Moderately elevated albuminuria
30–70	50–100	+ to ++	Dipstick positive
70–300	100–350	++ to +++	Glomerular disease more likely; equivalent to >1 g/24 hrs
>300	>350	+++ to ++++	Nephrotic range: almost always glomerular disease, equivalent to > 3.5 g/24 hrs

[1]Urinary albumin (mg/L)/urine creatinine (mmol/L). [2]Urine protein (mg/L)/urine creatinine (mmol/L). (If urine creatinine is measured in mg/dL, reference values for PCR and ACR can be derived by dividing by 11.31.) [3]Dipstick results are affected by urine concentration and are occasionally weakly positive on normal samples.

tract infection. Patients should be assessed for the presence of these conditions and urine testing repeated once the potential trigger has been treated or resolved.

Testing for proteinuria is best done on an early morning sample, as some individuals exhibit orthostatic proteinuria. In these patients, typically less than 1 g/24 hrs of protein is excreted only in association with an upright posture, the first morning sample being negative. Orthostatic proteinuria is regarded as a benign disorder that does not require treatment.

Moderately elevated albuminuria (microalbuminuria)

In healthy individuals, there is virtually no urinary excretion of large-molecular-weight serum proteins, such as albumin, in contrast to modest urinary excretion of tubule-derived proteins. The presence of even moderate amounts of albuminuria (previously referred to as microalbuminuria) is therefore abnormal, and may indicate early glomerular pathology, at a time when the standard dipstick test remains negative (Box 15.9). Screening for moderately elevated albuminuria should be performed regularly in patients with diabetes, as persistently elevated levels warrant therapy with inhibitors of the renin–angiotensin–aldosterone system, even in normotensive individuals, to reduce the rate of loss of renal function (see Box 20.39, p. 758). Persistent moderately increased albuminuria has also been associated with cardiovascular mortality in patients with and without diabetes, but an explanation for this association has not yet been established.

Overt (dipstick-positive) proteinuria

Urinary dipstick testing is a valuable screening tool for the detection of proteinuria; it is only semi-quantitative, however, as it is highly dependent on the concentration of the urine. Typically, standard dipsticks test positive for protein once the urinary protein exceeds approximately 0.5 g/24 hrs; however, trace to 1+ on dipstick may be observed in very concentrated urine from individuals with no evidence of renal pathology. Hence all patients with persistent proteinuria on dipstick should have the amount of protein quantified to guide further investigations (Fig. 15.10). When more than 1 g of protein per day is being excreted, glomerular disease is likely and this is an indication for renal biopsy. Since quantification by 24-hour urine collection is often inaccurate, the protein:creatinine ratio (PCR) in a spot sample of urine is preferred. This makes an allowance for the variable degree of urinary dilution and can be used to extrapolate to 24-hour values (Box 15.9). Changes in PCR also give valuable information about the progression of renal disease and response to therapy in CKD.

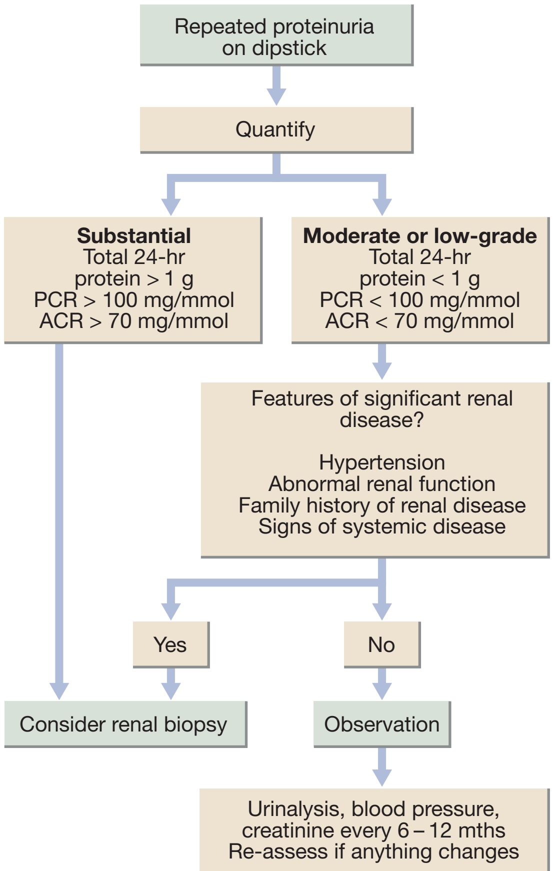

Fig. 15.10 Investigation of proteinuria. (ACR = albumin:creatinine ratio; PCR = protein:creatinine ratio.)

It is possible to measure albumin:creatinine ratio (ACR), but this requires a more expensive immunoassay and is usually reserved for situations when high sensitivity is required, such as detection of the early stages of diabetic nephropathy (p. 757).

It is sometimes helpful to identify the type of protein in the urine. Large amounts of low-molecular-weight proteins, such as β_2-microglobulin (molecular weight 12 kDa), in the urine suggest renal tubular damage and are referred to as tubular proteinuria. This rarely exceeds 1.5–2 g/24 hrs (maximum PCR 150–200 mg/mmol; see Box 15.9 for conversion of mg/mmol to mg/dL).

Free immunoglobulin light chains (molecular weight 25 kDa) are filtered freely at the glomerulus but are poorly identified by

dipstick tests. Hence, electrophoresis of the urine and specific immunodetection methods are required to detect immunoglobulin light chains, known as 'Bence Jones protein'. This may occur in AL amyloidosis (p. 81) and in B-cell dyscrasias but is particularly important as a marker for myeloma (p. 966).

Nephrotic syndrome

Nephrotic syndrome is characterised by very heavy proteinuria (>3.5 g/24 hrs), hypoalbuminaemia and oedema (see below). Blood volume may be normal, reduced or increased. Renal sodium retention is an early and universal feature; the mechanisms of this are shown in Figure 14.5 (p. 354). The diseases that cause nephrotic syndrome all affect the glomerulus (see Fig. 15.9), either directly, by damaging podocytes, or indirectly, by causing scarring or deposition of exogenous material such as amyloid into the glomerulus.

Investigation of nephrotic syndrome usually involves renal biopsy, although non-invasive tests may also be helpful in suggesting the underlying cause (Box 15.10). In children, minimal change disease is by far the most common cause of nephrotic syndrome and therefore renal biopsy is not usually required unless the patient fails to respond to high-dose glucocorticoid therapy. Similarly, most patients with diabetes presenting with nephrotic syndrome will have diabetic nephropathy, and so renal biopsy is usually not performed unless the course of the disease is atypical (rapidly increasing proteinuria or rapid decline in renal function; p. 757).

Management of nephrotic syndrome should be directed at the underlying cause. In addition, nephrotic syndrome is associated with a number of complications (Box 15.11), which may require supportive management unless the nephrosis is expected to resolve rapidly, such as in glucocorticoid-responsive minimal change disease.

15.10 Investigation of nephrotic syndrome

Cause	Typical age group	Investigations
Fulminant presentation		
Minimal change disease	Children, young adults, occasionally seen in older patients	None specific
Primary focal segmental glomerulosclerosis	Young adults	None specific
Subacute presentation		
Membranous nephropathy	Middle-aged to older patients	Hepatitis B, C + HIV serology, ANA, dsDNA
Amyloid	Older patients	Immunoglobulins, PPE, Bence Jones protein, serum free light chains
Gradual progression		
Diabetic nephropathy	Any age, but rarely <10 years from diagnosis of type 1 diabetes	Glucose, glycosylated haemoglobin

(ANA = antinuclear antibody; dsDNA = double-stranded DNA; HIV = human immunodeficiency virus; PPE = plasma protein electrophoresis)

Oedema

Oedema is caused by an excessive accumulation of fluid within the interstitial space. Clinically, this can be detected by persistence of an indentation in tissue following pressure on the affected area (pitting oedema). Pitting oedema tends to accumulate in the ankles during the day and improves overnight as the interstitial fluid is reabsorbed. Non-pitting oedema is typical of lymphatic obstruction and may also occur as the result of excessive matrix deposition in tissues: for example, in hypothyroidism (p. 639) or systemic sclerosis (p. 1037).

Clinical assessment

Dependent areas, such as the ankles and lower legs, are typically affected first but oedema can be restricted to the sacrum in bed-bound patients. With increasing severity, oedema spreads to affect the upper parts of the legs, the genitalia and abdomen. Ascites is common and often an earlier feature in children or young adults, and in liver disease. Pleural effusions are common but frank pulmonary oedema is rare. Facial oedema on waking is common. Features of intravascular volume depletion (tachycardia, postural hypotension) may occur when oedema is due to decreased

15.11 Consequences of the nephrotic syndrome and their management

Feature	Mechanism	Consequence	Management
Hypoalbuminaemia	Urinary protein losses exceed synthetic capacity of liver	Reduced oncotic pressure Oedema	Treatment of underlying cause
Avid sodium retention	Secondary hyperaldosteronism Additional poorly characterised intrarenal mechanisms	Oedema	Diuretics and a low-sodium diet*
Hypercholesterolaemia	Non-specific increase in lipoprotein synthesis by liver in response to low oncotic pressure	High rate of atherosclerosis	Statins, ezetimibe
Hypercoagulability	Relative loss of inhibitors of coagulation (antithrombin III, protein C and S) and increase in liver synthesis of procoagulant factors	Venous thromboembolism	Consideration of prophylaxis in chronic or severe nephrotic syndrome
Infection	Hypogammaglobulinaemia due to urinary loss of immunoglobulins	Pneumococcal and meningococcal infection	Consideration of vaccination

*Severe nephrotic syndrome may need very large doses of combinations of diuretics acting on different parts of the nephron (e.g. loop diuretic plus thiazide plus amiloride). In occasional patients with hypovolaemia, intravenous salt-poor albumin infusions may help to establish a diuresis, although efficacy is controversial. Over-diuresis risks secondary impairment of renal function through hypovolaemia.

15.12 Causes of oedema

Increased total extracellular fluid
- Congestive heart failure
- Renal failure
- Liver disease

High local venous pressure
- Deep venous thrombosis or venous insufficiency
- Pregnancy
- Pelvic tumour

Low plasma oncotic pressure/serum albumin
- Nephrotic syndrome
- Liver failure
- Malnutrition/malabsorption

Increased capillary permeability
- Leakage of proteins into the interstitium, reducing the osmotic pressure gradient that draws fluid into the lymphatics and blood
- Infection/inflammation
- Severe sepsis
- Calcium channel blockers

Lymphatic obstruction
- Infection: filariasis, lymphogranuloma venereum (pp. 290 and 341)
- Malignancy
- Radiation injury
- Congenital abnormality

oncotic pressure or increased capillary permeability. If oedema is localised – for example, to one ankle but not the other – then venous thrombosis, inflammation or lymphatic disease should be suspected.

Investigations

Oedema may be due to a number of causes (Box 15.12), which are usually apparent from the history and examination of the cardiovascular system and abdomen. Blood should be taken for measurement of urea and electrolytes, liver function and serum albumin, and the urine tested for protein. Further imaging of the liver, heart or kidneys may be indicated, based on history and clinical examination. Where ascites or pleural effusions occur in isolation, aspiration of fluid with measurement of protein and glucose, and microscopy for cells, will usually help to clarify the diagnosis in differentiating a transudate (typical of oedema) from an exudate (more suggestive of local pathology, p. 564).

Management

Mild oedema usually responds to elevation of the legs, compression stockings, or a thiazide or a low dose of a loop diuretic, such as furosemide or bumetanide. In nephrotic syndrome, renal failure and severe cardiac failure, very large doses of diuretics, sometimes in combination, may be required to achieve a negative sodium and fluid balance. Restriction of sodium intake and fluid intake may be required. Diuretics are not helpful in the treatment of oedema caused by venous or lymphatic obstruction or by increased capillary permeability. Specific causes of oedema, such as venous thrombosis, should be treated.

Hypertension

Hypertension is a very common feature of renal disease. Additionally, the presence of hypertension identifies a population at risk of developing CKD and current recommendations are that hypertensive patients should have renal function checked annually. Control of hypertension is very important in patients with renal impairment because of its close relationship with further decline of renal function (p. 420) and because of the exaggerated cardiovascular risk associated with CKD. Pathophysiology and management are discussed on pages 509 and 510.

Loin pain

Loin pain is often caused by musculoskeletal disease but can be a manifestation of renal tract disease; in the latter case, it may arise from renal stones, ureteric stones, renal tumours, acute pyelonephritis and urinary tract obstruction. Acute loin pain radiating anteriorly and often to the groin is termed renal colic. When combined with haematuria, this is typical of ureteric obstruction due to calculi (p. 431). Precipitation of loin pain by a large fluid intake (Dietl's crisis) suggests upper urinary tract obstruction caused by a congenital abnormality of the pelvi-ureteric junction (p. 433).

Dysuria

Dysuria refers to painful urination, often described as burning, scalding or stinging, and commonly accompanied by suprapubic pain. It is often associated with frequency of micturition and a feeling of incomplete emptying of the bladder. By far the most common cause is urinary tract infection, as described on page 426. Other diagnoses that need to be considered in patients with dysuria include sexually transmitted infections (p. 329) and bladder stones (p. 431).

Frequency

Frequency describes daytime micturition more often than a patient would expect. It may be a consequence of polyuria, when urine volume is normal or high, but is also found in patients with dysuria and prostatic diseases, when the urine volume is normal.

Polyuria

Polyuria is defined as a urine volume in excess of 3 L/24 hrs. Various underlying conditions, both renal and extrarenal, may be responsible, as outlined in Box 15.13.

Investigation of polyuria includes measurement of urea, creatinine and electrolytes, glucose, calcium and albumin. A 24-hour urine collection may be helpful to confirm the severity of polyuria. The presence of nocturnal polyuria suggests a

15.13 Causes of polyuria

- Excess fluid intake
- Osmotic diuresis: hyperglycaemia, hypercalcaemia
- Cranial diabetes insipidus
- Nephrogenic diabetes insipidus:
  - Rare inherited mutations in vasopressin receptor or aquaporin 2 genes
  - Lithium
  - Diuretics
  - Interstitial nephritis
  - Hypokalaemia
  - Hypercalcaemia

pathological cause. Investigation and management of suspected diabetes insipidus are described on page 688.

Nocturia

Nocturia is defined as waking up at night to void urine. It may be a consequence of polyuria but may also result from increased fluid intake or diuretic use in the late evening (including caffeine). Nocturia also occurs in CKD, and in prostatic enlargement when it is associated with poor stream, hesitancy, incomplete bladder emptying, terminal dribbling and urinary frequency due to partial urethral obstruction (p. 437). Nocturia may also occur due to sleep disturbance without any functional abnormalities of the urinary tract.

Urinary incontinence

Urinary incontinence is defined as any involuntary leakage of urine. It may occur in patients with a normal urinary tract, as the result of dementia or poor mobility, or transiently during an acute illness or hospitalisation, especially in older people (see Box 15.54, p. 436). The pathophysiology, investigation and management of urinary incontinence are discussed in detail later in the chapter (p. 436).

Glomerular diseases

Glomerular diseases account for a significant proportion of acute and chronic kidney disease. Most patients with glomerular disease do not present acutely and are asymptomatic until abnormalities are detected on routine screening of blood or urine samples.

There are many causes of glomerular damage, including immunological injury, inherited diseases such as Alport's syndrome (p. 403), metabolic diseases such as diabetes mellitus (p. 757), and deposition of abnormal proteins such as amyloid in the glomeruli (p. 81). The glomerular cell types that may be the target of injury are shown in Figure 15.11. Proteinuria is the hallmark of glomerular disease; however, the response of the glomerulus to injury and hence the predominant clinical features vary according to the nature of the insult, ranging from fulminant nephrotic syndrome to rapidly progressive glomerulonephritis (see Fig. 15.9). Several prognostic indicators are common to all causes of glomerulonephritis (Box 15.14) and may be helpful in assessing the need for immunosuppressive therapy.

Glomerulonephritis

While glomerulonephritis literally means 'inflammation of glomeruli', the term is often used more broadly to describe all types of glomerular disease, even though some of these (e.g. minimal change nephropathy) are not associated with inflammation.

i 15.14 Poor prognostic indicators in glomerular disease

- Male sex
- Hypertension
- Persistent and severe proteinuria
- Elevated creatinine at time of presentation
- Rapid rate of decline in renal function
- Tubulo-interstitial fibrosis observed on renal biopsy

Most types of glomerulonephritis are immunologically mediated and several respond to immunosuppressive drugs. Deposition of antibody occurs in many types of glomerulonephritis and testing for circulating or glomerular deposition of antibodies may aid diagnosis (see Fig. 15.11 and Boxes 15.8 and 15.10). In small-vessel vasculitis, no glomerular antibody deposition is observed (pauci-immune), but the antibodies may be indirectly pathogenic by activating neutrophils to promote endothelial injury (Fig. 15.11).

Glomerulonephritis is generally classified in terms of the histopathological appearances, as summarised in Box 15.15 and Figure 15.12. Many non-specialists find the terminology used in describing glomerulonephritis to be confusing; some definitions are provided in Box 15.16. It is important to stress that the histological appearance rarely confirms a specific renal disease but rather suggests a limited range of diagnoses, which may be confirmed by further investigation. Conversely, some diseases, such as lupus, are associated with more than one histological pattern of injury. The most common histological subtypes may be categorised according to their typical clinical presentation, as discussed below. Genetic disorders associated with glomerular disease are described later (p. 403).

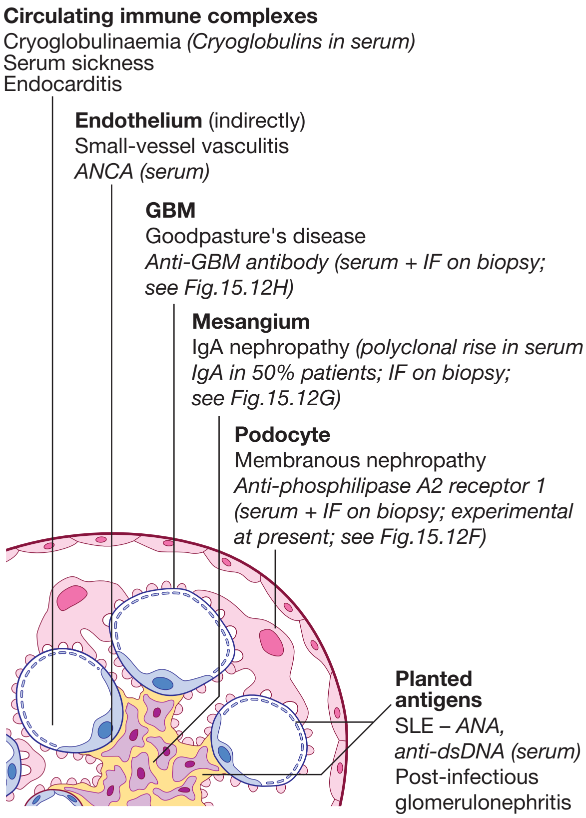

Fig. 15.11 Glomerulonephritis associated with antibody production. Antibodies and antigen–antibody (immune) complexes may target or be deposited in specific components of the glomerulus, resulting in different patterns of histological injury and clinical presentation. Testing for antibody deposition in the glomerulus by immunofluorescence (IF) on renal biopsy tissue or for antibodies in the serum may aid diagnosis. Diagnostic tests are shown in italics. (ANA = antinuclear antibody; ANCA = antineutrophil cytoplasmic antibody; dsDNA = double-stranded DNA; GBM = glomerular basement membrane; IgA = immunoglobulin A; SLE = systemic lupus erythematosus)

Diseases typically presenting with nephrotic syndrome

In these diseases, the injury is focused on the podocyte and there is little histological evidence of inflammation or cell proliferation in the glomerulus (non-proliferative, Fig. 15.12). Minimal change and primary focal segmental glomerulosclerosis (FSGS) typically present with fulminant nephrotic syndrome, whereas in membranous nephropathy and secondary FSGS, the nephrosis tends to be more indolent in nature. Other causes of nephrotic syndrome due to systemic disease are discussed elsewhere, including diabetic nephropathy (p. 757) and amyloid (p. 81).

Minimal change nephropathy

Minimal change disease occurs at all ages but accounts for most cases of nephrotic syndrome (see Box 15.15) in children and about one-quarter of adult cases. It is caused by reversible dysfunction of podocytes. On light microscopy, the glomeruli appear normal (Fig. 15.12A), but fusion of podocyte foot processes is observed on electron microscopy. The presentation is with nephrotic syndrome, which typically is severe; it remits

15.15 Glomerulonephritis categorised by clinical presentation and histological classification

Histology	Immune deposits	Pathogenesis	Associations	Comments
Nephrotic presentation				
Minimal change				
Normal, except on electron microscopy, where fusion of podocyte foot processes is observed (non-specific finding)	None	Unknown; probable circulating factor promoting podocyte injury Some cases are genetic (p. 403)	Atopy Drugs, most commonly NSAIDs Haematological malignancies	Acute and often severe nephrotic syndrome Good response to glucocorticoids Dominant cause of idiopathic nephrotic syndrome in childhood
Focal segmental glomerulosclerosis (FSGS)				
Segmental scars in some glomeruli No acute inflammation Podocyte foot process fusion seen in primary FSGS	Non-specific trapping in focal scars	Unknown; circulating factors may increase glomerular permeability Injury to podocytes may be common feature Some cases are genetic (p. 403)	*APOL1* variant in people of West African descent Causes of secondary FSGS include: Healing of previous local glomerular injury HIV infection Heroin misuse Morbid obesity Chronic hypertension	*Primary FSGS* presents as idiopathic nephrotic syndrome but is less responsive to treatment than minimal change; may progress to renal impairment, and can recur after transplantation *Secondary FSGS* presents with variable proteinuria and outcome
Membranous nephropathy				
Thickening of GBM Progressing to increased matrix deposition and glomerulosclerosis	Granular subepithelial IgG	Antibodies to a podocyte surface antigen (commonly phospholipase A_2 receptor 1), with complement-dependent podocyte injury	*HLA-DQA1* (for idiopathic) Drugs: Penicillamine, NSAIDs, heavy metals Hepatitis B virus Malignancy Lupus[1]	Common cause of adult idiopathic nephrotic syndrome One-third progress, one-third spontaneously remit and one-third remain stable; may respond to glucocorticoids and immunosuppressants
Mild glomerulonephritic presentation				
IgA nephropathy				
Increased mesangial matrix and cells Focal segmental nephritis in acute disease	Mesangial IgA (and C3)	Unknown Mucosal infections (e.g. helminths) may be involved	Usually idiopathic, flares triggered by upper respiratory infection Liver disease Coeliac disease	Common disease with range of presentations, usually including haematuria and hypertension Henoch–Schönlein purpura is an acute IgA variant common in children
Mesangiocapillary glomerulonephritis				
Immunoglobulin type	Immunoglobulins	Deposition of circulating immune complexes or ‘planted’ antigens	Infections, autoimmunity or monoclonal gammopathies	Most common pattern found in association with subacute bacterial infection, but also with cryoglobulinaemia ± hepatitis C virus, and others
Complement type	Complement components	Complement abnormalities, inherited or acquired Dense deposit disease is associated with abnormal activation of alternative complement pathway	Complement gene mutations C3 nephritic factor and partial lipodystrophy	In dense deposit disease, intramembranous deposits No proven treatments

Continued

15.15 Glomerulonephritis categorised by clinical presentation and histological classification – continued

Histology	Immune deposits	Pathogenesis	Associations	Comments
Rapidly progressive glomerulonephritis presentation				
Focal necrotising glomerulonephritis				
Segmental inflammation and/or necrosis in some glomeruli ± crescent formation	Variable according to cause but typically negative (or 'pauci-immune')	Small-vessel vasculitis, often ANCA-mediated	Primary or secondary small-vessel vasculitis	Often occurs in systemic disease Responds to treatment with glucocorticoids and immunosuppressants
Diffuse proliferative glomerulonephritis[2]				
Infection-related diffuse proliferative glomerulonephritis[3]				
Diffuse proliferation of endothelial and mesangial cells Infiltration by neutrophils and macrophages ± crescent formation	Subendothelial and subepithelial	Immune complex-mediated (e.g. to streptococcal infection with presumed cross-reactive epitopes)	Post-streptococcal Concurrent infection with staphylococci, endocarditis	Presents with severe sodium and fluid retention, hypertension, haematuria, oliguria Usually resolves spontaneously
Anti-glomerular basement membrane disease				
Usually crescentic nephritis	Linear IgG along GBM	Autoantibodies to $\alpha 3$ chain of type IV collagen in GBM	*HLA-DR15* (previously known as *DR2*)	Associated with lung haemorrhage but renal or lung disease may occur alone Treat with glucocorticoids, cyclophosphamide and plasma exchange

[1]Systemic lupus erythematosus can cause almost any histological injury pattern, most commonly membranous nephropathy or diffuse proliferative glomerulonephritis. [2]In addition to the association with infection and anti-GBM disease, a diffuse proliferative glomerulonephritis picture may also be seen with lupus and occasionally IgA nephropathy. [3]Infection may also present with mesangioproliferative glomerulonephritis and membranous nephropathy (HIV).
(ANA = antinuclear antibody; ANCA = antineutrophil cytoplasmic antibody; *APOL1* = apolipoprotein L1; GBM = glomerular basement membrane; HLA = human leucocyte antigen; IgA = immunoglobulin A; NSAIDs = non-steroidal anti-inflammatory drugs)

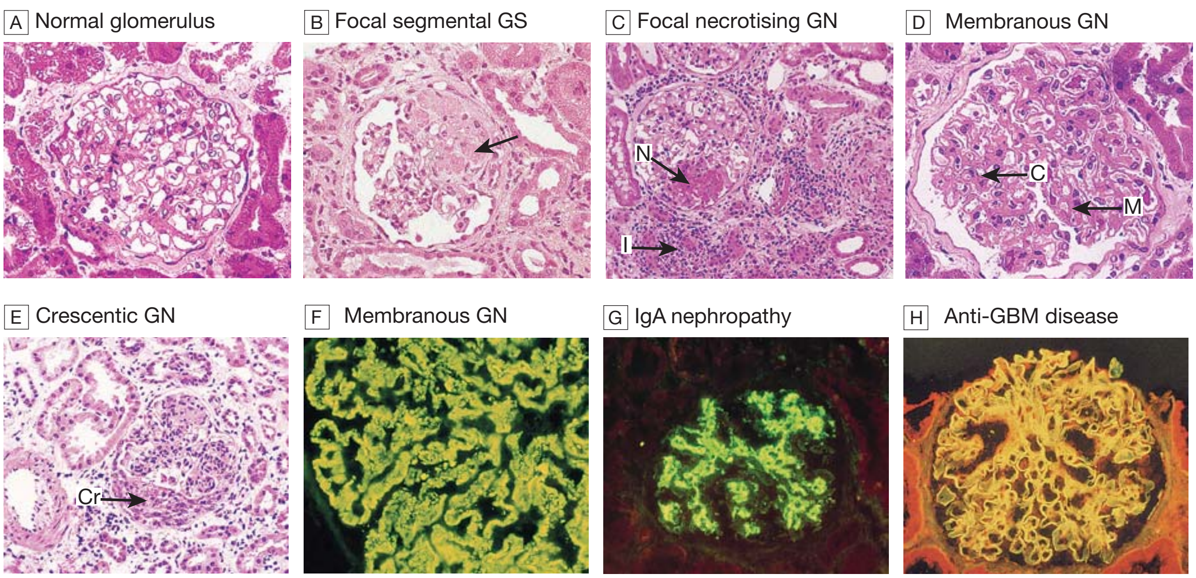

Fig. 15.12 Histopathology of glomerular disease. *(A–E Light microscopy)* A A normal glomerulus. Note the open capillary loops and thinness of their walls. B Focal segmental glomerulosclerosis (GS). The portion of the glomerulus arrowed shows loss of capillary loops and cells, which are replaced by matrix. C Focal necrotising glomerulonephritis (GN). A portion of the glomerulus (N = focal necrotising lesion) is replaced by bright pink material with some 'nuclear dust'. Neutrophils may be seen elsewhere in the glomerulus. There is surrounding interstitial inflammation (I). This is most commonly associated with small-vessel vasculitis and may progress to crescentic nephritis (see E). D Membranous glomerulonephritis. The capillary loops (C) are thickened (compare with the normal glomerulus) and there is expansion of the mesangial regions by matrix deposition (M). However, there is no gross cellular proliferation or excess of inflammatory cells. E Crescentic glomerulonephritis. The lower part of Bowman's space is occupied by a semicircular formation ('crescent', Cr) of large pale cells, compressing the glomerular tuft. This is seen in aggressive inflammatory glomerulonephritis. *Antibody deposition in the glomerulus. (F–H Direct immunofluorescence)* F Granular deposits of IgG along the basement membrane in a subepithelial pattern, typical of membranous GN. G Immunoglobulin A (IgA) deposits in the mesangium, as seen in IgA nephropathy. H Ribbon-like linear deposits of anti-GBM antibodies along the glomerular basement membrane in Goodpasture's disease. The glomerular structure is well preserved in all of these examples. *(A, C, D, E) Courtesy of Dr J.G. Simpson, Aberdeen Royal Infirmary. (F, G, H) Courtesy of Dr R. Herriot.*

i 15.16 Terminology used in glomerulonephritis

Light microscopy

- *Focal*: affecting some but not all glomeruli
- *Diffuse*: affecting >50% of glomeruli
- *Segmental*: affecting a portion of a glomerulus
- *Global*: affecting all of the glomerulus
- *Necrotising*: severe injury leading to an area of necrosis, usually associated with vasculitis
- *Crescentic*: a crescent-shaped area of inflammatory cells responding to severe glomerular injury

Electron microscopy

- *Subendothelial immune deposits*: found between the endothelial cell and the GBM – often found in nephritic presentations
- *Intramembranous immune deposits*: found within the GBM – found in the dense deposit variant of mesangiocapillary glomerulonephritis
- *Subepithelial immune deposits*: found between the epithelial cell and the GBM – often found in nephrotic presentations, including membranous presentation of lupus

(GBM = glomerular basement membrane)

with high-dose glucocorticoid therapy (1 mg/kg prednisolone for 6 weeks), though the response to therapy is often less satisfactory in older patients. Some patients who respond incompletely (glucocorticoid-resistant) or relapse frequently need maintenance glucocorticoids (glucocorticoid dependence), cytotoxic therapy or other agents. Glucocorticoid resistance in children warrants a biopsy to exclude an alternative diagnosis, but if minimal change is confirmed, a genetic cause should be considered (p. 403). Minimal change disease typically does not progress to CKD but can present with problems related to the nephrotic syndrome (see Box 15.11) and complications of treatment.

Focal segmental glomerulosclerosis

Primary focal segmental glomerulosclerosis (FSGS) (Fig. 15.12B) can occur in all age groups but is particularly common in people of West African descent, who, compared with other ethnicities, have a much higher carriage rate of an apolipoprotein L1 (*APOL1*) gene variant that is associated with increased risk of FSGS. Histological analysis shows sclerosis initially limited to segments of the glomeruli, which may also show positive staining for deposits of C3 and IgM on immunofluorescence. Since FSGS is a focal process, abnormal glomeruli may not be seen on renal biopsy if only a few are sampled, leading to an initial diagnosis of minimal change nephropathy. In most cases the underlying cause is unknown (primary FSGS) and these patients typically present with abrupt onset of severe nephrotic syndrome. Primary FSGS may respond to high-dose glucocorticoid therapy (0.5–2.0 mg/kg/day) but the response is rarely as rapid or complete as for minimal change disease. Immunosuppressive drugs, such as ciclosporin, cyclophosphamide and mycophenolate mofetil, have also been used but their efficacy is uncertain. Progression to CKD is common in patients who do not respond to glucocorticoids and the disease frequently recurs after renal transplantation.

FSGS may also be secondary to other diseases such as human immunodeficiency virus (HIV) renal disease (particularly in African Americans), morbid obesity or chronic hypertension. In addition, it may reflect scarring from previous focal glomerular injury resulting from HUS, cholesterol embolism or vasculitis. Patients with secondary FSGS typically present with more modest proteinuria than those with primary disease and rarely exhibit full-blown nephrotic syndrome. Management of secondary FSGS is focused on treating the underlying cause and reducing proteinuria by inhibiting the renin–angiotensin system (p. 417).

Membranous nephropathy

Membranous nephropathy is the most common cause of nephrotic syndrome in Caucasian adults. It is caused by antibodies (usually autoantibodies) directed at antigen(s) expressed on the surface of podocytes, including the M-type phospholipase A_2 receptor 1. While most cases are idiopathic, a proportion are associated with other causes, such as heavy metal poisoning, drugs, infections, lupus and tumours (see Box 15.15 and Fig. 15.12D and F). Approximately one-third of patients with idiopathic membranous nephropathy undergo spontaneous remission, one-third remain in a nephrotic state, and one-third develop progressive CKD. High doses of glucocorticoids and cyclophosphamide may improve both the nephrotic syndrome and the long-term prognosis. However, because of the toxicity of these regimens, many nephrologists reserve such treatment for those with severe nephrotic syndrome or deteriorating renal function. Treatment of secondary membranous nephropathy is directed at the underlying cause.

Diseases typically presenting with mild nephritic syndrome

Patients with mild glomerulonephritis typically present with non-visible haematuria and modest proteinuria, and their renal disease tends to follow a slowly progressive course. IgA nephropathy and mesangiocapillary glomerulonephritis (MCGN) typically fall in this category. Their presentation is highly variable, however; IgA nephropathy occasionally presents with rapidly progressive glomerulonephritis while MCGN may present with nephrotic syndrome. Other diseases that present with haematuria, modest proteinuria and slow progression include Alport's syndrome (p. 403).

IgA nephropathy

This is one of the most common types of glomerulonephritis and can present in many ways. Haematuria is the earliest sign and non-visible haematuria is almost universal, while hypertension is also very common. These are often detected during routine screening: for example, at occupational medical examinations. Proteinuria can also occur but is usually a later feature. In many cases, there is slowly progressive loss of renal function leading to end-stage renal disease (ESRD). A particular hallmark of IgA nephropathy in young adults is the occurrence of acute self-limiting exacerbations, often with visible haematuria, in association with minor respiratory infections. This may be so acute as to resemble acute post-infectious glomerulonephritis, with fluid retention, hypertension and oliguria with dark or red urine. Characteristically, the latency from clinical infection to nephritis is short: a few days or less. Asymptomatic presentations dominate in older adults, with non-visible haematuria, hypertension and reduction in GFR. Occasionally, IgA nephropathy progresses rapidly in association with crescent formation on biopsy. Management is largely directed towards the control of blood pressure, with renin–angiotensin system inhibitors preferable in those with proteinuria. There is some evidence for additional benefit from several months of high-dose glucocorticoid treatment in those at high-risk of progressive disease (see Box 15.14), but no strong evidence for other immunosuppressive agents. A role for other therapies, such as fish oil, remains uncertain.

Henoch–Schönlein purpura

This condition most commonly occurs in children but can also be observed in adults. It is a systemic vasculitis that often arises in response to an infectious trigger. It presents with a tetrad of features:

- a characteristic petechial rash typically affecting buttocks and lower legs
- abdominal pain due to vasculitis involving the gastrointestinal tract
- arthralgia
- renal disease characterised by visible or non-visible haematuria, with or without proteinuria.

Renal biopsy shows mesangial IgA deposition and appearances that are indistinguishable from acute IgA nephropathy (Fig. 15.12G). Treatment is supportive in nature; in most patients, the prognosis is good, with spontaneous resolution, though relapses are common. Some patients, particularly adults and those with severe or persistent proteinuria, progress to develop ESRD.

Mesangiocapillary glomerulonephritis

Mesangiocapillary glomerulonephritis (MCGN), also known as membranoproliferative glomerulonephritis, is a pattern of injury seen on renal biopsy that is characterised by an increase in mesangial cellularity with thickening of glomerular capillary walls. The typical presentation is with proteinuria and haematuria. Several underlying causes have been identified, as summarised in Box 15.15. It can be classified into two main subtypes. The first is characterised by deposition of immunoglobulins within the glomeruli. This subtype is associated with chronic infections, autoimmune diseases and monoclonal gammopathy. The second is characterised by deposition of complement in the glomeruli and is associated with inherited or acquired abnormalities in the complement pathway. This category comprises 'dense deposit disease', which is typified by electron-dense deposits within the GBM, and C3 glomerulonephritis that shows deposits similar to immunoglobulin-type MCGN.

Treatment of MCGN associated with immunoglobulin deposits consists of the identification and treatment of the underlying disease, if possible, and the use of immunosuppressive drugs such as mycophenolate mofetil or cyclophosphamide. There are few specific treatments for MCGN associated with complement dysregulation, although eculizumab, the anti-C5 inhibitor that prevents formation of the membrane attack complex, has shown promise.

Diseases typically presenting with rapidly progressive glomerulonephritis

Rapidly progressive glomerulonephritis (RPGN) is characterised by rapid loss of renal function over days to weeks, usually in association with hypertension and oedema. Non-visible haematuria is almost always present with variable amounts of proteinuria, while characteristic red cell casts and dysmorphic red cells may be observed on urine microscopy (see Fig. 15.3). Renal biopsy typically shows crescentic lesions (see Fig. 15.12E), often associated with necrotising lesions within the glomerulus (Fig. 15.12C), particularly in small-vessel vasculitides.

This pattern of presentation is typical of post-infectious glomerulonephritis, anti-GBM disease and small-vessel vasculitides (p. 1040). It can also be observed in SLE (p. 1034) and occasionally in IgA and other nephropathies (see Fig. 15.9).

i 15.17 Causes of glomerulonephritis associated with low serum complement

- Post-infectious glomerulonephritis
- Subacute bacterial infection, especially endocarditis
- Systemic lupus erythematosus
- Cryoglobulinaemia
- Mesangiocapillary glomerulonephritis, usually complement type

Anti-glomerular basement membrane disease

Anti-GBM disease is a rare autoimmune disease in which antibodies develop against the α3 chain of type 4 collagen GBM. Expression of the α3 chain is largely restricted to the basement membranes of glomeruli and lungs, and hence the disease may present with rapidly progressive glomerulonephritis, lung haemorrhage, or disease of both organs, when it is known as Goodpasture's disease. Goodpasture's disease is more common in younger patients, while elderly patients often present with renal-limited disease. Patients with anti-GBM disease should be treated with plasma exchange combined with glucocorticoids and immunosuppressants, but early diagnosis is essential, as renal function is rarely recoverable in those requiring dialysis at presentation.

The combination of glomerulonephritis and pulmonary haemorrhage (Goodpasture's syndrome) may also be observed with small-vessel vasculitis (particularly granulomatosis with polyangiitis, previously known as Wegener's granulomatosis) and lupus.

15

Infection-related glomerulonephritis

RPGN may occur either during or following an infection. In both cases, circulating immune complexes are present and activation of the complement system promotes consumption of complement factors, resulting in low serum C3 and C4 concentration, as observed in many causes of glomerulonephritis (Box 15.17).

Post-infectious glomerulonephritis is observed most commonly in children and young adults, and typically presents 10 days *after* a streptococcal throat infection or longer after a skin infection. The clinical presentation ranges from mild abnormalities on urinalysis to RPGN with severe AKI. The anti-streptolysin (ASO) test is positive in up to 95% of patients with streptococcal throat infections. Treatment is supportive, with control of blood pressure and fluid overload with salt restriction, diuretics and dialysis if required. Antibiotic therapy is rarely needed, as the renal disease occurs after the infection has subsided. The medium-term prognosis for children and most adults is good, with recovery of renal function typical even in those requiring dialysis therapy. Some patients may develop CKD 20–30 years after the original presentation, however.

An immune complex-mediated disease may also be observed *during* an infection, typically a staphylococcal infection such as endocarditis, skin infection or pneumonia, but also with subacute endocarditis due to *Streptococcus viridans*. This occurs more commonly in older adults and the presentation tends not to be as fulminant as with post-streptococcal disease. In addition to supportive measures, antibiotic therapy is required, as infection is usually concurrent with renal disease.

Tubulo-interstitial diseases

These diseases primarily affect the renal tubules and interstitial components of the renal parenchyma. They are characterised

by tubular dysfunction with electrolyte abnormalities, moderate levels of proteinuria and varying degrees of renal impairment. Often the urinary output may be relatively preserved for any given GFR, and indeed there may be polyuria and nocturia.

Acute interstitial nephritis

Acute interstitial nephritis (AIN) is an immune-mediated disorder, characterised by acute inflammation affecting the tubulo-interstitium of the kidney. It is commonly drug-induced, with proton pump inhibitors (PPIs) fast becoming the most common cause, but can be caused by other toxins, and can complicate a variety of systemic diseases and infections (Box 15.18).

Clinical features

The clinical presentation is typically with renal impairment but, in some patients with drug-induced AIN, there may be signs of a generalised drug hypersensitivity reaction with fever, rash and eosinophilia. Proteinuria is generally modest (PCR < 100 mg/mmol) and tubular in type (see Box 15.25, p. 412). The urine may contain white blood cells and white cell casts but is sterile on culture. Eosinophils are present in up to 70% of patients but this is a non-specific finding. AIN should always be considered in patients with non-oliguric AKI. There may be a rapid deterioration of renal function in some cases of drug-induced AIN, causing the condition to be mistaken for RPGN.

15.18 Causes of acute interstitial nephritis

Allergic	
Many drugs but particularly:	
• Penicillins	• Proton pump inhibitors
• Non-steroidal anti-inflammatory drugs (NSAIDs)	• Mesalazine (delayed)
Immune	
• Autoimmune nephritis ± uveitis	• Transplant rejection
Infections	
• Acute bacterial pyelonephritis	• Tuberculosis
• Leptospirosis	• Hantavirus
Toxic	
• Myeloma light chains	• Mushrooms (*Cortinarius*)

Investigations

Renal biopsy is usually required to confirm the diagnosis (Fig. 15.13D). This typically shows evidence of intense inflammation, with infiltration of the tubules and interstitium by polymorphonuclear leucocytes and lymphocytes. Eosinophils may also be observed, especially in drug-induced AIN. Often granulomas may be evident, especially in drug-induced AIN or sarcoidosis (p. 608). The degree of chronic inflammation in a biopsy is a useful predictor of long-term renal function. Eosinophiluria may be present but is not a good discriminator for AIN.

Management

Some patients with drug-induced AIN recover following withdrawal of the drug alone, but high-dose glucocorticoids (prednisolone 1 mg/kg/day) may accelerate recovery and prevent long-term scarring. Other specific causes (see Box 15.18) should be treated, if possible.

Chronic interstitial nephritis

Chronic interstitial nephritis (CIN) is characterised by renal dysfunction with fibrosis and infiltration of the renal parenchyma by lymphocytes, plasma cells and macrophages, in association with tubular damage.

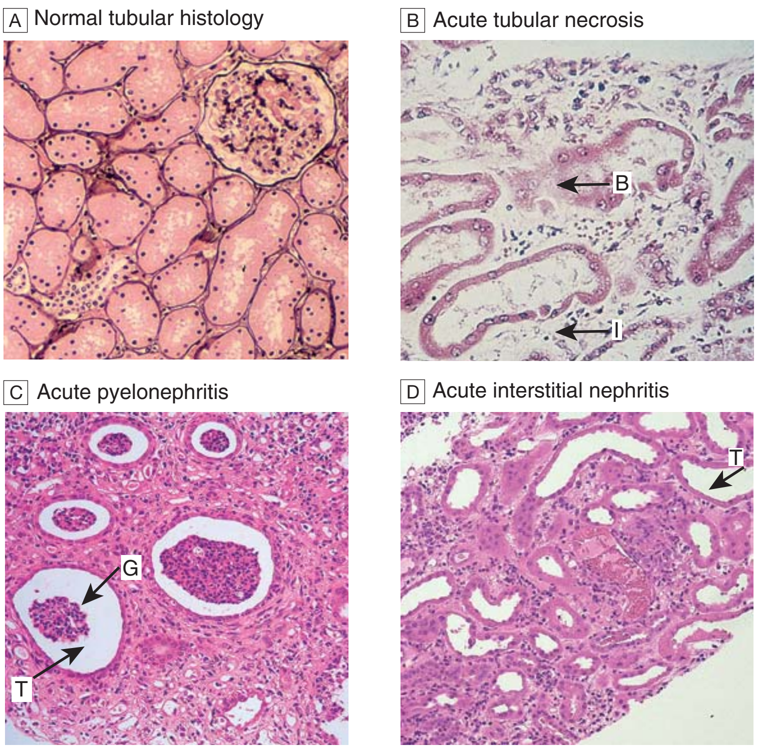

Fig. 15.13 Tubular histopathology. **A** Normal tubular histology. The tubules are back to back. Brush borders can be seen on the luminal borders of cells in the proximal tubule. **B** Acute tubular necrosis. There are scattered breaks (B) in tubular basement membranes, swelling and vacuolation of tubular cells, and, in places, apoptosis and necrosis of tubular cells with shedding of cells into the lumen. During the regenerative phase, there is increased tubular mitotic activity. The interstitium (I) is oedematous and infiltrated by inflammatory cells. The glomeruli (not shown) are relatively normal, although there may be endothelial cell swelling and fibrin deposition. **C** Acute bacterial pyelonephritis. A widespread inflammatory infiltrate that includes many neutrophils is seen. Granulocyte casts (G) are forming within some dilated tubules (T). Other tubules are scarcely visible because of the extent of the inflammation and damage. **D** Acute (allergic) interstitial nephritis. In this patient who received a non-steroidal anti-inflammatory drug (NSAID), an extensive mononuclear cell infiltrate (no neutrophils) involving tubules (T) is seen. This inflammation does not involve the glomeruli (not shown). Sometimes eosinophils are prominent. Transplant rejection looks similar to this.

Pathophysiology

This disease may follow on from AIN that does not resolve, or may be associated with ingestion of various toxins and drugs, or with metabolic and chronic inflammatory diseases, as summarised in Box 15.19. In many patients, CIN presents at a late stage and no underlying cause can be identified. Genetic causes may underlie many of these cases (p. 404). Toxins that have been associated with CIN include those contained within the plant *Aristolochia clematitis* (birthwort). These are probably responsible for the severe nephrotoxicity that can be associated with treatment with herbal medicines in Asia and for Balkan nephropathy, which affects isolated rural communities in Bosnia, Bulgaria, Croatia, Romania and Serbia, possibly through contaminated flour. The nephropathy is commonly linked with tumours of the collecting system and is probably due to the mutagenic effects of the plant toxin on the urothelial epithelium. Ingestion of mushrooms within the *Cortinarius* genus can cause a devastating and irreversible renal tubular toxicity. It is encountered occasionally in Scandinavia and Scotland.

15.19 Causes of chronic interstitial nephritis

Acute interstitial nephritis
- Any of the causes of acute interstitial nephritis, if persistent (see Box 15.18)

Glomerulonephritis
- Varying degrees of interstitial inflammation occur in association with most types of inflammatory glomerulonephritis

Immune/inflammatory
- Sarcoidosis
- Sjögren's syndrome
- Chronic transplant rejection
- Systemic lupus erythematosus, primary autoimmune

Toxic
- *Aristolochia* in herbal medicines
- Lead
- Balkan nephropathy
- Mushrooms (*Cortinarius*)

Drugs
- All drugs causing acute interstitial nephritis
- Tenofovir
- Lithium toxicity
- Analgesic nephropathy
- Ciclosporin, tacrolimus

Infection
- Consequence of severe pyelonephritis

Congenital/developmental
- Vesico-ureteric reflux: associated but causation not clear
- Renal dysplasias: often associated with reflux
- Inherited: now well recognised but mechanisms unclear
- Other: Wilson's disease, sickle-cell nephropathy, medullary sponge kidney (nephrocalcinosis)

Metabolic and systemic diseases
- Calcium phosphate crystallisation after excessive phosphate administration (e.g. phosphate enemas in patients with chronic kidney disease)
- Hypokalaemia
- Hyperoxaluria

Clinical features

Most patients with CIN present in adult life with CKD, hypertension and small kidneys. Urinalysis abnormalities are non-specific. A minority present with salt-losing nephropathy, characterised by hypotension, polyuria and features of sodium and water depletion. People with CIN have an impairment of urine-concentrating ability and sodium conservation, which puts them at risk of AKI due to salt and water depletion during an acute illness. Renal tubular acidosis (p. 365) may complicate CIN but is seen most often in myeloma, sarcoidosis, cystinosis, amyloidosis and Sjögren's syndrome.

Management

Management is supportive in nature, with correction of acidosis and hyperkalaemia; replacement of fluid and electrolytes, as required; and renal replacement therapy if irreversible renal damage has occurred.

Papillary necrosis

The renal papillae lie within a hypertonic environment in the renal medulla, at the end of the vasa recta. They are susceptible to ischaemic damage because of this and can undergo necrosis when their vascular supply is impaired as the result of diabetes mellitus, sickle-cell disease or long-term ingestion of NSAIDs. The condition may occasionally occur in other diseases. There is an association with pyelonephritis but it is difficult to determine whether this is a cause of papillary necrosis or a complication. The clinical presentation is variable. Some patients are asymptomatic and clinically silent, whereas others present with renal colic and renal impairment as necrosed papillae slough off and cause ureteric obstruction. Urinalysis may be normal but more frequently haematuria and sterile pyuria are present. Significant proteinuria is unusual, unless there is renal failure. The imaging method of choice to make the diagnosis is CTU or intravenous pyelography. Management is based on relieving obstruction, where present, and withdrawal of the offending drugs.

Genetic renal diseases

The advent of modern genetic techniques such as next-generation sequencing has allowed us to understand the breadth of inherited renal diseases on a much deeper level than before.

Inherited glomerular diseases

Alport's syndrome

A number of uncommon diseases may involve the glomerulus in childhood but the most important one affecting adults is Alport's syndrome. Most cases arise from a mutation or deletion of the *COL4A5* gene on the X chromosome, which encodes type IV collagen, resulting in inheritance as an X-linked recessive disorder (p. 48). Mutations in *COL4A3* or *COL4A4* genes are less common and cause autosomal recessive disease. The accumulation of abnormal collagen results in a progressive degeneration of the GBM (Fig. 15.14). Affected patients progress from haematuria to ESRD in their late teens or twenties. Female carriers of *COL4A5* mutations usually have haematuria but less commonly develop significant renal disease. Some other basement membranes containing the same collagen isoforms are similarly involved, notably in the cochlea, so that Alport's syndrome is associated with sensorineural deafness and ocular abnormalities.

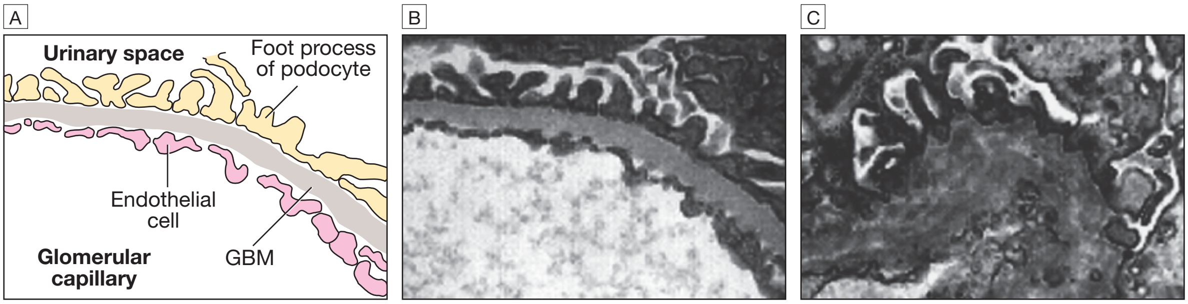

Fig. 15.14 Alport's syndrome. A Diagrammatic structure of the normal glomerular basement membrane (GBM). B The normal GBM (electron micrograph) contains mostly the tissue-specific (α3, α4 and α5) chains of type IV collagen. C In Alport's syndrome, this network is disrupted and replaced by α1 and α2 chains. Although the GBM appears structurally normal in early life, in time thinning appears, progressing to thickening, splitting and degeneration. *(B, C) Courtesy of Dr J. Collar, St Mary's Hospital, London.*

Angiotensin-converting enzyme (ACE) inhibitors may slow but not prevent loss of kidney function. Patients with Alport's syndrome are good candidates for renal replacement therapy (RRT), as they are young and usually otherwise healthy. They can develop an immune response to the normal collagen antigens present in the GBM of the donor kidney and, in a small minority, anti-GBM disease develops and destroys the allograft.

Thin glomerular basement membrane disease

In thin glomerular basement membrane disease there is glomerular bleeding, which is usually non-visible, without associated hypertension, proteinuria or a reduction in GFR. The glomeruli appear normal by light microscopy but, on electron microscopy, the GBM is abnormally thin. The condition may be familial and some patients are carriers of Alport mutations. This does not appear to account for all cases, and in many patients the cause is unclear. Monitoring of these patients is advisable, as proteinuria may develop in some and there appears to be an increased rate of progressive CKD in the long term.

Hereditary nephrotic syndrome

Many genes have been discovered that cause early-onset nephrotic syndrome, often with an FSGS pattern of injury. Inheritance may be autosomal dominant or recessive, the former conditions having a less severe and later-onset phenotype and often exhibiting incomplete penetrance. The involved genes almost all code for podocyte proteins, including nephrin ('Finnish-type' nephropathy) and podocin, which both cause early congenital nephrotic syndrome. Autosomal dominant mutations in various genes may cause FSGS as part of systemic syndromes; the genes include *INF2* (Charcot–Marie–Tooth disease), *LMX1B* (nail–patella syndrome) and *WT1* (abnormal genitalia, Wilms' tumour, mental retardation).

Inheriting variants in the *APOL1* gene, which is observed predominantly in people of West African ancestry, leads to a greatly increased risk of kidney disease including FSGS (p. 400).

Inherited tubulo-interstitial diseases

It has become evident in recent years that a significant number of cases of CKD with low or absent proteinuria have genetic causes, which may be inherited in an autosomal dominant or recessive pattern (Box 15.20). The histological pattern of injury is identical to other forms of CIN (p. 402). This is a heterogeneous group of inherited disorders. Small cysts are sometimes evident, explaining the previous name of medullary cystic kidney disease, but tubulo-interstitial nephritis is the predominant pattern of injury. Many of these conditions, especially those formerly known as nephronophthisis, are associated with retinal dystrophies and brain or other abnormalities, and some may be associated with hyperuricaemia or gout (*UMOD* or *HNF1-beta* mutations). Modern genetics have brought clarity to a disease spectrum comprising many different conditions with inexact previous names.

15.20 Hereditary tubulo-interstitial kidney diseases

Inheritance	Gene(s)	Other name(s)	Clinical features
Autosomal dominant	*UMOD*	MCKD type 2 Juvenile hyperuricaemic nephropathy	Gout
	MUC1	MCKD type 1	Progressive CKD without other manifestations
	HNF1-beta	Juvenile hyperuricaemic nephropathy	Cystic kidneys, solitary kidney; gout; MODY; abnormal LFTs; pancreatic atrophy; hypomagnesaemia
	REN (codes for renin)	Juvenile hyperuricaemic nephropathy	Gout; hyperkalaemia; salt-losing nephropathy
Autosomal recessive	*NPHP* genes (17 discovered so far)	Nephronophthisis Part of many syndromes (Bardet–Biedl)	Common cause of paediatric ESRD Occurs earlier than AD interstitial nephritis Extrarenal manifestation common (learning difficulty, eye/limb problems)

(AD = autosomal dominant; CKD = chronic kidney disease; ESRD = end-stage renal disease; LFTs = liver function tests; MCKD = medullary cystic kidney disease; MODY = maturity-onset diabetes of the young)

Isolated defects of tubular function

An increasing number of disorders have been identified that are caused by specific defects in transporter molecules expressed in renal tubular cells. Only the most common are mentioned here. Renal glycosuria is a benign autosomal recessive defect of tubular reabsorption of glucose, caused by mutations of the sodium/glucose co-transporter *SGLT2*. Glucose appears in the urine in the presence of a normal blood glucose concentration. It is notable that *SGLT2* inhibitors have been developed as a treatment for diabetes mellitus and evidence suggests they may improve renal and cardiovascular outcomes.

Cystinuria is a rare condition, in which reabsorption of filtered cystine, ornithine, arginine and lysine is defective. It is caused by mutations in the *SLC3A1* amino acid transporter gene. The high concentration of cystine in urine leads to cystine stone formation (p. 431).

Other uncommon tubular disorders include hereditary hypophosphataemic rickets (p. 1052), in which reabsorption of filtered phosphate is reduced; nephrogenic diabetes insipidus (p. 687), in which the tubules are resistant to the effects of vasopressin (antidiuretic hormone, ADH); and Bartter's and Gitelman's syndromes, in which there is sodium-wasting and hypokalaemia (p. 361).

The term 'Fanconi's syndrome' is used to describe generalised proximal tubular dysfunction. The condition typically presents with low blood phosphate and uric acid concentrations, glycosuria, aminoaciduria and proximal renal tubular acidosis. In addition to the causes of interstitial nephritis described above, some congenital metabolic disorders are associated with Fanconi's syndrome, notably Wilson's disease, cystinosis and hereditary fructose intolerance.

Renal tubular acidosis describes the common end-point of a variety of diseases affecting distal (classical or type 1) or proximal (type 2) renal tubular function. These syndromes are described on page 365.

Cystic diseases of the kidney

It is common to encounter patients with a single renal cyst or even multiple cysts as an incidental finding, especially in those aged 50 years and over. Usually, these cysts are of no clinical consequence and are asymptomatic, but occasionally they can cause pain or haematuria. In addition, several specific diseases are recognised as being caused by the formation of multiple renal cysts. These are discussed in more detail below.

Adult polycystic kidney disease

Adult polycystic kidney disease (PKD) is a common condition, with a prevalence of approximately 1:1000, and is inherited as an autosomal dominant trait. Small cysts lined by tubular epithelium develop from infancy or childhood and enlarge slowly and irregularly. The surrounding normal kidney tissue is compressed and progressively damaged. Mutations in the *PKD1* gene account for 85% of cases and those in *PKD2* for about 15% (coding for polycystin 1 and 2, respectively). ESRD occurs in approximately 50% of patients with *PKD1* mutations, with a mean age of onset of 52 years, but in a minority of patients with *PKD2* mutations, with a mean age of onset of 69 years. It has been estimated that between 5% and 10% of patients on RRT have PKD.

15.21 Adult polycystic kidney disease: common clinical features

- Vague discomfort in loin or abdomen due to increasing mass of renal tissue
- Acute loin pain or renal colic due to haemorrhage into a cyst
- Hypertension
- Haematuria (with little or no proteinuria)
- Urinary tract or cyst infections
- Renal failure

Clinical features

Common clinical features are shown in Box 15.21. Affected people are usually asymptomatic until later life but hypertension usually occurs from the age of 20 onwards. One or both kidneys may be palpable and the surface may feel nodular. About 30% of patients with PKD also have hepatic cysts (see Fig. 22.39, p. 893) but disturbance of liver function is rare. Sometimes (almost always in women) this causes massive and symptomatic hepatomegaly, usually concurrent with renal enlargement but occasionally with only minor renal involvement. Berry aneurysms of cerebral vessels are an associated feature in about 5% of patients with PKD. This feature appears to be largely restricted to certain families (and presumably specific mutations). Mitral and aortic regurgitation is frequent but rarely severe, and colonic diverticula and abdominal wall hernias may occur.

Investigations

The diagnosis is usually based on family history, clinical findings and ultrasound examination. Ultrasound demonstrates cysts in approximately 95% of affected patients over the age of 20 and is the screening method of choice, but may not detect small developing cysts in younger subjects. Cysts may also be identified by other imaging modalities, such as MRI (Fig. 15.15). Simple renal cysts may occur in normal individuals but are uncommon below the age of 30. The following criteria exist for an ultrasound diagnosis of PKD in patients with a family history but unknown genotype:

- 15–39 years of age: at least three unilateral or bilateral kidney cysts
- 40–59 years of age: at least two cysts in each kidney
- 60 years or older: at least four cysts in each kidney.

It is now possible to make a molecular diagnosis by mutation screening of *PDK1* or *PDK2* but this is seldom used in routine clinical practice because the *PKD1* gene is so large and has many possible mutations. Next-generation sequencing allows faster and simpler genetic screening for *PKD1* and *PKD2*. This is likely to be used in cases with an uncertain diagnosis (young patients, few cysts, lack of family history), for workup of living kidney donors, or for screening for mutations associated with a worse prognosis (see below). Screening for intracranial aneurysms is not generally indicated but can be done by MR angiography in families with a history of subarachnoid haemorrhage. The yield of screening is low, however, and the risk:benefit ratio of intervention in asymptomatic aneurysms in this disease is not clear.

Management

Blood pressure control is important because cardiovascular morbidity and mortality are so common in renal disease, but evidence is lacking that controlling blood pressure to generally recommended CKD targets (e.g. <130/80 mmHg) influences renal outcomes. There are data suggesting that targeting a very low blood pressure (<110/75 mmHg) with ACE inhibitors or angiotensin II

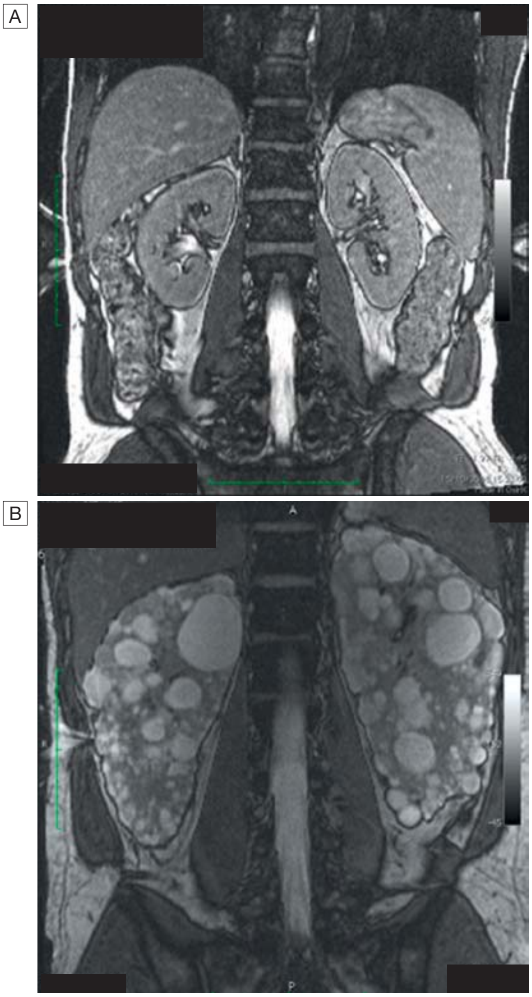

Fig. 15.15 MRI images of the kidneys. **A** Normal kidneys. **B** Polycystic kidneys; although the kidney enlargement is extreme, this patient had only slightly reduced GFR.

receptor blocker (ARBs) leads to slower increases in kidney volume, but no improvements in eGFR decline were observed and these targets are often not tolerated. This tight blood pressure target did lead to a greater decline in left ventricular mass index, which may have implications for improved cardiovascular risk later in life.

The vasopressin V2 receptor antagonist tolvaptan may retard kidney volume increase and slow the rate of GFR decline. It has now been licensed in many countries for patients at high risk of progression. Risk factors for progression include large kidneys (more specifically height-adjusted kidney volume), truncating *PKD1* mutations, and family history of early progression, as well as male sex, hypertension, proteinuria and development of early symptomatic cysts.

Patients with PKD are usually good candidates for dialysis and transplantation. Sometimes kidneys are so large that one or both have to be removed to make space for a renal transplant. Otherwise, they are usually left in situ unless they are a source of pain or infection.

Other cystic diseases

Renal cysts and diabetes syndrome is caused by *HNF1-beta* mutations (see above); it has a varying renal phenotype that often causes cysts but also may cause a tubulo-interstitial pattern of injury or congenital absence of a kidney. It also causes a form of MODY (p. 733).

Autosomal recessive PKD is caused by mutations in the *PKHD1* gene, encoding fibrocystin. It is less common than autosomal dominant PKD (about 1:20 000 live births). Patients often present in infancy or young childhood with renal cysts and congenital hepatic fibrosis.

Some uncommon autosomal dominantly inherited conditions are associated with multiple renal cysts and tumours in adult life. In tuberous sclerosis (p. 1264), replacement of renal tissue by multiple angiomyolipomas may occasionally cause renal failure in adults. Patients may also develop renal cysts and have a higher risk of renal cell carcinoma. Other organs affected include the skin (adenoma sebaceum on the face) and brain (causing seizures and mental retardation). The von Hippel–Lindau syndrome (p. 1132) is associated with multiple renal cysts, renal adenomas and renal adenocarcinoma. Other involved organs include the central nervous system (haemangioblastomas), pancreas (serous cystadenomas) and adrenals (phaeochromocytoma).

A number of other rarer inherited cystic diseases are recognised that have some similarities to PKD but distinct genetic causes. Multicystic dysplastic kidneys are often unilateral and are a developmental abnormality found in children. Most of these seem to involute during growth, leaving a solitary kidney in adults.

Acquired cystic kidney disease can develop in patients with a very long history of renal failure, so it is not an inherited cystic disease. It is associated with increased erythropoietin production and sometimes with the development of renal cell carcinoma.

Renal vascular diseases

Diseases that affect renal blood vessels may cause renal ischaemia, leading to acute or chronic kidney disease or secondary hypertension. The rising prevalence of atherosclerosis and diabetes mellitus in ageing populations has made renovascular disease an important cause of ESRD.

Renal artery stenosis

A stenosis of more than 50% may be observed on imaging of the renal arteries in up to 20% of older patients with advanced kidney disease; however, a haemodynamically significant effect will be present in only a relatively small proportion. Renal artery stenosis is the most common cause of secondary hypertension, with an estimated prevalence of about 2% in unselected patients, but this may increase to 4% in older patients who have evidence of atherosclerotic disease elsewhere. Most cases of renal artery stenosis are caused by atherosclerosis but fibromuscular dysplasia involving the vessel wall may be responsible in younger patients. Rare causes include vasculitis, thromboembolism and aneurysms of the renal artery.

Pathophysiology

Renal artery stenosis results in a reduction in renal perfusion pressure, which activates the renin–angiotensin system, leading to increased circulating levels of angiotensin II. This results in hypertension by provoking vasoconstriction and increasing aldosterone production by the adrenal, causing sodium retention by the renal tubules (p. 351). Significant reduction of renal blood flow occurs when there is more than 70% narrowing of the artery, and this is commonly associated with distal, post-stenotic

dilatation. Atherosclerotic lesions are typically ostial and are associated with more widespread atherosclerosis within the aorta and other vessels, particularly the iliac vessels. There is often concurrent small-vessel disease in affected kidneys, due to subclinical atheroemboli. As the stenosis becomes more severe, global renal ischaemia leads to shrinkage of the affected kidney and may cause renal failure if bilateral, or if unilateral in the presence of a single kidney (ischaemic nephropathy).

In younger patients, fibromuscular dysplasia is a more likely cause of renal artery stenosis. This is an uncommon disorder of unknown cause. It is characterised by hypertrophy of the media (medial fibroplasia), which narrows the artery but rarely leads to total occlusion. It may be associated with disease in other arteries; for example, those who have carotid artery dissections are more likely to have renal arteries with this appearance. It most commonly presents with hypertension in patients aged 15–30 years, and women are affected more frequently than men. Irregular narrowing (beading) may occur in the distal renal artery and this sometimes extends into the intrarenal branches of the vessel. Rarely, renal artery stenosis may occur as a complication of large-vessel vasculitis, such as Takayasu's arteritis and polyarteritis nodosa (pp. 1041 and 1042).

Untreated, atheromatous renal artery stenosis is thought to progress to complete arterial occlusion in about 15% of cases. This figure increases with more severe degrees of stenosis. If the progression is gradual, collateral vessels may develop and some function may be preserved, preventing infarction and loss of kidney structure. Conversely, at least 85% of patients with renal artery stenosis will not develop progressive renal impairment, and many patients die from coronary, cerebral or other vascular disease rather than renal failure. Unfortunately, methods of predicting which patients are at risk of progression or who will respond to treatment are still imperfect.

Clinical features

Renal artery stenosis can present in various ways including hypertension, acute pulmonary oedema, progressive renal failure (with bilateral disease) or a deterioration in renal function when ACE inhibitors or ARBs are administered. Although many patients experience a slight drop in GFR when commencing these drugs, an increase in serum creatinine of 30% or more raises the possibility of renal artery stenosis. Acute pulmonary oedema is particularly characteristic of bilateral renovascular disease. It typically occurs at night and is associated with severe hypertension, often in the context of normal or only mildly impaired renal and cardiac function. Clinical evidence of generalised vascular disease may be observed, particularly in the legs and in older patients with atherosclerotic renal artery stenosis. Clinical features associated with an increased risk of renal artery stenosis in hypertensive patients are summarised in Box 15.22. However, given the risk of imaging and angiography in patients with renal disease (see Box 15.4, p. 390), further investigation should only be performed if intervention is being contemplated (see below).

Investigations

When appropriate, imaging of the renal vasculature with either CT angiography or MR angiography should be performed to confirm the diagnosis (Fig. 15.16). Both give good views of the main renal arteries, the vessels predominantly involved and the most amenable to intervention. Biochemical testing may reveal impaired renal function and an elevated plasma renin activity, sometimes with hypokalaemia due to hyperaldosteronism. Ultrasound may also reveal a discrepancy in size between the two kidneys, although this is insufficiently sensitive or specific to be of value in diagnosis of renovascular disease in hypertensive patients.

Management

The first-line management in patients with renal artery stenosis is medical therapy with antihypertensive drugs, supplemented, where appropriate, by statins and low-dose aspirin in those with atherosclerotic disease. Interventions to correct the vessel narrowing should be considered in:

- young patients (age below 40) suspected of having renal artery stenosis
- those whose blood pressure cannot easily be controlled with antihypertensive agents
- those who have a history of 'flash' pulmonary oedema
- those with accelerated phase (malignant) hypertension
- those whose renal function is deteriorating.

The most commonly used technique is angioplasty. The best results are obtained in non-atheromatous fibromuscular dysplasia, where correction of the stenosis has a high chance of success in improving blood pressure and protecting renal function. Beyond the indications above, angioplasty and stenting is now rarely

i 15.22 Presentation and clinical features of renal artery stenosis

Renal artery stenosis is more likely if:

- hypertension is severe, of recent onset or difficult to control
- kidneys are asymmetrical in size
- flash pulmonary oedema occurs repeatedly*
- there is peripheral vascular disease of the lower limbs
- there is renal impairment*
- renal function has deteriorated on angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers

*Particularly with bilateral disease.

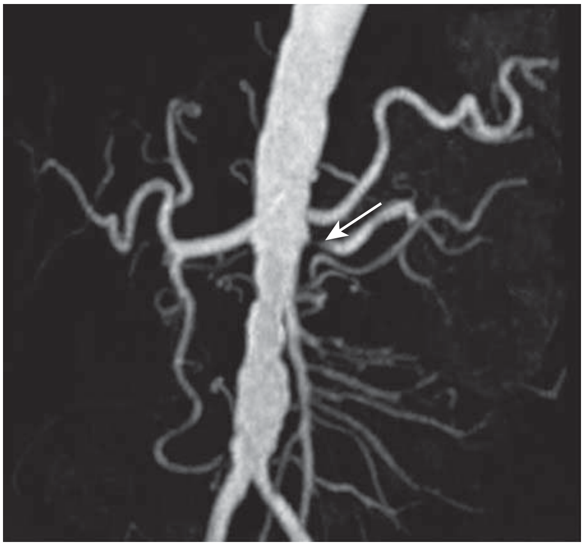

Fig. 15.16 Renal artery stenosis. A magnetic resonance angiogram following injection of contrast. The abdominal aorta is severely irregular and atheromatous. The left renal artery is stenosed (arrow).

15

performed in atherosclerotic disease, as randomised trials such as ASTRAL and CORAL have produced no convincing evidence for overall benefit in terms of renal function, blood pressure control or cardiovascular outcomes. The risks of angioplasty and stenting include renal artery occlusion, renal infarction and atheroemboli (p. 409) from manipulations in a severely diseased aorta. Small-vessel disease distal to the stenosis may preclude substantial functional recovery.

Acute renal infarction

This is an uncommon condition that occurs as the result of sudden occlusion of the renal arteries. The presentation is typically with loin pain of acute onset, usually in association with non-visible haematuria, but pain may be absent in some cases. Severe hypertension is common but not universal. Blood levels of lactate dehydrogenase (LDH) and CRP are commonly raised. The condition may be caused by thrombosis of a renal artery or by thromboemboli from a distant source, when occlusion may occur in branch arteries distal to the main renal artery. This can cause multiple infarcts within the renal parenchyma of both kidneys, which may be visualised by CT scanning. If occlusion of the main renal arteries is bilateral or if there is occlusion in a single functioning kidney, the presentation is with AKI and the patient is typically anuric. Patients with bilateral occlusion usually have evidence of widespread vascular disease and may show evidence of aortic occlusion, with absent femoral pulses and reduced lower limb perfusion. Management is largely supportive, and includes anticoagulation if a source of thromboembolism is identified. It is sometimes possible to perform stenting of an acutely blocked main renal artery to try to restore renal blood flow; in most cases, however, presentation is too late to salvage renal function.

Diseases of small intrarenal vessels

Thrombotic microangiopathies

A number of conditions are associated with acute damage and occlusion of small blood vessels (arterioles and capillaries) in the kidney (Box 15.23) and other organs. A common feature of these syndromes is microangiopathic haemolytic anaemia (MAHA), in which haemolysis and red cell fragmentation arise as consequences of damage incurred to red blood cells during passage through the abnormal vessels. The red blood cell fragments (schistocytes) may be observed on blood films, together with laboratory features of intravascular haemolysis (p. 947), including an elevated unconjugated bilirubin level, raised serum LDH concentration and decreased circulating levels of haptoglobin. A reticulocytosis is often seen. Endothelial injury is pronounced, leading to increased platelet adherence and a marked reduction in the platelet count. These abnormal blood parameters should alert the physician to the possibility of a thrombotic microangiopathy and may also be useful in monitoring response to treatment. The key is to distinguish between the various aetiologies, as the management differs according to the primary cause (Box 15.23).

Haemolytic uraemic syndrome

Haemolytic uraemic syndrome (HUS) is characterised by thrombotic microangiopathy that predominantly affects the renal microcirculation, with involvement of other organs (including the brain) observed in more severe cases.

The most common cause of HUS is infection with organisms that produce enterotoxins called Shiga-like toxin or verotoxins. The organisms most commonly implicated are enterohaemorrhagic *Escherichia coli* (p. 263) and *Shigella dysenteriae* (p. 265). The

15.23 Thrombotic microangiopathies associated with acute renal damage

Condition	Typical features	Management
Primary thrombotic microangiopathies		
Haemolytic uraemic syndrome:	Renal failure prominent in all causes	
Shiga toxin +ve HUS	Bloody diarrhoea; check stool for *Escherichia coli* 0157:H7	Supportive therapy
Complement-mediated	Positive family history; screen for complement factor mutations	Plasma exchange, eculizumab
Drug-induced: quinine, calcineurin and VEGF-A inhibitors	Drug exposure, fever with quinine	Cessation of offending drug
Thrombotic thrombocytopenic purpura	Neurological manifestations prominent; check ADAMTS-13 activity	Plasma exchange (p. 979)
Thrombotic microangiopathy associated with systemic disorders		
Disseminated intravascular coagulation (DIC)	Clotting system involvement: elevated D-dimers, low fibrinogen, prolonged PT and APTT	Treatment of primary cause (p. 979)
Malignancy	May occur with breast, prostate, lung, pancreas and GI tumours	Treatment of tumour where possible
Systemic sclerosis	Cutaneous features of systemic sclerosis	Blood pressure control with ACE inhibitors (p. 1037)
Pre-eclampsia and HELLP syndrome	Typically in third trimester; abnormal LFTs	Resolution with delivery (p. 1276)
Malignant hypertension	Blood pressure typically very high; evidence of hypertensive retinopathy including papilloedema	Blood pressure control

(ACE = angiotensin-converting enzyme; ADAMTS-13 = a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13; APTT = activated partial thromboplastin time; GI = gastrointestinal; HELLP = haemolysis, elevated liver enzymes and low platelets; HUS = haemolytic uraemic syndrome; LFTs = liver function tests; PT = prothrombin time; VEGF = vascular endothelial growth factor)

E. coli O157:H7 serotype is the best known but other serotypes that produce verotoxins may also be responsible. Although these bacteria live as commensals in the gut of cattle and other livestock, they can cause haemorrhagic diarrhoea in humans when the infection is contracted from contaminated food products, water or other infected individuals. In a proportion of cases, verotoxin produced by the organisms enters the circulation and binds to specific glycolipid receptors that are expressed on the surface of microvascular endothelial cells. Most cases are sporadic but large outbreaks related to poor sanitation may occur. In developed countries, Shiga-like toxin-associated HUS is now the most common cause of AKI in children. Recovery is good in most patients but sometimes RRT may be required for up to 14 days. No other specific treatments have been shown to accelerate renal recovery.

In the absence of bloody diarrhoea, other (atypical) causes of HUS should be considered: in particular, abnormalities of the complement system. Familial forms are due to mutations in various genes that encode components or regulators of the complement cascade, including factor H (*CFH*), factor B (*CFB*), membrane co-factor protein (*MCP*) and complement component 3 (*C3*). The penetrance of familial HUS is incomplete, indicating that environmental triggers are also involved: often infection, including diarrhoea. Sporadic cases may be associated with the development of autoantibodies to complement factor H. In addition to supportive care, including RRT if necessary, management of complement-mediated HUS includes plasma exchange to replace complement component and remove pathogenic autoantibodies. Recently, impressive results have been reported with the anti-C5 monoclonal antibody, eculizumab, which binds to C5, thereby preventing activation of the terminal complement cascade.

Thrombotic thrombocytopenic purpura

Like HUS, thrombotic thrombocytopenic purpura (TTP) is characterised by microangiopathic haemolytic anaemia and thrombocytopenia; in contrast, however, the brain is more commonly affected in TTP and involvement of the kidney is usually less prominent. TTP is an autoimmune disorder caused by antibodies against ADAMTS-13, which is involved in regulating platelet aggregation, and a low (< 10%) serum ADAMTS-13 activity level may be useful in distinguishing TTP from HUS. This distinction is important, as early therapy with plasma exchange is crucial in TTP. More details are provided on page 979.

Cholesterol emboli

These present with renal impairment, haematuria, proteinuria and sometimes eosinophilia with inflammatory features that can mimic a small-vessel vasculitis. The symptoms are provoked by showers of cholesterol-containing microemboli, arising in atheromatous plaques in major arteries. The diagnosis should be suspected when these clinical features occur in patients with widespread atheromatous disease, who have undergone interventions such as surgery or arteriography. They may also be precipitated by anticoagulants and thrombolytic agents. On clinical examination, signs of large-vessel disease and microvascular occlusion in the lower limbs (ischaemic toes, livedo reticularis) are common but not invariable (Fig. 15.17). There is no specific treatment.

Small-vessel vasculitis

Renal disease caused by small-vessel vasculitis usually presents with a clinical picture typical of a glomerulonephritis (see Figs 15.9 and 15.12C, pp. 393 and 399). More information is given on page 410.

Fig. 15.17 **The foot of a patient who suffered extensive atheroembolism following coronary artery stenting.**

Renal involvement in systemic conditions

The kidneys may be directly involved in a number of multisystem diseases or secondarily affected by diseases of other organs. Involvement may be at a pre-renal, renal (glomerular or interstitial) or post-renal level. Many of the diseases are described in other sections of this chapter or in other chapters of the book.

Diabetes mellitus

Diabetic nephropathy is the most common cause of CKD in developed countries. In patients with diabetes, there is a steady advance from moderately elevated albuminuria (microalbuminuria) to dipstick-positive proteinuria, in association with evolving hypertensive and progressive renal failure, as described on page 757. Few patients require renal biopsy to establish the diagnosis, but atypical features such as very rapid progression of proteinuria/decline in renal function or the absence of other microvascular damage, including retinopathy, should lead to suspicion that an alternative condition could be present.

Management with ACE inhibitors and ARBs to slow progression is described on page 757. In some patients, proteinuria may be eradicated and progression completely halted, even if renal function is abnormal, although most still have progressive disease, albeit at a slower rate. Emerging evidence suggests that SGLT2 inhibitors, such as empagliflozin, a new agent for diabetes that causes glycosuria (p. 748), may lead to improved cardiovascular and renal outcomes, at the expense of increased genital infections.

Multiple myeloma

In myeloma, a malignant clone of plasma cells produces a paraprotein, often a monoclonal light chain (p. 966). Renal manifestations are dominated by these toxic light chains, which may cause a variety of insults (Box 15.24). Hypercalcaemia may also occur due to bony metastases.

Hepatic–renal disease

Severe hepatic dysfunction may cause a haemodynamically mediated type of renal failure, hepatorenal syndrome (HRS), described on page 864. Patients with chronic liver disease are also predisposed to develop AKI (acute tubular necrosis) in response to relatively minor insults, including bleeding, diuretic therapy and infection. Differentiating true HRS from AKI can be difficult. Patients with true HRS are often difficult to treat

15.24 Renal manifestations of multiple myeloma

Condition	Presentation	Pathogenesis
Cast nephropathy ('myeloma kidney')	AKI Little/no proteinuria	Light chains combine with Tamm–Horsfall protein precipitating in tubules
Fanconi's syndrome	Aminoaciduria, phosphaturia, glycosuria Proximal (type II) RTA	Proximal tubular injury due to light chain deposition in tubular epithelium
AL (primary) amyloidosis*	Proteinuria/nephrotic syndrome Renal impairment	Misfolded lights chains (usually lambda) form amyloid, which is deposited in glomeruli
Monoclonal immunoglobulin deposition disease*	Proteinuria (may be in nephrotic range) Renal impairment	Usually light chains (frequently kappa) are deposited in glomeruli, causing a nodular glomerulosclerosis
Hypercalcaemia	Thirst, polyuria, bony and abdominal pain, headache	Bony destruction from metastases

*These may also occur as primary conditions without myeloma being present.
(AKI = acute kidney injury; RTA = renal tubular acidosis)

by dialysis and have a poor prognosis. Where treatment is justified – for example, if there is a good chance of recovery or of a liver transplant – slow or continuous treatments are less likely to precipitate or exacerbate hepatic encephalopathy. IgA nephropathy (p. 400) is more common in patients with chronic liver disease.

Sarcoidosis

The most common renal manifestation of sarcoidosis is hypercalcaemia from 1-α-vitamin D formation in granulomas. Less commonly, it may lead to a granulomatous interstitial nephritis, sometimes presenting acutely, where renal function may improve with glucocorticoid therapy. Postmortem examinations reveal a chronic interstitial nephritis in 15–30% of patients with sarcoidosis but clinically relevant disease appears to be much less common.

Systemic vasculitis

Small-vessel vasculitis (p. 1040) commonly affects the kidneys, with rapid and profound impairment of glomerular function. Histologically, there is a focal inflammatory glomerulonephritis, usually with focal necrosis (see Box 15.15, p. 398, and Fig. 15.12C, p. 399) and often with crescentic changes (see Fig. 15.12C). Typically, the patient is systemically unwell with an acute phase response, weight loss and arthralgia. In some patients, it presents as a kidney-limited disorder, with rapidly deteriorating renal function and crescentic nephritis (a rapidly progressive glomerulonephritis). In others, pulmonary haemorrhage may occur, which can be life-threatening.

The most important cause is ANCA vasculitis (p. 1041). Two subtypes are recognised, microscopic polyangiitis (MPA) and granulomatosis with polyangiitis. Both may present with glomerulonephritis and pulmonary haemorrhage, along with constitutional symptoms. Gastrointestinal involvement and neuropathy may also occur. Serological testing for antibodies to myeloperoxidase (MPO) and proteinase 3 (PR3) is usually positive but these are not specific and a biopsy of affected tissue should be obtained, if possible, to confirm the diagnosis.

The standard treatment of glomerulonephritis associated with systemic vasculitis is high-dose glucocorticoids combined with cyclophosphamide, or mycophenolate mofetil (p. 1041). Recent studies indicate that rituximab (p. 1006), when combined with high-dose glucocorticoids, is as effective as oral cyclophosphamide and high-dose glucocorticoids in the treatment of ANCA-associated vasculitis. Plasma exchange can offer additional benefit in patients with progressive renal damage who are not responding adequately to immunosuppressive therapy.

Glomerulonephritis secondary to vasculitis may rarely be seen in rheumatoid arthritis, SLE and cryoglobulinaemia, although SLE usually involves the kidney in different ways (see below).

Medium- to large-vessel vasculitis, such as polyarteritis nodosa (p. 1042), does not cause glomerulonephritis but can cause hypertension, renal aneurysms and infarction if the renal vessels are involved.

Systemic sclerosis

Renal involvement is a serious complication of systemic sclerosis, which is more likely to occur in diffuse cutaneous systemic sclerosis (DCSS) than in limited cutaneous systemic sclerosis (LCSS) (p. 1037). The renal lesion is caused by intimal cell proliferation and luminal narrowing of intrarenal arteries and arterioles. There is intense intrarenal vasospasm and plasma renin activity is markedly elevated. Renal involvement usually presents clinically with severe hypertension, microangiopathic features and progressive oliguric renal failure ('scleroderma renal crisis'). Use of ACE inhibitors to control the hypertension has improved the 1-year survival from 20% to 75% but about 50% of patients continue to require RRT. Onset or acceleration of the syndrome after glucocorticoid use or cessation of ACE inhibitors is well described.

Systemic lupus erythematosus

Subclinical renal involvement, with non-visible haematuria and proteinuria but minimally impaired or normal renal function, is common in systemic lupus erythematosus (SLE). Usually, this is due to glomerular disease, although interstitial nephritis may also occur, particularly in patients with overlap syndromes such as mixed connective tissue disease and Sjögren's syndrome (p. 1038).

Almost any histological pattern of glomerular disease can be observed in SLE and the clinical presentation ranges from florid, rapidly progressive glomerulonephritis to nephrotic syndrome. The most common presentation is with subacute disease and inflammatory features (haematuria, hypertension, variable renal impairment), accompanied by heavy proteinuria that often reaches nephrotic levels. In severely affected patients, the most common histological pattern is a proliferative glomerulonephritis with substantial deposits of immunoglobulins on immunofluorescence. Randomised controlled trials have shown that the risk of ESRD in lupus nephritis is significantly reduced by high-dose glucocorticoids administered in combination with cyclophosphamide, usually given as regular intravenous pulses. Subsequently, it has been shown that the combination of glucocorticoids and mycophenolate mofetil is equally as effective, for both induction and maintenance treatment.

Many patients with SLE who develop ESRD go into remission, possibly because of immunosuppression related to the ESRD.

Patients with ESRD caused by SLE are usually good candidates for dialysis and transplantation. Although it may recur in renal allografts, the immunosuppression required to prevent allograft rejection usually controls SLE.

Sickle-cell nephropathy

Improved survival of patients with sickle-cell disease (p. 951) means that a high proportion now live to develop chronic complications of microvascular occlusion. In the kidney, these changes are most pronounced in the medulla, where the vasa recta are the site of sickling because of hypoxia and hypertonicity. Loss of urinary concentrating ability and polyuria are the earliest changes; distal renal tubular acidosis and impaired potassium excretion are typical. Papillary necrosis may also occur (p. 403). A minority of patients develop ESRD. This is managed according to the usual principles, but response to recombinant erythropoietin is poor because of the haemoglobinopathy. Patients with sickle trait have an increased incidence of unexplained non-visible haematuria.

Acute kidney injury

Acute kidney injury (AKI), previously referred to as acute renal failure, is not a diagnosis; rather it describes the situation where there is a sudden and often reversible loss of renal function, which develops over days or weeks and is often accompanied by a reduction in urine volume. Approximately 7% of all hospitalised patients and 20% of acutely ill patients develop AKI. In uncomplicated AKI mortality is low, even when RRT is required. In AKI associated with sepsis and multiple organ failure, mortality is 50–70% and the outcome is usually determined by the severity of the underlying disorder and other complications, rather than by kidney injury itself. Elderly patients are at higher risk of developing AKI and have a worse outcome (Box 15.25).

Pathophysiology

There are many causes of AKI and it is frequently multifactorial. It is helpful to classify it into three subtypes:

- 'pre-renal', when perfusion to the kidney is reduced
- 'renal', when the primary insult affects the kidney itself
- 'post-renal', when there is obstruction to urine flow at any point from the tubule to the urethra (Fig. 15.18).

In pre-renal AKI, a reduction in perfusion reduces GFR. If the insult is not corrected, this may lead to 'renal' injury: namely, acute tubular necrosis (ATN). Histologically, the kidney shows inflammatory changes, focal breaks in the tubular basement membrane and interstitial oedema (see Fig. 15.13B, p. 402). Dead tubular cells may also be shed into the tubular lumen, leading to tubular obstruction. Although tubular cell damage is the dominant feature under the microscope, there may also be profound alterations in the renal microcirculation. Renal AKI may be caused by nephrotoxic drugs (p. 426), which can cause ATN or allergic interstitial nephritis. The other common 'renal' cause is glomerulonephritis, in which there is direct inflammatory damage to the glomeruli (p. 416).

Post-renal AKI occurs as the result of obstruction to the renal tract. This leads to elevation of intraluminal ureteral pressure transmitted to the nephrons after prolonged obstruction, with a subsequent fall in GFR. If the obstruction is not relieved, the low GFR is maintained by a drop in renal blood flow rate via thromboxane A_2 and angiotensin II. This leads to chronic

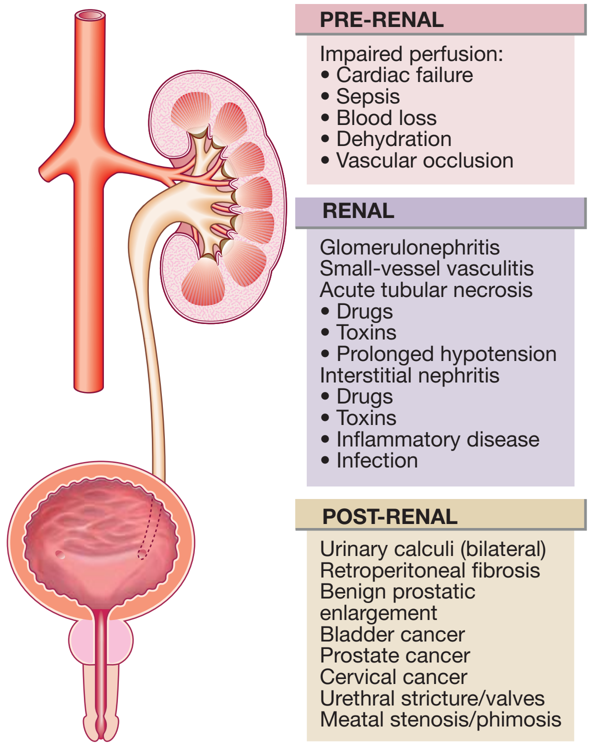

Fig. 15.18 Causes of acute kidney injury.

renal injury over time (several weeks). Recovery of renal function depends on the duration of obstruction and also the pre-morbid GFR.

Clinical features

Early recognition and intervention is important in AKI; all emergency admissions to hospital should have renal function, blood pressure, temperature and pulse checked on arrival and should undergo a risk assessment for the likelihood of developing AKI. This includes looking at coexisting diseases such as diabetes and vascular and liver disease, which make AKI more likely, as well as gathering information on drug treatments such as ACE inhibitors and NSAIDs, which may be associated with renal dysfunction. If a patient is found to have a high serum creatinine, it is important to establish whether this is an acute or acute-on-chronic phenomenon, or a sign of CKD (see Fig. 15.22, p. 416). Previous measurements of renal function can be of great value in differentiating these possibilities. Patients with AKI need to be assessed quickly to determine the likely underlying cause. Clinical features and pertinent investigations for the different causes of AKI are shown in Box 15.25. Various criteria have been proposed to classify AKI and to help identify high-risk patients, guide treatment and provide information regarding prognosis but are mostly used in a research setting to standardise diagnosis. The most commonly used are the KDIGO, AKIN and RIFLE criteria.

Pre-renal AKI

Patients with pre-renal AKI are typically hypotensive and tachycardic with signs of poor peripheral perfusion, such as delayed capillary return. Tachycardia and postural hypotension (a fall in blood pressure of >20/10 mmHg from lying to standing) are valuable signs of early hypovolaemia. Many patients with sepsis

15.25 Categorising acute kidney injury based on history, examination and investigations

Type of AKI	History	Examination	Investigations
Pre-renal	Volume depletion (vomiting, diarrhoea, burns, haemorrhage) Drugs (diuretics, ACE inhibitors, ARBs, NSAIDs, calcineurin inhibitors, iodinated contrast) Liver disease Cardiac failure	Low BP (including postural drop) Tachycardia Weight decrease Dry mucous membranes and increased skin turgor JVP not visible even when lying down	Urine Na <20 mmol/L Fractional excretion Na <1% High urea:creatinine ratio Urinalysis bland
Renal			
ATN	Prolonged pre-renal state Sepsis Toxic ATN: drugs (aminoglycosides, cisplatin, tenofovir, methotrexate, iodinated contrast) Other (rhabdomyolysis, snake bite, *Amanita* mushrooms)	Vital signs Fluid assessment Limbs for compartment syndrome	Urine Na >40 mmol/L Fractional excretion Na ≥1% Dense granular ('muddy brown') casts Creatine kinase
Glomerular	Rash, weight loss, arthralgia Chest symptoms (pulmonary renal syndromes) IV drug use	Hypertension Oedema Purpuric rash, uveitis, arthritis	Proteinuria, haematuria Red cell casts, dysmorphic red cells ANCA, anti-GBM, ANA, C3 and C4 Viral hepatitis screen, HIV Renal biopsy
Tubulo-interstitial	Interstitial nephritis: drugs (PPIs, penicillins, NSAIDs) Sarcoidosis	Fever Rash	Leucocyturia Eosinophiluria (and a peripheral eosinophilia) White cell casts Minimal proteinuria
	Tubular obstruction: 1. Myeloma (cast nephropathy) 2. Tubular crystal nephropathy: Drugs (aciclovir, indinavir, triamterene, methotrexate) Oxalate (fat malabsorption, ethylene glycol) Urate (tumour lysis)		Paraprotein Calcium (myeloma, sarcoidosis) Urine microscopy for crystals Serum urate Urine collection for oxalate
Vascular (including renal infarction, renal vein thrombosis, cholesterol emboli, malignant hypertension)	Flank pain, trauma Anticoagulation Recent angiography (cholesterol emboli) Nephrotic syndrome (renal vein thrombosis) Systemic sclerosis (renal crisis) Diarrhoea (HUS)	BP (malignant hypertension) Fundoscopy Livedo reticularis (cholesterol emboli) Sclerodactyly	Normal urinalysis or some haematuria C3 and C4 (cholesterol emboli, TMA) Doppler renal ultrasound CT angiography Platelets, haemolytic screen, LDH Consider ADAMTS13 and complement genetics (if TMA)
Post-renal	Prostate cancer history Neurogenic bladder Cervical carcinoma Retroperitoneal fibrosis Bladder outlet symptoms	Rectal examination (prostate and anal tone) Distended bladder Pelvic mass	Urinalysis frequently normal (may reveal haematuria depending on cause) Renal ultrasound (hydronephrosis) Isotope renogram (delayed excretion) if ultrasound inconclusive

(ACE = angiotensin-converting enzyme; ANA = antinuclear antibody; ANCA = antineutrophil cytoplasmic antibody; ARBs = angiotensin receptor blockers; BP = blood pressure; GBM = glomerular basement membrane; HIV = human immunodeficiency virus; HUS = haemolytic uraemic syndrome; JVP = jugular venous pulse; LDH = lactate dehydrogenase; Na = sodium; NSAIDs = non-steroidal anti-inflammatory drugs; PPIs = proton pump inhibitors; TMA = thrombotic microangiopathy)

initially present with poor peripheral perfusion, as mentioned above, but then show evidence of peripheral vasodilatation once they have undergone initial resuscitation with intravenous fluids. However, this is accompanied by relative underfilling of the arterial tree and the kidney responds as it would to absolute hypovolaemia, with renal vasoconstriction. It is important to note that pre-renal AKI may also occur without systemic hypotension, particularly in patients taking NSAIDs or ACE inhibitors (Fig. 15.19). The cause of hypotension is often obvious, but concealed blood loss can occur into the gastrointestinal tract, retroperitoneum, following trauma (particularly with pelvic and femoral fractures), and into the pregnant uterus. Large volumes of intravascular fluid may also be lost into tissues after crush injuries or burns, and in severe inflammatory skin diseases or sepsis. Uncorrected renal hypoperfusion causing pre-renal azotaemia may progress to ATN.

Renal AKI

Factors that can help differentiate the various causes of intrinsic renal AKI are summarised in Box 15.25. Patients with

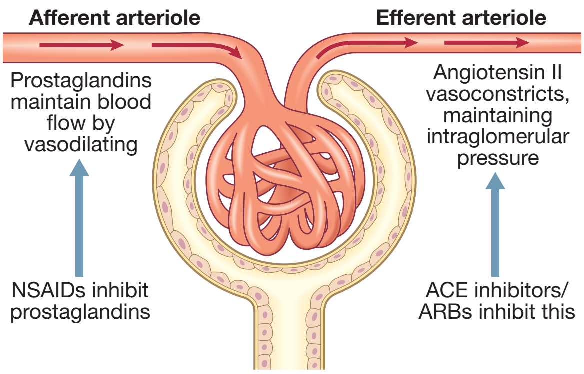

Fig. 15.19 Renal haemodynamics and autoregulation of glomerular filtration rate (GFR). It is evident from this figure how angiotensin-converting enzyme (ACE) inhibitors/angiotensin receptor blockers (ARBs) may be associated with profound drops in GFR in the context of bilateral renal artery stenosis or intravascular volume depletion (which decrease perfusion to afferent arterioles). (NSAIDs = non-steroidal anti-inflammatory drugs)

glomerulonephritis demonstrate haematuria and proteinuria, and may have clinical manifestations of an underlying disease, such as SLE or systemic vasculitis. Although blood tests, including an immunological screen, should be performed to clarify the diagnosis in glomerulonephritis, a renal biopsy is usually required. Drug-induced acute interstitial nephritis is harder to spot but should be suspected in a previously well patient if there is an acute deterioration of renal function coinciding with introduction of a new drug treatment. Drugs that are commonly implicated include PPIs, NSAIDs and many antibiotics.

Post-renal AKI

Patients should be examined clinically to look for evidence of a distended bladder and should also undergo imaging with ultrasound to detect evidence of obstruction above the level of the bladder. Post-renal AKI is usually accompanied by hydronephrosis.

Management

Management options common to all forms of AKI are discussed in more detail below and summarised in Box 15.26.

Haemodynamic status

If hypovolaemia is present, it should be corrected by replacement of intravenous fluid or blood; excessive administration of fluid should be avoided, since this can provoke pulmonary oedema and worsen outcome in AKI. Monitoring of central venous pressure may be of value in determining the rate of administration of fluid in these circumstances. Balanced crystalloid solutions, such as Plasma-Lyte, Hartmann's or Ringer's lactate, may be preferable to isotonic saline (0.9% NaCl) when large volumes of fluid resuscitation are required, in order to avoid hyperchloraemic acidosis, but whether this substantially influences outcome remains unclear. Administration of hydroxyethyl starch solutions should be avoided, since they have been associated with higher rates of established AKI. Critically ill patients may require inotropic drugs to restore an effective blood pressure but clinical trials do not support a specific role for low-dose dopamine.

Hyperkalaemia and acidosis

Hyperkalaemia is common, particularly in patients with rhabdomyolysis, burns, haemolysis or metabolic acidosis (p. 362). If serum K^+ concentration is >6.5 mmol/L, this should be treated immediately, as described in Box 14.17 (p. 363), to prevent life-threatening cardiac arrhythmias. Metabolic acidosis develops unless prevented by loss of hydrogen ions through vomiting. Severe acidosis can be ameliorated with sodium bicarbonate if volume status allows. Restoration of blood volume will correct acidosis by restoring kidney function. Infusions of isotonic sodium bicarbonate may also be used, if acidosis is severe, to reduce life-threatening hyperkalaemia (Box 15.26).

Cardiopulmonary complications

Pulmonary oedema (Fig. 15.20) may be caused by the administration of excessive amounts of fluids relative to urine

15.26 Management of acute kidney injury

- Assess fluid status as this will determine fluid prescription:
  - If hypovolaemic: optimise systemic haemodynamic status with fluid challenge and inotropic drugs if necessary
  - Once euvolaemic, match fluid intake to urine output plus an additional 500 mL to cover insensible losses
  - If fluid-overloaded, prescribe diuretics (loop diuretics at high dose will often be required); if the response is unsatisfactory, dialysis may be required
- Administer calcium resonium to stabilise myocardium and glucose and insulin to correct hyperkalaemia if K^+ >6.5 mmol/L (see Box 14.17, p. 363) as a holding measure until a definitive method of removing potassium is achieved (dialysis or restoration of renal function)
- Consider administering sodium bicarbonate (100 mmol) to correct acidosis if H^+ is >100 nmol/L (pH <7.0)
- Discontinue potentially nephrotoxic drugs and reduce doses of therapeutic drugs according to level of renal function
- Ensure adequate nutritional support
- Consider proton pump inhibitors to reduce the risk of upper gastrointestinal bleeding
- Screen for intercurrent infections and treat promptly if present
- In case of urinary tract obstruction, drain lower or upper urinary tract as necessary

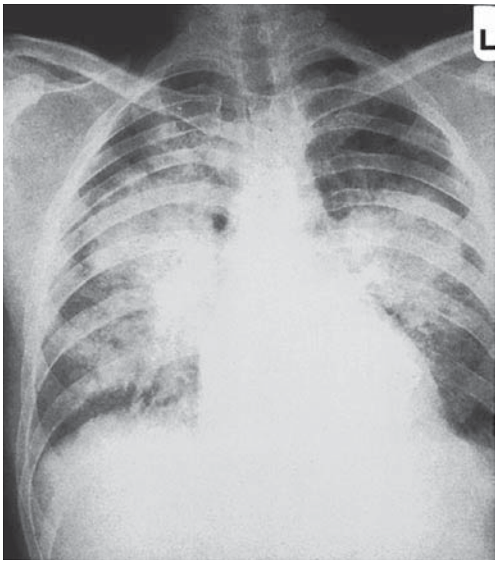

Fig. 15.20 Pulmonary oedema in acute kidney injury. The appearances are indistinguishable from left ventricular failure but the heart size is usually normal. Blood pressure is often high.

15

output and by increased pulmonary capillary permeability. If pulmonary oedema is present and urine output cannot be rapidly restored, treatment with dialysis may be required to remove excess fluid. Temporary respiratory support may also be necessary using non-invasive ventilation. Once initial resuscitation has been performed, fluid intake should be matched to urine output plus 500 mL per day to cover insensible losses, unless diarrhoea is present, in which case additional fluids may be required.

Electrolyte disturbances

Electrolyte disturbances, such as dilutional hyponatraemia, may occur if the patient has continued to drink freely despite oliguria or has received inappropriate amounts of intravenous dextrose. They can be avoided by paying careful attention to fluid balance and by giving intravenous fluids slowly. Modest hypocalcaemia is common but rarely requires treatment. Serum phosphate levels are usually high but may fall in patients on daily or continuous renal replacement therapy (CRRT), necessitating phosphate replacement.

Dietary measures

Adequate nutritional support should be ensured and it is important to give sufficient amounts of energy and adequate amounts of protein; high protein intake should be avoided. This is particularly important in patients with sepsis and burns who are hypercatabolic. Enteral or parenteral nutrition may be required (p. 707).

Infection

Patients with AKI are at substantial risk of intercurrent infection because humoral and cellular immune mechanisms are depressed. Regular clinical examination, supplemented by microbiological investigation where appropriate, is required to diagnose infection. If infection is discovered, it should be treated promptly according to standard principles (Ch. 6).

Medications

Patients with drug-induced kidney injury (p. 402) should have the offending drug withdrawn. Additionally, vasoactive medications, such as NSAIDs and ACE inhibitors, should be discontinued, as they may prolong AKI (see Fig 15.19). H_2-receptor antagonists or PPIs should be given to prevent gastrointestinal bleeding. Other drug treatments should be reviewed and the doses adjusted if necessary, to take account of renal function. Non-essential drug treatments should be stopped.

Renal tract obstruction

In post-renal AKI, the obstruction should be relieved as soon as possible. This may involve urinary catheterisation for bladder outflow obstruction, or correction of ureteric obstruction with a ureteric stent or percutaneous nephrostomy.

Renal replacement therapy

Conservative management can be successful in AKI with meticulous attention to fluid balance, electrolytes and nutrition, but RRT may be required in patients who are not showing signs of recovery with these measures (Box 15.26). No specific cut-off values for serum urea or creatinine have been identified at which RRT should be commenced, and clinical trials of earlier versus later RRT in unselected patients with AKI have not shown differences in outcome. Furthermore, RRT can be a risky intervention, since it requires the placement of central venous catheters that may become infected and it may represent a major haemodynamic challenge in unstable patients. Accordingly, the decision to institute RRT should be made on an individual basis, taking account of the potential risks and benefits, comorbidity and an assessment of whether early or delayed recovery is likely. Severe uraemia with pericarditis and neurological signs (uraemic encephalopathy) is uncommon in AKI but, when present, is a strong indication for RRT; other indications are given in Box 15.35 (p. 422). The two main options for RRT in AKI are intermittent haemodialysis and CRRT (see Box 15.38, p. 424). Peritoneal dialysis is also an option if haemodialysis is not available (p. 424).

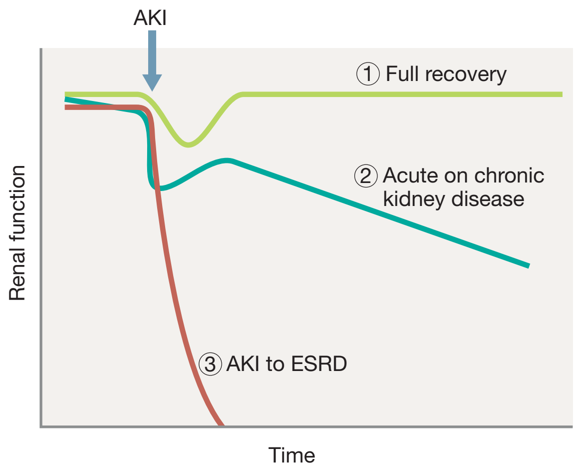

Fig. 15.21 Recovery from acute kidney injury (AKI). Many patients make a full recovery of renal function (1). If the insult is prolonged or prior renal function not normal, however, patients may develop progressive chronic kidney disease (2) or, rarely, irreversible, complete loss of renal function (3). (ESRD = end-stage renal disease)

Recovery from AKI

Most cases of AKI will recover after the insult resolves but recovery may be impaired in pre-existing CKD or a prolonged severe insult (Fig. 15.21). Recovery is heralded by a gradual return of urine output and a steady improvement in plasma biochemistry. Initially, there is often a diuretic phase in which urine output increases rapidly and remains excessive for several days before returning to normal. This may be due in part to tubular damage and to temporary loss of the medullary concentration gradient. After a few days, urine volume falls to normal as the concentrating

15.27 Acute kidney injury in old age

- **Physiological change**: nephrons decline in number with age and average GFR falls progressively, so many elderly patients will have established CKD and less functional reserve. Small acute declines in renal function may therefore have a significant impact.
- **Creatinine**: as muscle mass falls with age, less creatinine is produced each day. Serum creatinine can be misleading as a guide to renal function.
- **Renal tubular function**: declines with age, leading to loss of urinary concentrating ability.
- **Drugs**: increased drug prescription in older people (diuretics, ACE inhibitors and NSAIDs) may contribute to the risk of AKI.
- **Causes**: infection, renal vascular disease, prostatic obstruction, hypovolaemia and severe cardiac dysfunction are common.
- **Mortality**: rises with age, primarily because of comorbid conditions.

mechanism and tubular reabsorption are restored. During the recovery phase of AKI, it may be necessary to provide temporary supplementation of bicarbonate, potassium and sometimes calcium, phosphate and magnesium.

AKI in old age is described in Box 15.27.

Chronic kidney disease

Chronic kidney disease (CKD) refers to an irreversible deterioration in renal function that usually develops over a period of years (see Box 15.3, p. 388). Initially, it manifests only as a biochemical abnormality but, eventually, loss of the excretory, metabolic and endocrine functions of the kidney leads to the clinical symptoms and signs of renal failure, collectively referred to as uraemia. When death is likely without RRT (CKD stage 5), it is called end-stage renal disease (ESRD).

Epidemiology

The social and economic consequences of CKD are considerable. In many countries, estimates of the prevalence of CKD stages 3–5 (eGFR <60 mL/min/1.73 m^2) are around 5–7%, mostly affecting people aged 65 years and above (see Box 15.3). The prevalence of CKD in patients with hypertension, diabetes and vascular disease is substantially higher, and targeted screening for CKD should be considered in these and other high-risk groups. More than 25% of the population aged over 75 years have an eGFR of <60 mL/min/1.73 m^2, mostly stage 3A CKD, which in this context typically reflects an increased cardiovascular risk burden. In these patients, investigation and management should be focused on cardiovascular risk prevention, as very few will ever develop ESRD. Many primary renal diseases, however, are more common in the elderly, so investigation is warranted for those with declining renal function or with haematuria/proteinuria on dipstick.

Pathophysiology

Common causes of CKD are shown in Box 15.28. In many cases, the underlying diagnosis is unclear, especially among the large number of elderly patients with stage 3 CKD (see Box 15.3).

15.28 Common causes of chronic kidney disease

Disease	Proportion	Comments
Diabetes mellitus	20–40%	Large racial and geographical differences
Interstitial diseases	20–30%	Often drug-induced
Glomerular diseases	10–20%	IgA nephropathy is most common
Hypertension	5–20%	Causality controversial, much may be secondary to another primary renal disease
Systemic inflammatory diseases	5–10%	Systemic lupus erythematosus, vasculitis
Renovascular disease	5%	Mostly atheromatous, may be more common
Congenital and inherited	5%	Polycystic kidney disease, Alport's syndrome
Unknown	5–20%	

Many patients diagnosed at a late stage have bilateral small kidneys; renal biopsy is rarely undertaken in this group since it is more risky, less likely to provide a histological diagnosis because of the severity of damage, and unlikely to alter management.

Clinical features

The typical presentation is for a raised urea and creatinine to be found incidentally during routine blood tests, often during screening of high-risk patients, such as those with diabetes or hypertension. Most patients with slowly progressive disease are asymptomatic until GFR falls below 30 mL/min/1.73 m^2 and some can remain asymptomatic with much lower GFR values than this. An early symptom is nocturia, due to the loss of concentrating ability and increased osmotic load per nephron, but this is non-specific. When GFR falls below 15–20 mL/min/1.73 m^2, symptoms and signs are common and can affect almost all body systems (Fig. 15.22). They typically include tiredness or breathlessness, which may, in part, be related to renal anaemia or fluid overload. With further deterioration in renal function, patients may suffer pruritus, anorexia, weight loss, nausea, vomiting and hiccups. In very advanced renal failure, respiration may be particularly deep (Kussmaul breathing) due to profound metabolic acidosis, and patients may develop muscular twitching, fits, drowsiness and coma.

Investigations

The recommended investigations in patients with CKD are shown in Box 15.29. Their main aims are:

- to exclude AKI requiring rapid investigation; in patients with unexpectedly high urea and creatinine (when there is an increase from previous results or no prior results are available), renal function should be retested within 2 weeks to avoid missing AKI
- to identify the underlying cause where possible, since this may influence the treatment
- to identify reversible factors that may worsen renal function, such as hypertension or urinary tract obstruction
- to screen for complications of CKD, such as anaemia and renal osteodystrophy
- to screen for cardiovascular risk factors.

Referral to a nephrologist is appropriate for patients with potentially treatable underlying disease and those who are likely to progress to ESRD. Suggested referral criteria are listed in Box 15.30.

Management

The aims of management in CKD are to:

- monitor renal function
- prevent or slow further renal damage
- limit complications of renal failure
- treat risk factors for cardiovascular disease
- prepare for RRT, if appropriate (p. 420).

Monitoring of renal function

The rate of change in renal function varies between patients and may vary over time in each individual. Renal function should therefore be monitored every 6 months in patients with stage 3 CKD, but more frequently in patients who are deteriorating rapidly or have stage 4 or 5 CKD. A plot of GFR against time (Fig. 15.23) can demonstrate whether therapy has been successful in slowing progression, detect any unexpected increase in the rate of decline that may warrant further investigation, and help

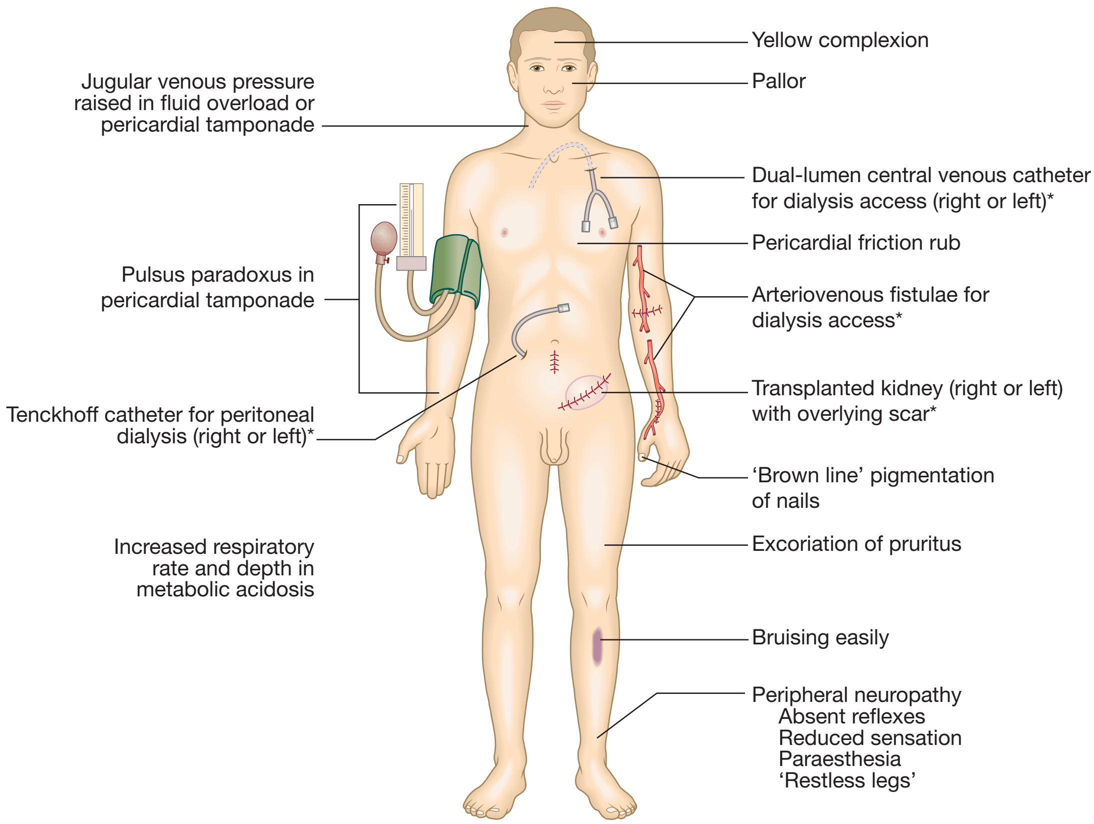

Fig. 15.22 Physical signs in advanced chronic kidney disease. (*Features of renal replacement therapy)

15.29 Suggested investigations in chronic kidney disease

Initial tests	Interpretation
Urea and creatinine	To assess stability/progression: compare to previous results
Urinalysis and quantification of proteinuria	Haematuria and proteinuria may indicate glomerular disease and need for biopsy (p. 391). Proteinuria indicates risk of progressive CKD requiring preventive ACE inhibitor or ARB therapy
Electrolytes	To identify hyperkalaemia and acidosis
Calcium, phosphate, parathyroid hormone and 25(OH)D	Assessment of renal osteodystrophy
Albumin	Low albumin: consider malnutrition, inflammation, nephrotic syndrome
Full blood count (±Fe, ferritin, folate, B_{12})	If anaemic, exclude common non-renal explanations, then manage as renal anaemia
Lipids, glucose ±HbA_{1c}	Cardiovascular risk high in CKD: treat risk factors aggressively
Renal ultrasound	Only if there are obstructive urinary symptoms, persistent haematuria, family history of polycystic kidney disease or progressive CKD. Small kidneys suggest chronicity. Asymmetric renal size suggests renovascular or developmental disease
Hepatitis and HIV serology	If dialysis or transplant is planned. Hepatitis B vaccination recommended if seronegative
Other tests	Consider relevant tests from Box 15.25, especially if the cause of CKD is unknown

(ACE = angiotensin-converting enzyme; ARB = angiotensin II receptor blocker; 25(OH)D = 25-hydroxyvitamin D)

predict when ESRF will be reached to facilitate timely planning for RRT.

Reduction of rate of progression

Slowing the rate of progression of CKD may reduce complications and delay symptom onset and the need for RRT (Fig. 15.23). Therapies directed towards the primary cause of CKD should be employed where possible; tight blood pressure control is applicable to CKD regardless of cause, however, and reducing proteinuria is a key target in those with glomerular disease.

Antihypertensive therapy Lowering of blood pressure slows the rate at which renal function declines in CKD, independently of the agent used (apart from those with proteinuria; see below) and

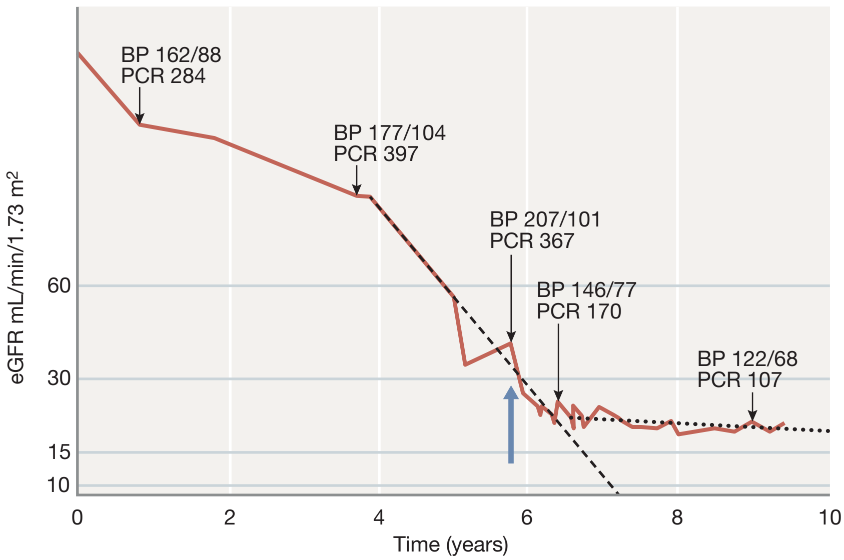

Fig. 15.23 Plot of estimated glomerular filtration rate (eGFR) against time in a patient with type 1 diabetes mellitus. After approximately 6 years of monitoring (blue arrow), this patient entered an aggressive treatment programme aimed at optimising blood pressure (BP) and glycaemic control. The reduction in BP was accompanied by a fall in proteinuria (protein:creatinine ratio, PCR; shown in mg/mmol). At the previous rate of decline in renal function (dashed line), he was likely to reach the level of renal function at which dialysis therapy is typically required (eGFR = 10 mL/min/1.73 m^2) within 18 months; however, the relative stabilisation in his renal function (dotted line) means that this has been deferred, potentially for several years.

i 15.30 Criteria for referral of chronic kidney disease patients to a nephrologist

- eGFR < 30 mL/min/1.73 m^2
- Rapid deterioration in renal function (> 25% from previous or > 15 mL/min/1.73 m^2/year)
- Significant proteinuria (PCR > 100 mg/mmol or ACR > 70 mg/mmol), unless known to be due to diabetes and patient is already on appropriate medications
- ACR > 30 mg/mmol with non-visible haematuria
- Hypertension that remains poorly controlled despite at least four antihypertensive medications
- Suspicion of renal involvement in multisystem disease

has additional benefits in lowering the risk of hypertensive heart failure, stroke and peripheral vascular disease. No threshold for beneficial effects has been identified and any reduction of blood pressure appears to be beneficial. Various targets have been suggested, such as 140/90 mmHg for patients with CKD and no albuminuria (ACR <3 mg/mmol). A lower target of 130/80 mmHg should be considered for those who have moderately elevated albuminuria (ACR 3–3 mg/mmol), and is recommended for those with an ACR of more than 30 mg/mmol. Even lower targets, such as 125/75 mmHg, may be prudent in patients with CKD and heavy proteinuria (PCR >100 mg/mmol or ACR >70 mg/mmol). Achieving these blood pressure targets often requires multiple drugs, and therapeutic success may be limited by adverse effects and poor adherence.

Reduction of proteinuria Patients with proteinuria are at higher risk of progression of renal disease, and there is strong evidence that reducing proteinuria reduces the risk of progression. ACE inhibitors and ARBs reduce proteinuria and retard the progression of CKD. These effects are partly due to the reduction in blood pressure but there is evidence for a specific beneficial effect in patients with proteinuria (PCR >50 mg/mmol or ACR >30 mg/mmol) through a reduction in glomerular perfusion pressure. In addition, ACE inhibitors have been shown to reduce the risk of cardiovascular events and all-cause mortality in CKD. Accordingly, ACE inhibitors and/or ARBs should be prescribed to all patients with diabetic nephropathy and patients with CKD and proteinuria, irrespective of whether or not hypertension is present.

While ACE inhibitors and ARBs are excellent drugs for patients with diabetes or CKD and proteinuria, they need to be prescribed with care in certain circumstances. Initiation of treatment with ACE inhibitors and ARBs may be accompanied by an immediate reduction in GFR; patients should therefore have their renal function checked within 7–10 days of initiating or increasing the dose of an ACE inhibitor or ARB. Treatment can be continued so long as the reduction in GFR is not greater than 25% and is not progressive. Angiotensin II is critical for autoregulation of GFR in the context of low renal perfusion (see Fig. 15.1D, p. 385), and so ACE inhibitors or ARBs may exacerbate pre-renal failure (see Fig. 15.19). Patients on ACE inhibitors/ARBs should therefore be warned to stop taking the medication if they become unwell, such as with fever, vomiting or diarrhoea, restarting once they are better. This also applies to other common medications used in patients with CKD, such as diuretics, metformin and NSAIDs, and this advice may be reinforced by providing written information such as 'sick-day rule' cards (Box 15.31). ACE inhibitors and ARBs increase serum potassium and should not be commenced in patients with baseline potassium >5.5 mmol/L. In patients with serum potassium >6.0 mmol/L, the dose of ACE inhibitors or ARBs should be reduced or discontinued entirely, but only after all other measures to reduce potassium have been considered (see below). Combination therapy with ACE inhibitors and ARBs or direct renin inhibitors has not been shown to reduce progression of kidney disease but is associated with higher rates of hyperkalaemia and AKI, and is therefore to be avoided.

15.31 Exemplar medicine sick-day card

When you are unwell with vomiting, diarrhoea or fever, stop taking the following medications:

- ACE inhibitors: medicines ending in '-pril', e.g. lisinopril, ramipril
- Angiotensin receptor blockers: medicines ending in '-sartan', e.g. irbesartan, losartan, candesartan
- Non-steroidal anti-inflammatory painkillers: e.g. ibuprofen (Brufen), diclofenac (Voltarol)
- Diuretics: e.g. furosemide, bendroflumethiazide, indapamide, spironolactone
- Metformin: a medicine for diabetes.

Restart when you are well again (after 24–48 hours of eating and drinking normally).

15.32 Foods high in potassium

- Fruit: bananas, avocados, figs, rhubarb
- Vegetables: tomatoes, spinach, parsnips, courgettes, sprouts, potatoes (including baked, fries, wedges; boiling vegetables reduces potassium content)
- Sweets/snacks: crisps, chocolate, toffee, nuts (including peanut butter)
- Drinks: beer, cider, wine (spirits contain less potassium), hot chocolate, fruit juice, milk, yoghurt
- Salt substitutes, such as Lo-Salt: sodium chloride is substituted with potassium chloride

Treatment of complications

The kidneys have many functions in addition to excretion of waste (p. 384). Treatments that substitute for all of the normal roles of the kidneys must therefore be instigated to maintain normal body homeostasis and prevent complications.

Maintenance of fluid and electrolyte balance The kidneys excrete waste and regulate many electrolytes, and so patients with CKD may accumulate waste products and develop electrolyte abnormalities.

Urea is a key product of protein degradation and accumulates with progressive CKD. All patients with stages 4 and 5 CKD should be given dietetic advice aimed at preventing excessive consumption of protein. Severe protein restriction is not recommended, however; there is no evidence that this reduces the rate of decline in renal function but may lead to malnutrition.

Potassium often accumulates in patients with advanced CKD, who should be provided with dietary advice to reduce daily potassium intake to below 70 mmol (Box 15.32). Potassium-binding compounds limit absorption of potassium from the gut and may be a useful adjunctive therapy. Calcium resonium is not recommended other than as a very short-term measure, as it can be associated with bowel necrosis; however, newer agents, such as zirconium cyclosilicate and patiromer, appear promising for chronic use. Other measures that may help regulate potassium include diuretic therapy and control of acidosis with sodium bicarbonate (see below). Consideration should be given to stopping or reducing drugs that elevate potassium, such as potassium-sparing diuretics and ACE inhibitors/ARBs; however, this has to be balanced against the potential benefit that such drugs may have on retarding progression of renal and cardiovascular disease, and hence withdrawal should be reserved for when other measures have failed.

The inability of the failing kidney to excrete sodium and water loads commonly leads to their accumulation, which may manifest as oedema and may drive hypertension. Patients with evidence of volume expansion should be instructed to consume a low-sodium diet (<100 mmol/24 hrs), and in severe cases fluid intake should also be restricted. Diuretics are commonly required, and as renal function deteriorates, increasing doses of potent loop diuretics or synergistic combinations of loop, thiazide and potassium-sparing diuretics may be necessary.

Occasionally, some patients with tubulo-interstitial disease can develop 'salt-wasting' disease and may require a high sodium and water intake, including supplements of sodium salts, to prevent fluid depletion and worsening of renal function.

Acid–base balance Reduced ability to excrete organic acids in patients with CKD may lead to an anion-gap metabolic acidosis. In addition, in patients with tubulo-interstitial disease or diabetic nephropathy, there may be specific defects in acid–base regulation within the kidney, causing a non-anion-gap renal tubular acidosis (p. 365). Although acidosis is usually asymptomatic, it may be associated with increased tissue catabolism and decreased protein synthesis, and may exacerbate bone disease and the rate of decline in renal function. Hence, plasma bicarbonate concentrations should be maintained above 22 mmol/L by prescribing sodium bicarbonate supplements (starting dose of 1 g 8-hourly, increasing as required). There is some evidence that correcting acidosis may reduce the rate of decline in renal function.

Renal bone disease Disturbances of calcium and phosphate metabolism are almost universal in advanced CKD (Fig. 15.24). The sequence of events that leads to renal bone disease is complex, but two primary factors are impaired excretion of phosphate and failure of the renal tubular cells to convert 25-hydroxyvitamin D to its active metabolite, 1,25-dihydroxyvitamin D. A rise in serum phosphate levels promotes production of the hormone fibroblast growth factor 23 (FGF23) from osteocytes (Fig. 24.3, p. 986) and stimulates parathyroid hormone (PTH) release and hyperplasia of the parathyroid glands. The FGF23 and PTH promote tubular phosphate excretion, thereby partly compensating for the reduced glomerular filtration of phosphate. The reduced 1,25-dihydroxyvitamin D levels impair intestinal absorption of calcium. In addition, raised levels of serum phosphate complex with calcium in the extracellular space, leading to calcium phosphate deposition. Both the reduced absorption and increased deposition of calcium cause hypocalcaemia, which also stimulates PTH production by the parathyroid glands. Hence in many patients with CKD, compensatory responses initially maintain phosphate and calcium levels at the upper and lower ends of their respective normal ranges, at the expense of an elevated PTH level (secondary hyperparathyroidism). This is associated with a gradual transfer of calcium and phosphate from the bone to other tissues, leading to bone resorption (osteitis fibrosa cystica), and in severe cases this may result in bony pain and increased risk of fractures. Conversely there is increased deposition of calcium phosphate in many tissues, most notably blood vessels and heart valves, which may contribute to the increased risk of cardiovascular disease in patients with CKD (p. 420). In some cases, tertiary hyperparathyroidism supervenes, due to autonomous production of PTH by the enlarged parathyroid glands; this presents with hypercalcaemia. Additional problems in bone metabolism include low bone turnover (adynamic bone disease) in patients who have been over-treated with vitamin D metabolites, osteomalacia with over-treatment of

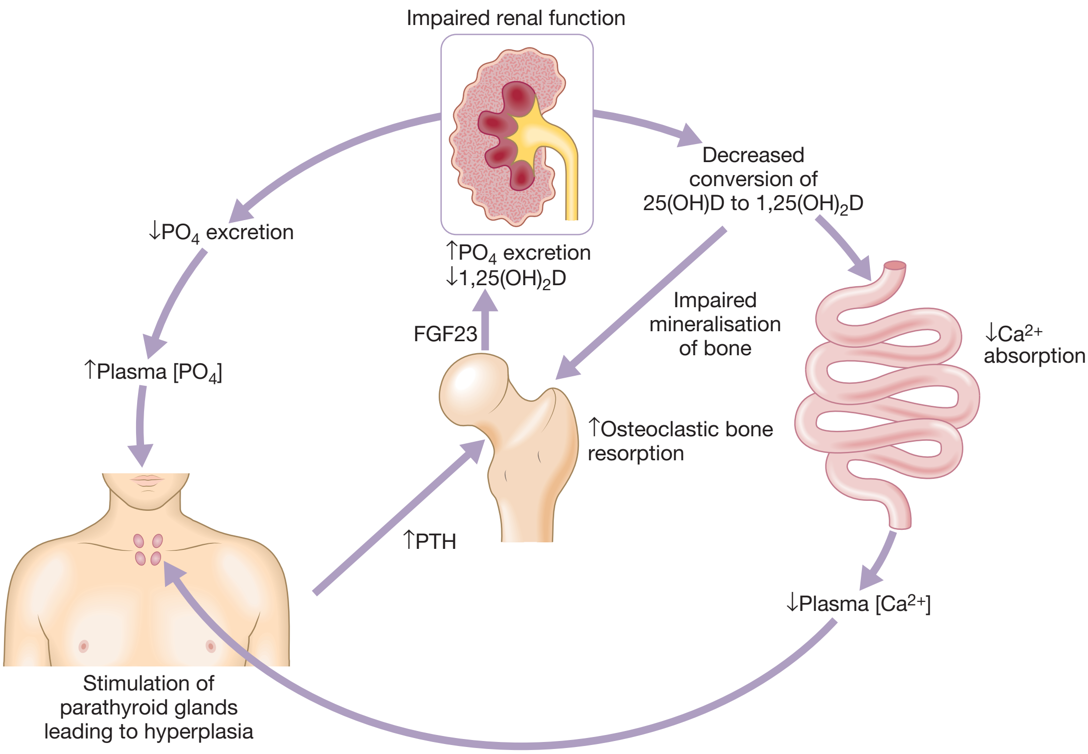

Fig. 15.24 Pathogenesis of renal osteodystrophy. Low 1,25-dihydroxyvitamin D (1,25(OH)$_2$D) levels cause calcium malabsorption and this, combined with high phosphate levels, causes hypocalcaemia, which increases parathyroid hormone (PTH) production by the parathyroid glands. The raised level of PTH increases osteoclastic bone resorption. Although production of fibroblast growth factor 23 (FGF23) from osteocytes also increases, promoting phosphate excretion, this is insufficient to prevent hyperphosphataemia in advanced chronic kidney disease.

hyperphosphataemia (p. 369), and osteoporosis in patients with poor nutritional intake.

The key focus in the management of renal bone disease should be directed towards the two main driving factors, hyperphosphataemia and inadequate activation of vitamin D. Hyperphosphataemia should be treated by dietary restriction of foods with high phosphate content (milk, cheese, eggs and protein-rich foods) and by the use of phosphate-binding drugs. Various drugs are available, including calcium carbonate, aluminium hydroxide, lanthanum carbonate and polymer-based phosphate binders such as sevelamer. The aim is to maintain serum phosphate values at or below 1.5 mmol/L (4.6 mg/dL) if possible, but many of these drugs are difficult to take and adherence can be a problem. Active vitamin D metabolites (either 1-α-hydroxyvitamin D or 1,25-dihydroxyvitamin D) should be administered in patients who are hypocalcaemic or have serum PTH levels more than twice the upper limit of normal. The dose should be adjusted to try to reduce PTH levels to between 2 and 4 times the upper limit of normal to limit hyperparathyroidism while avoiding over-suppression of bone turnover and adynamic bone disease, but care must be exercised in order to avoid hypercalcaemia. In patients with persistent hypercalcaemia (tertiary hyperparathyroidism), parathyroidectomy may be required. If parathyroidectomy is unsuccessful or not possible, calcimimetic agents, such as cinacalcet, may be used. These bind to the calcium-sensing receptor in the parathyroid glands and reduce PTH secretion.

Anaemia Anaemia is common in patients with CKD and contributes to many of the non-specific symptoms, including fatigue and shortness of breath. Haemoglobin can be as low as 50–70 g/L in CKD stage 5, although it is often less severe or absent in patients with polycystic kidney disease. Several mechanisms are implicated, as summarised in Box 15.33. Iron deficiency is common in patients with CKD, and even more prevalent in those on haemodialysis as a result of haemolysis in the dialysis circuit. Hence many patients require iron supplements, which may be given intravenously for those with iron intolerance or in situations where adherence may be difficult. Once iron deficiency and other causes of anaemia have been excluded or corrected, recombinant human erythropoietin is very effective in correcting the anaemia of CKD and improving symptoms. Erythropoietin treatment does not influence mortality, however, and correcting haemoglobin to normal levels may carry some extra risk, including hypertension and thrombosis. The target haemoglobin is usually between 100 and 120 g/L. Erythropoietin is less effective in the presence of iron deficiency, active inflammation or malignancy, in particular myeloma.

i 15.33 Causes of anaemia in chronic kidney disease

- Deficiency of erythropoietin
- Toxic effects of uraemia on marrow precursor cells
- Reduced red cell survival
- Blood loss due to capillary fragility and poor platelet function
- Reduced intake, absorption and utilisation of dietary iron

Treatment of risk factors for cardiovascular disease

The risk of cardiovascular disease is substantially increased in patients with a GFR below 60 mL/min/1.73 m^2 and in those with proteinuria, the combination of reduced eGFR and proteinuria being particularly unfavourable. Patients with CKD have a higher prevalence of traditional risk factors for atherosclerosis, such as hypertension, hyperlipidaemia and diabetes; however, additional mechanisms of cardiovascular disease may also be implicated. Left ventricular hypertrophy is commonly found in patients with CKD, secondary to hypertension or anaemia. Calcification of the media of blood vessels, heart valves, myocardium and the conduction system of the heart is also common and may be due, in part, to the high serum phosphate levels. Reflecting this fact, serum FGF23 levels, which increase in response to serum phosphate, are an independent predictor of mortality in CKD. Both left ventricular hypertrophy and cardiac calcification may increase the risk of arrhythmias and sudden cardiac death, which is a much more common mode of death in patients with CKD than in the general population, particularly in those with more advanced disease and those on dialysis.

To reduce vascular risk, patients with CKD should be encouraged to adopt a healthy lifestyle, including regular exercise, and weight loss and smoking cessation where appropriate. Lipid-lowering drugs reduce cardiovascular events in patients with CKD, although their efficacy may be less once patients require dialysis.

Preparing for renal replacement therapy

It is crucial for patients who are known to have progressive CKD to be prepared well in advance for the institution of RRT. This involves ensuring that they are referred to a nephrologist in a timely manner, as those who are referred late, when they are either at the stage of or very close to requiring dialysis, tend to have poorer outcomes.

Several decisions need to be taken in discussion with the patient and family. The first is to decide whether RRT is an appropriate choice or whether conservative treatment might be preferable (p. 421). This is especially relevant in patients with significant comorbidity. For those who decide to go ahead with RRT, there are further choices between haemodialysis and peritoneal dialysis (Box 15.34), between hospital and home treatment, and on referral for renal transplantation.

Since there is no evidence that early initiation of RRT improves outcome, the overall aim is to commence RRT when symptoms of CKD begin to impact on quality of life but before serious complications have occurred. While there is wide variation between patients, this typically occurs when the eGFR approaches 10 mL/min/1.73 m^2. This may be a useful marker to predict the timing of initiation of RRT by extrapolating from a plot of serial eGFR measurements over time (see Fig. 15.23).

Preparations for starting RRT should begin at least 12 months before the predicted start date. This involves providing the patient with psychological and social support, assessing home circumstances and discussing the various choices of treatment (Fig. 15.25). Depression is common in patients who are on or approaching RRT, and support from the renal multidisciplinary team should be provided both for them and for their relatives, to explain and help them adapt to the changes to lifestyle that may be necessary once RRT starts; this may help to reduce their anxieties about these changes. Physical preparations include establishment of timely access for haemodialysis or peritoneal dialysis and vaccination against hepatitis B.

i 15.34 Comparison of haemodialysis and peritoneal dialysis

Haemodialysis	Peritoneal dialysis
Efficient; 4 hrs three times per week is usually adequate	Less efficient; four exchanges per day are usually required, each taking 30–60 mins (continuous ambulatory peritoneal dialysis) or 8–10 hrs each night (automated peritoneal dialysis)
2–3 days between treatments	A few hours between treatments
Requires visits to hospital (although home treatment is possible for some patients)	Performed at home
Requires adequate venous circulation for vascular access	Requires an intact peritoneal cavity without major scarring from previous surgery
Careful adherence to diet and fluid restrictions required between treatments	Diet and fluid less restricted
Fluid removal compressed into treatment periods; may cause symptoms and haemodynamic instability	Slow continuous fluid removal, usually asymptomatic
Infections related to vascular access may occur	Peritonitis and catheter-related infections may occur
Patients are usually dependent on others	Patients can take full responsibility for their treatment

Renal replacement therapy

Renal replacement therapy (RRT) may be required on a temporary basis in patients with AKI or on a permanent basis for those with advanced CKD. Since the advent of long-term RRT in the 1960s, the numbers of patients with ESRD who are kept alive by dialysis and transplantation have increased considerably. By the end of 2014, almost 59 000 patients were on RRT in the UK, with a median age of 65 years. After a long period of expansion, the number of patients on dialysis in the UK and USA has begun to stabilise; however, the total number of patients on RRT continues to expand, due to an increasing proportion (53%) of patients with a functional transplant. The remaining patients were on haemodialysis (41%) and peritoneal dialysis (6%).

There are variations in the numbers of patients receiving RRT in different countries because of differences in the incidence of predisposing disease, as well as differences in medical practice. For example, the incidence rate for RRT in the USA was about three times higher than in the UK (363 versus 115 patients per million population), and the prevalence rate was more than twice as high (2034 versus 913 per million population). Diabetic kidney disease is the most common cause of ESRD in many countries, accounting for 26% of all ESRD in the UK and almost 50% in the USA. The large increase in the prevalence of type 2 diabetes in developing countries is resulting in a predictable rise in cases of ESRD, which is challenging already stretched health-care resources.

Survival on dialysis is strongly influenced by age and presence of complications such as diabetes (Fig. 15.26). For this reason, conservative care rather than RRT may be a more appropriate option for older patients or those with extensive comorbidities Although many young patients without extrarenal disease lead

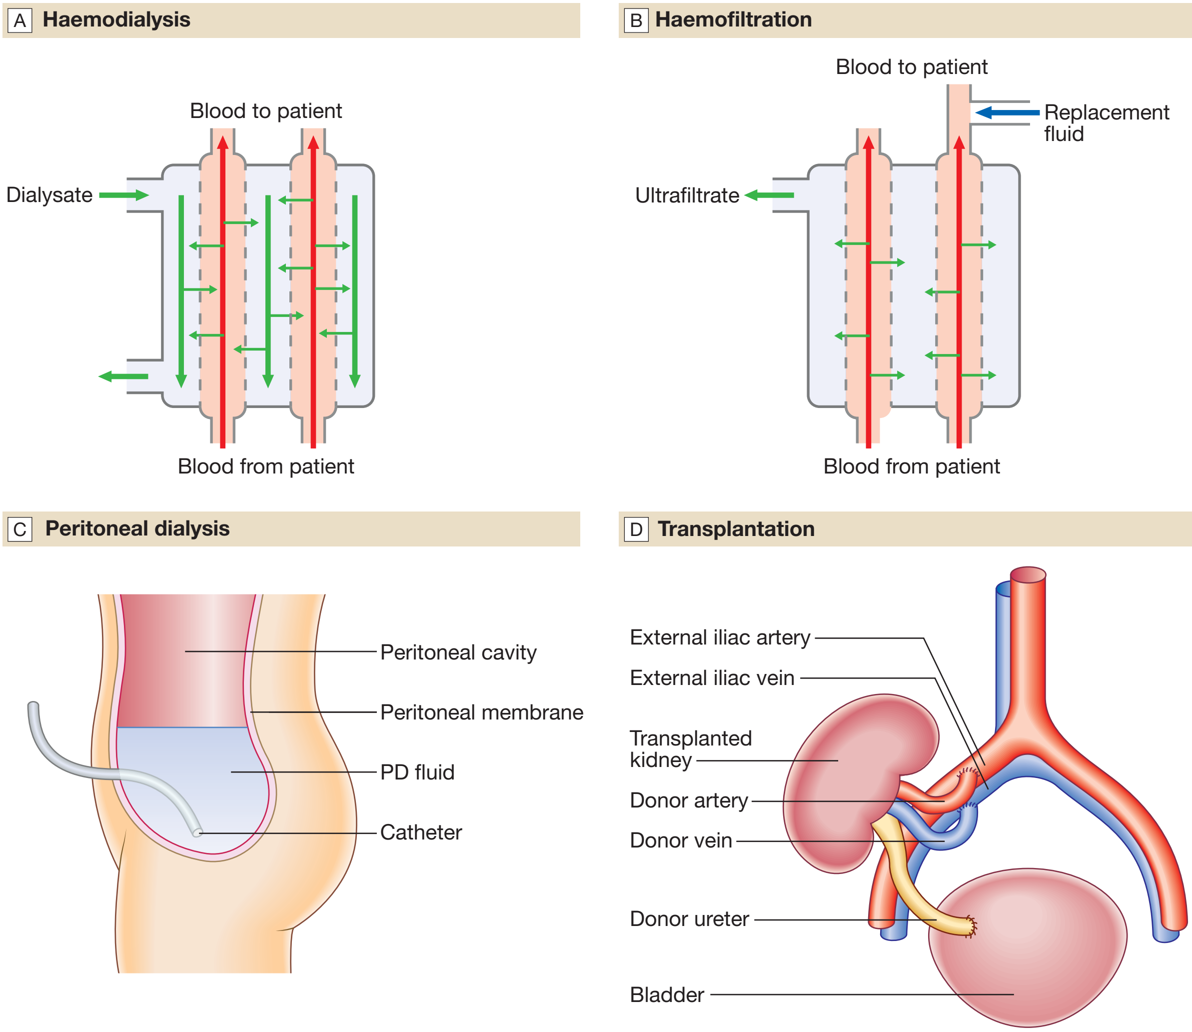

Fig. 15.25 Options for renal replacement therapy. A In haemodialysis, there is diffusion of solutes from blood to dialysate across a semipermeable membrane down a concentration gradient. B In haemofiltration, both water and solutes are filtered across a porous semipermeable membrane by a pressure gradient. Replacement fluid is added to the filtered blood before it is returned to the patient. C In peritoneal dialysis (PD), fluid is introduced into the abdominal cavity using a catheter. Solutes diffuse from blood across the peritoneal membrane to PD fluid down a concentration gradient, and water diffuses through osmosis (see text for details). D In transplantation, the blood supply of the transplanted kidney is generally anastomosed to the external iliac vessels and the ureter to the bladder. The transplanted kidney replaces all functions of the failed kidney.

normal and active lives on RRT, those aged 30–34 have a mortality rate 25 times higher than that of age-matched controls.

The aim of RRT is to replace the excretory functions of the kidney and to maintain normal electrolyte concentrations and fluid balance. Various options are available, including haemodialysis, haemofiltration, haemodiafiltration, peritoneal dialysis and renal transplantation, and each of these is discussed in more detail below. Indications for starting RRT in both AKI and CKD may be found in Box 15.35.

Conservative treatment

In older patients with multiple comorbidities, conservative treatment of stage 5 CKD, aimed at limiting the adverse symptoms of ESRD without commencing RRT, is increasingly viewed as a positive choice (Box 15.36). Current evidence suggests that survival of these patients without dialysis can be similar or only slightly shorter than that of patients who undergo RRT, but they avoid the hospitalisation and interventions associated with dialysis. Patients are offered full medical, psychological and social support to optimise and sustain their existing renal function and to treat complications, such as anaemia, for as long as possible, with appropriate palliative care in the terminal phase of their disease. Many of these patients enjoy a good quality of life for several years. When quality of life on dialysis is poor, it is appropriate to consider discontinuing it, following discussion with the patient and family, and to offer palliative care.

Haemodialysis

Haemodialysis is the most common form of RRT in ESRD and is also used in AKI. Haemodialysis involves gaining access to the circulation, either through a central venous catheter or an arteriovenous fistula or graft. The patient's blood is pumped through a haemodialyser, which allows bidirectional diffusion of

15.35 Indications for dialysis with examples for AKI and CKD

Indication*	Acute examples	Chronic examples
Fluid overload	Acute pulmonary oedema	Intractable dependent oedema resistant to diuretics Pulmonary oedema Severe hypertension
Hyperkalaemia	High potassium (generally >6.5 mmol/L) with ECG changes (especially broad QRS)	Potassium resistant to dietary control and medical intervention
Uraemia	Pericarditis Encephalopathy	Uraemic syndrome including anorexia, nausea, lethargy etc. (generally not until eGFR <10 mL/min/1.73 m^2)
Metabolic acidosis	Severe acidosis (H^+ >79 nmol/L; pH <7.1)	Chronic acidosis resistant to bicarbonate therapy
Other (often relative indications)	Bleeding diathesis considered due to uraemia-induced platelet dysfunction	Intractable anaemia despite erythropoietin and iron Hyperphosphataemia despite binders

*The presence of anuria in AKI will modify the above indications, as these complications will not resolve if the patient is persistently anuric. Most indications to commence chronic dialysis are relative indications; a holistic approach is taken to making this decision.
(ECG = electrocardiogram; eGFR = estimated glomerular filtration rate)

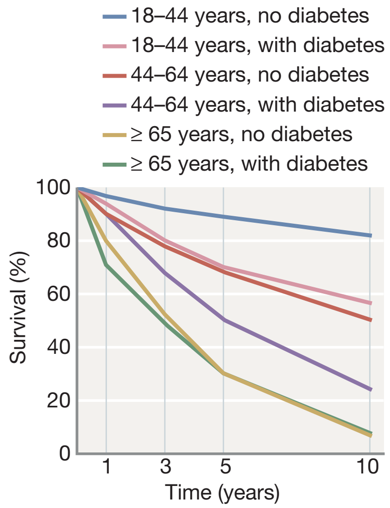

Fig. 15.26 **Percentage survival after commencing renal replacement therapy according to age group and presence of diabetes.**

solutes between blood and the dialysate across a semipermeable membrane down a concentration gradient (Fig. 15.25A). The composition of the dialysate can be varied to achieve the desired gradient, and fluid can be removed by applying negative pressure to the dialysate side.

Haemodialysis in AKI

Haemodialysis offers the best rate of small solute clearance in AKI, compared with other techniques such as haemofiltration, but should be started gradually because of the risk of delirium and convulsions due to cerebral oedema (dialysis disequilibrium). Typically, 1–2 hours of dialysis is prescribed initially but, subsequently, patients with AKI who are haemodynamically stable can be treated by 4–5 hours of haemodialysis on alternate days, or 2–3 hours every day. During dialysis, it is standard practice to anticoagulate patients with heparin but the dose may be reduced if there is a bleeding risk. Epoprostenol can be used as an alternative but carries a risk of hypotension. In patients undergoing short treatments and in those with abnormal clotting, it may be possible to avoid anticoagulation altogether.

15.36 Renal replacement therapy in old age

- **Quality of life**: age itself is not a barrier to good quality of life on RRT.
- **Coexisting cardiovascular disease**: older people are more sensitive to fluid balance changes, predisposing to hypotension during dialysis with rebound hypertension between dialysis sessions. A failing heart cannot cope with fluid overload, and pulmonary oedema develops easily.
- **Provision of treatment**: often only hospital-provided haemodialysis is suitable and older patients require more medical and nursing time.
- **Survival on dialysis**: difficult to predict for an individual patient, but old age plus substantial comorbidity are associated with poor median survival. Similar survival may be achieved through conservative care, without the complications associated with dialysis.
- **Withdrawal from dialysis**: may be appropriate whenever quality of life deteriorates irreversibly, usually in the context of severe comorbidity.
- **Transplantation**: relative risks of surgery and immunosuppression exclude most older people from transplantation.
- **Conservative therapy**: without dialysis but with adequate support. This is an appropriate option for patients at high risk of complications from dialysis, who have a limited prognosis and little hope of functional recovery.

In AKI, dialysis is performed through a large-bore, dual-lumen catheter inserted into the femoral or internal jugular vein (Fig. 15.27A). Subclavian lines are avoided where possible, largely due to bleeding risk. Also, thromboses or stenoses here will compromise the ability to form a functioning fistula in the arm if the patient fails to recover renal function and needs chronic dialysis.

Haemodialysis in CKD

In CKD, vascular access for haemodialysis is gained by formation of an arteriovenous fistula (AVF), usually in the forearm, up to a year before dialysis is contemplated (Fig. 15.27B). After 4–6 weeks, increased pressure transmitted from the artery to the vein leading from the fistula causes distension and thickening of the vessel wall (arterialisation). Large-bore needles can then be

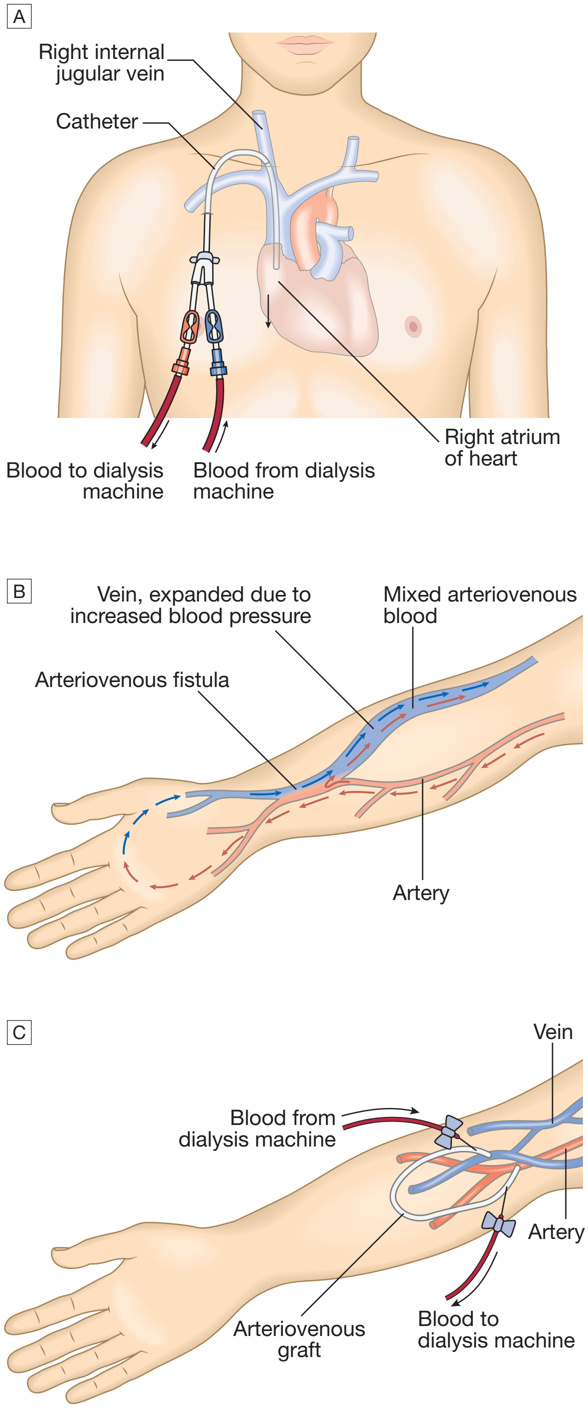

Fig. 15.27 Haemodialysis access. **A** A tunnelled cuffed dialysis catheter. **B** An arteriovenous fistula. **C** An arteriovenous graft.

inserted into the vein to provide access for each haemodialysis treatment.

Preservation of arm veins is thus very important in patients with progressive renal disease who may require haemodialysis in the future. If creation of an AVF is not possible, synthetic polytetrafluoroethylene (PTFE) grafts may be fashioned between an artery and a vein, or central venous catheters may be used for short-term access (Fig. 15.27C). These are tunnelled under the skin to reduce infection risk. All patients must be screened in advance for hepatitis B, hepatitis C and HIV, and vaccinated against hepatitis B if they are not immune. All dialysis units should have segregation facilities for hepatitis B-positive patients, given its easy transmissibility. Patients with hepatitis C and HIV are less infectious and can be treated satisfactorily using machine segregation and standard infection control measures.

Haemodialysis is usually carried out for 3–5 hours three times weekly, either at home or in an outpatient dialysis unit. The intensity and frequency of dialysis should be adjusted to achieve a reduction in urea during dialysis (urea reduction ratio) of over 65%; below this level there is an associated increase in mortality. Most patients notice an improvement in symptoms during the first 6 weeks of treatment. The intensity of dialysis can be increased by:

- escalating the number of standard sessions to four or more per week
- performing short, frequent dialysis sessions of 2–3 hours 5–7 times per week
- performing nocturnal haemodialysis, when low blood-pump speeds and single-needle dialysis are used for approximately 8 hours overnight 5–6 times per week.

More frequent dialysis and nocturnal dialysis can achieve better fluid balance and phosphate control, improve left ventricular mass and possibly improve mortality, although the latter has not yet been robustly demonstrated. Box 15.37 summarises some of the problems related to haemodialysis.

15

Haemofiltration

This technique is principally used in the treatment of AKI as CRRT (Box 15.38). Large volumes of water are filtered from blood across a porous semipermeable membrane under a pressure gradient. Solutes are removed via ‘solvent drag’. Replacement fluid of a suitable electrolyte composition is added to the blood after it exits the haemofilter. If removal of fluid is required, then less fluid is added back than is removed (see Fig. 15.25B). Haemofiltration may be either intermittent or continuous, and typically 1–2 L of filtrate is replaced per hour (equivalent to a GFR of 15–30 mL/min/1.73 m^2); higher rates of filtration may be of benefit in patients with sepsis and multi-organ failure. In continuous arteriovenous haemofiltration (CAVH), the extracorporeal blood circuit is driven by the arteriovenous pressure difference, but poor filtration rates and clotting of the filter are common and this treatment has fallen out of favour. Continuous venovenous haemofiltration (CVVH) is pump-driven, providing a reliable extracorporeal circulation. Issues concerning anticoagulation are similar to those for haemodialysis, but may be more problematic because longer or continuous anticoagulation is necessary.

Haemodiafiltration

This technique combines haemodialysis with approximately 20–30 L of ultrafiltration (with replacement of filtrate) over a 3–5-hour treatment. It uses a large-pore membrane and combines the improved clearance of medium-sized molecules observed in haemofiltration with the higher small-solute clearance of haemodialysis. It is sometimes used in the treatment of AKI, often as continuous therapy (Box 15.38). It is increasingly favoured in the treatment of CKD but is more expensive than haemodialysis and the long-term benefits are not yet established.

15.37 Problems with haemodialysis

Problem	Clinical features	Cause	Treatment
During treatments			
Hypotension	Sudden ↓BP; often leg cramps; sometimes chest pain	Fluid removal and hypovolaemia	Saline infusion; exclude cardiac ischaemia; quinine may help cramp
Cardiac arrhythmias	Hypotension; sometimes chest pain	Potassium and acid–base shifts	Check K^+ and arterial blood gases; review dialysis prescription; stop dialysis
Haemorrhage	Blood loss (overt or occult); hypotension	Anticoagulation Venous needle disconnection	Stop dialysis; seek source; consider heparin-free treatment
Air embolism	Circulatory collapse; cardiac arrest	Disconnected or faulty lines and equipment malfunction	Stop dialysis
Dialyser hypersensitivity	Acute circulatory collapse	Allergic reaction to dialysis membrane or sterilisant	Stop dialysis; change to different artificial kidney
Between treatments			
Pulmonary oedema	Breathlessness	Fluid overload	Ultrafiltration ± dialysis
Systemic sepsis	Rigors; fever; ↓BP	Usually involves vascular access devices (catheter or fistula)	Blood cultures; antibiotics

(BP = blood pressure)

15.38 Types of continuous renal replacement therapy (CRRT) used in AKI management*

- CVVH: continuous venovenous haemofiltration
- CVVHD: continuous venovenous haemodialysis
- CVVHDF: continuous venovenous haemodiafiltration

*Most CRRT machines may perform all of these treatments. Continuous arteriovenous treatments (i.e. continuous arteriovenous haemofiltration) have fallen out of favour.

Peritoneal dialysis

Peritoneal dialysis is principally used in the treatment of CKD, though it may occasionally be employed in AKI. It requires the insertion of a permanent Silastic catheter into the peritoneal cavity (see Fig. 15.25C). Two types are in common use. In continuous ambulatory peritoneal dialysis (CAPD), about 2 L of sterile, isotonic dialysis fluid are introduced and left in place for approximately 4–6 hours. Metabolic waste products diffuse from peritoneal capillaries into the dialysis fluid down a concentration gradient. The fluid is then drained and fresh dialysis fluid introduced, in a continuous four-times-daily cycle. The inflow fluid is rendered hyperosmolar by the addition of glucose or glucose polymer; this results in net removal of fluid from the patient during each cycle, due to diffusion of water from the blood through the peritoneal membrane down an osmotic gradient (ultrafiltration). The patient is mobile and able to undertake normal daily activities. Automated peritoneal dialysis (APD) is similar to CAPD but uses a mechanical device to perform the fluid exchanges during the night, leaving the patient free, or with only a single exchange to perform, during the day.

CAPD is particularly useful in children, as a first treatment in adults with residual renal function, and as a treatment for elderly patients with cardiovascular instability. The long-term use of peritoneal dialysis may be limited by episodes of bacterial peritonitis and damage to the peritoneal membrane, including encapsulating peritoneal sclerosis, but some patients have been treated successfully for more than 10 years. Box 15.39 summarises some of the problems related to CAPD treatment.

Renal transplantation

Renal transplantation offers the best chance of long-term survival in ESRD and is the most cost-effective treatment. All patients with ESRD should be considered for transplantation but many are not suitable due to a combination of comorbidity and advanced age (although no absolute age limit applies). Active malignancy, vasculitis, cardiovascular disease and a high risk of recurrence of renal disease (generally glomerulonephritides) are common contraindications to transplantation.

Kidney grafts may be taken from a deceased donor in the UK after brain death (40%) or circulatory death (24%), or from a living donor (36%). As described on page 88, matching of a donor to a specific recipient is strongly influenced by immunological factors, since graft rejection is the major cause of transplant failure. Compatibility of ABO blood group between donor and recipient is usually required and the degree of matching for major histocompatibility (MHC) antigens, particularly human leucocyte antigen DR (HLA-DR), influences the incidence of rejection. Immediately prior to transplantation, cross-matching should be performed for anti-HLA antibodies (traditionally mixing of recipient serum with donor lymphocytes) (p. 88). Positive tests predict early rejection and worse graft survival. Although some ABO- and HLA-incompatible transplants are now possible, this involves appropriate preparation with pre-transplant plasma exchange and/or immunosuppression, so that recipient antibodies to the donor's tissue are reduced to acceptably low levels. This option is generally only available for living donor transplants because of the preparation required. Paired exchanges, in which a donor–recipient pair who are incompatible, either in blood group or HLA, are computer-matched with another pair to overcome the mismatch, are also used to help increase the number of successful transplants that can be performed.

During the transplant operation, the kidney is placed in the pelvis; the donor vessels are usually anastomosed to the recipient's external iliac artery and vein, and the donor ureter to the bladder (see Fig. 15.25D). The native kidneys are usually left in place but may be removed pre-transplant if they are a source of repeated sepsis or to make room for a transplant in patients with very large kidneys due to adult polycystic kidney disease.

15.39 Problems with continuous ambulatory peritoneal dialysis

Problem	Clinical features	Cause	Treatment
Peritonitis	Cloudy drainage fluid; abdominal pain and systemic sepsis are variable	Usually entry of skin contaminants via catheter; bowel organisms less common	Culture of peritoneal dialysis fluid Intraperitoneal antibiotics, tobramycin, vancomycin Catheter removal sometimes required
Catheter exit site infection	Erythema and pus around exit site	Usually skin organisms	Antibiotics; sometimes surgical drainage
Ultrafiltration failure	Fluid overload	Damage to peritoneal membrane, leading to rapid transport of glucose and loss of osmotic gradient	Replacement of glucose with synthetic, poorly absorbed polymers for some exchanges (icodextrin)
Peritoneal membrane failure	Inadequate clearance of urea etc.	Scarring/damage to peritoneal membrane	Increase in exchange volumes; consideration of automated peritoneal dialysis or switch to haemodialysis
Sclerosing peritonitis	Intermittent bowel obstruction Malnutrition	Unknown; typically occurs after many years	Switch to haemodialysis (may still progress) Surgery and tamoxifen may be used

15.40 Common causes of renal allograft dysfunction

Time post transplant	Cause	Risk factors
Hours to days	Renal artery/vein thrombosis	Technically difficult surgery Thrombophilia/SLE
	Ureteric leak	Small bladder/anuria pre-transplant
	Delayed graft function (i.e. transplant does not start working immediately)	Prolonged cold ischaemia time* Donation after circulatory death Older, hypertensive donor with stroke as cause of death, high tacrolimus level
	Hyperacute rejection	Pre-formed anti-HLA antibodies HLA mismatch Previous transplant
Weeks	Acute rejection (especially <3 months; can occur later with non-adherence/insufficient immunosuppression)	Pre-formed anti-HLA antibodies HLA mismatch Previous transplant
Months	BK virus nephropathy	Intensive immunosuppression Ureteric stent use
	Renal artery stenosis	Donor disease Injury at organ retrieval
Years	Chronic allograft injury (often antibody-mediated)	Previous acute rejections Non-adherence/insufficient immunosuppression
Any time	Tacrolimus/ciclosporin toxicity	High doses/serum levels Concurrent use of drugs that inhibit cytochrome P450 system
	Sepsis (opportunistic and conventional)	
	Recurrence of disease: Early (FSGS/MCGN) Later (IgA nephropathy/membranous glomerulonephritis)	 Primary FSGS and MCGN Previous transplant recurrence

*Time from organ retrieval in the donor, with cold perfusion occurring ex vivo, until implantation into the recipient. (FSGS = focal segmental glomerulosclerosis; HLA = human leucocyte antigen; IgA = immunoglobulin A; MCGN = mesangiocapillary glomerulonephritis; SLE = systemic lupus erythematosus)

All transplant patients require regular life-long follow-up to monitor renal function and complications of immunosuppression. Allograft dysfunction is often asymptomatic and picked up during routine surveillance blood tests. The common causes at different time points post transplant are summarised in Box 15.40. Immunosuppressive therapy (see Box 4.26, p. 89) is required to prevent rejection and is more intensive in the early post-transplantation period, when rejection risk is highest. A common regimen is triple therapy with prednisolone; ciclosporin or tacrolimus; and azathioprine or mycophenolate mofetil. Sirolimus is an alternative that can be introduced later but is generally not used initially due to impaired wound healing. Antibodies to deplete or modulate specific lymphocyte populations are increasingly used for induction and for treatment of glucocorticoid-resistant acute rejection. Basiliximab, an interleukin (IL)-2 receptor antagonist, is frequently used at induction to lower rates of rejection. Acute cellular rejection is usually treated, in the first instance, by short courses of high-dose glucocorticoids, such as intravenous methylprednisolone on three consecutive days. Anti-lymphocyte preparations (e.g. anti-thymocyte globulin, ATG) are used for glucocorticoid-resistant rejection. Antibody-mediated rejection is more difficult to treat and usually requires plasma exchange

and intravenous immunoglobulin (p. 89). Complications of immunosuppression include infections and malignancy (p. 89). Approximately 50% of white patients develop skin malignancy by 15 years after transplantation.

The prognosis after kidney transplantation is good. Recent UK statistics for transplants from cadaver donors indicate 96% patient survival and 93% graft survival at 1 year, and 88% patient survival and 84% graft survival at 5 years. Even better figures are obtained with living donor transplantation (91% graft survival at 5 years).

Renal disease in pregnancy

Pregnancy has important physiological effects on the renal system. Some diseases are more common in pregnancy (Box 15.41), the manifestations of others are modified during pregnancy, and a few diseases, such as pre-eclampsia (see Box 30.8, p. 1276), are unique to pregnancy. These are discussed in detail in Chapter 30.

15.41 Renal diseases in pregnancy

- **Eclampsia**: severe hypertension, encephalopathy and fits
- **Disseminated intravascular coagulation**
- **Thrombotic microangiopathy**: may also occur post-partum (post-partum thrombotic thrombocytopenic purpura/haemolytic uraemic syndrome)
- **Acute fatty liver of pregnancy**
- **'HELLP' syndrome**: haemolysis, elevated liver enzymes, low platelets (thrombotic microangiopathy with abnormal liver function)

Renal disease in adolescence

Many causes of renal failure present during infancy or childhood, such as congenital urological malformations and inherited disorders like cystinosis and autosomal recessive polycystic kidney disease. The consequences continue throughout the patient's life and the situation often arises whereby patients transition from paediatric to adult nephrology services. Some of the issues and challenges surrounding this transition are summarised in Box 15.42.

15.42 Kidney disease in adolescence

- **Adherence**: young adults moving from parental supervision may become disengaged. There may also be reduced adherence to prophylactic and therapeutic treatment.
- **Adverse events**: there is an increased risk of transplant loss and other adverse events in young adults on renal replacement therapy.
- **Management**: joint transition clinics should be established with the paediatric team to facilitate transfer to adult specialist clinics.

Drugs and the kidney

Drug-induced renal disease

The kidney is susceptible to damage by drugs because it is the route of excretion of many water-soluble compounds, including drugs and their metabolites. Some may reach high concentrations in the renal cortex as a result of proximal tubular transport mechanisms. Others are concentrated in the medulla by the operation of the countercurrent system. The same applies to certain toxins.

Toxic renal damage may occur by a variety of mechanisms (Box 15.43). Very commonly, drugs contribute to the development of acute tubular necrosis as one of multiple insults. Numerically, reactions to NSAIDs and ACE inhibitors are the most important. Haemodynamic renal impairment, acute tubular necrosis and allergic reactions are usually reversible if recognised early enough. Other types, however, especially those associated with extensive fibrosis, are less likely to be reversible.

Non-steroidal anti-inflammatory drugs

Impairment of renal function may develop in patients on NSAIDs, since prostaglandins play an important role in regulating renal blood flow by vasodilating afferent arterioles (see Fig. 15.19, p. 413). This is particularly likely in patients with other disorders, such as volume depletion, heart failure, cirrhosis, sepsis and pre-existing renal impairment. In addition, idiosyncratic immune reactions may occur, causing minimal change nephrotic syndrome, membranous nephropathy (p. 400) and acute interstitial nephritis (p. 402). Analgesic nephropathy (p. 403) is now a rare complication of long-term use.

ACE inhibitors

These abolish the compensatory angiotensin II-mediated vasoconstriction of the glomerular efferent arteriole that takes place in order to maintain glomerular perfusion pressure distal to a renal artery stenosis and in renal hypoperfusion (see Figs 15.1 and 15.19, pp. 385 and 413). Monitoring of renal function before and after initiation of therapy is essential and an expected rise in creatinine of about 20% is frequently observed.

Prescribing in renal disease

Many drugs and drug metabolites are excreted by the kidney and so the presence of renal impairment alters the required dose and frequency (p. 31).

Infections of the urinary tract

In health, bacterial colonisation is confined to the lower end of the urethra and the remainder of the urinary tract is sterile (see Ch. 6). The urinary tract can become infected with various bacteria but the most common is *E. coli* derived from the gastrointestinal tract. The most common presenting problem is cystitis with urethritis (generally referred to as urinary tract infection).

Urinary tract infection

Urinary tract infection (UTI) is the term used to describe acute urethritis and cystitis caused by a microorganism. It is a common disorder, accounting for 1–3% of consultations in general medical practice. The prevalence of UTI in women is about 3% at the age of 20, increasing by about 1% in each subsequent decade. In males, UTI is uncommon, except in the first year of life and in men over 60, when it may complicate bladder outflow obstruction.

15.43 Mechanisms and examples of drug-induced renal disease/dysfunction

Mechanism	Drug or toxin	Comments
Haemodynamic	NSAIDs	Reduce renal blood flow due to inhibition of prostaglandin synthesis causing afferent arteriolar vasoconstriction
	ACE inhibitors	Reduce efferent glomerular arteriolar tone, so especially problematic in the presence of renal artery stenosis and other causes of renal hypoperfusion (e.g. NSAIDs)
	Radiographic contrast media	Multifactorial aetiology may include intense vasoconstriction
Acute tubular necrosis	Aminoglycosides, amphotericin	In most examples there is evidence of direct tubular toxicity but haemodynamic and other factors probably contribute
	Paracetamol overdose	May occur with or without serious hepatotoxicity
	Radiographic contrast media	Directly toxic to proximal tubular cells
Loss of tubular/collecting duct function	Lithium	Dose-related, partially reversible loss of concentrating ability
	Cisplatin	Occurs at lower exposures than cause acute tubular necrosis
	Aminoglycosides, amphotericin	
Glomerulonephritis (immune-mediated)	Penicillamine, gold	Membranous nephropathy
	Penicillamine, propylthiouracil, hydralazine	Crescentic or focal necrotising glomerulonephritis in association with ANCA and systemic small-vessel vasculitis
	NSAIDs	Minimal change nephropathy, membranous nephropathy
Interstitial nephritis (immune-mediated)	NSAIDs, penicillins, proton pump inhibitors, many others	Acute interstitial nephritis
Interstitial nephritis (toxicity)	Lithium	As a consequence of acute toxicity
		Chronic interstitial nephritis
	Ciclosporin, tacrolimus	
Interstitial nephritis (with papillary necrosis)	Various NSAIDs (p. 403)	Ischaemic damage secondary to NSAID effects on renal blood flow
Tubular obstruction (crystal formation)	Aciclovir	Crystals of the drug form in tubules
		Aciclovir is now more common than the original example of sulphonamides
	Chemotherapy	Uric acid crystals form as a consequence of tumour lysis (typically, a first-dose effect in haematological malignancy)
Nephrocalcinosis	Oral sodium phosphate-containing bowel cleansing agents	Precipitation of calcium phosphate occurring in 1–4% and exacerbated by volume depletion
		Usually mild but damage can be irreversible
Retroperitoneal fibrosis	Ergolinic dopamine agonists (cabergoline), methysergide*, practolol*	Idiopathic retroperitoneal fibrosis is more common (p. 434)

*These drugs are no longer in use in the UK.
(ACE = angiotensin-converting enzyme; ANCA = antineutrophil cytoplasmic antibody; NSAIDs = non-steroidal anti-inflammatory drugs)

Pathophysiology

Urine is an excellent culture medium for bacteria; in addition, the urothelium of susceptible persons may have more receptors, to which virulent strains of *E. coli* become adherent. In women, the ascent of organisms into the bladder is easier than in men; the urethra is shorter and the absence of bactericidal prostatic secretions may be relevant. Sexual intercourse may cause minor urethral trauma and transfer bacteria from the perineum into the bladder. Instrumentation of the bladder may also introduce organisms. Multiplication of organisms then depends on a number of factors, including the size of the inoculum and virulence of the bacteria. Conditions that predispose to UTI are shown in Box 15.44.

Clinical features

Typical features of cystitis and urethritis include:

- abrupt onset of frequency of micturition and urgency
- burning pain in the urethra during micturition (dysuria)
- suprapubic pain during and after voiding
- intense desire to pass more urine after micturition, due to spasm of the inflamed bladder wall (strangury)
- urine that may appear cloudy and have an unpleasant odour
- non-visible or visible haematuria.

Systemic symptoms are usually slight or absent. However, infection in the lower urinary tract can spread to cause acute pyelonephritis. This is suggested by prominent systemic symptoms with fever, rigors, vomiting, hypotension and loin pain, guarding or tenderness, and may be an indication for hospitalisation. Only about 30% of patients with acute pyelonephritis have associated symptoms of cystitis or urethritis. Prostatitis is suggested by perineal or suprapubic pain, pain on ejaculation and prostatic tenderness on rectal examination.

The differential diagnosis of lower urinary tract symptoms includes urethritis due to sexually transmitted disease, notably chlamydia (p. 340) and urethritis associated with reactive arthritis (p. 1031). Some patients, usually female, have symptoms suggestive of urethritis and cystitis but no bacteria are cultured from the urine (the 'urethral syndrome'). Possible explanations include infection with organisms not readily cultured by ordinary

15.44 Risk factors for urinary tract infection

Bladder outflow obstruction

- Benign prostatic enlargement
- Prostate cancer
- Urethral stricture

Anatomical abnormalities

- Vesico-ureteric reflux
- Uterine prolapse
- Bladder fistula

Neurological problems

- Multiple sclerosis
- Spina bifida
- Diabetic neuropathy

Foreign bodies

- Urethral suprapubic catheter
- Ureteric stent
- Nephrostomy tube
- Urolithiasis

Loss of host defences

- Atrophic urethritis and vaginitis in post-menopausal women
- Diabetes mellitus

15.45 Investigation of patients with urinary tract infection

All patients

- Dipstick* estimation of nitrite, leucocyte esterase and glucose
- Microscopy/cytometry of urine for white blood cells, organisms
- Urine culture

Infants, children, and anyone with fever or complicated infection

- Full blood count; urea, electrolytes, creatinine
- Blood cultures

Pyelonephritis: men; children; women with recurrent infections

- Renal tract ultrasound or CT
- Pelvic examination in women, rectal examination in men

Continuing haematuria or other suspicion of bladder lesion

- Cystoscopy

*May substitute for microscopy and culture in simple uncomplicated infection.

methods (such as *Chlamydia* and certain anaerobes), intermittent or low-count bacteriuria, reaction to toiletries or disinfectants, symptoms related to sexual intercourse, or post-menopausal atrophic vaginitis.

The differential diagnosis of acute pyelonephritis includes pyelonephrosis, acute appendicitis, diverticulitis, cholecystitis, salpingitis, ruptured ovarian cyst or ectopic pregnancy. In pyelonephrosis due to upper urinary tract obstruction, patients may become extremely ill, with fever, leucocytosis and positive blood cultures. With a perinephric abscess, there is marked pain and tenderness, and often bulging of the loin on the affected side. Urinary symptoms may be absent in this situation and urine testing negative, containing neither pus cells nor organisms.

Investigations

An approach to investigation is shown in Box 15.45. In an otherwise healthy woman with a single lower urinary tract infection, urine culture prior to treatment is not mandatory. Investigation is necessary, however, in patients with recurrent infection or after failure of initial treatment, during pregnancy, or in patients susceptible to serious infection, such as the immunocompromised, those with diabetes or an indwelling catheter, and older people (Box 15.46). The diagnosis can be made from the combination

15.46 Urinary infection in old age

- **Prevalence of asymptomatic bacteriuria**: rises with age. Among the most frail in institutional care it rises to 40% in women and 30% in men.
- **Decision to treat**: treating asymptomatic bacteriuria does not improve chronic incontinence or decrease mortality or morbidity from symptomatic urinary infection. It risks adverse effects from the antibiotic and promotion of the emergence of resistant organisms. Bacteriuria should not be treated in the absence of urinary symptoms.
- **Source of infection**: the urinary tract is the most frequent source of bacteraemia in older patients admitted to hospital.
- **Incontinence**: new or increased incontinence is a common presentation of UTI in older women.
- **Treatment**: post-menopausal women with acute lower urinary tract symptoms may require longer than 3 days' therapy.

of typical clinical features and abnormalities on urinalysis. Most urinary pathogens can reduce nitrate to nitrite, and neutrophils and nitrites can usually be detected in symptomatic infections by urine dipstick tests for leucocyte esterase and nitrite, respectively. The absence of both nitrites and leucocyte esterase in the urine makes UTI unlikely. Interpretation of bacterial counts in the urine, and of what is a 'significant' culture result, is based on probabilities. Urine taken by suprapubic aspiration should be sterile, so the presence of any organisms is significant. If the patient has symptoms and there are neutrophils in the urine, a small number of organisms is significant. In asymptomatic patients, more than 10^5 organisms/mL is usually regarded as significant (asymptomatic bacteriuria; see below).

Typical organisms causing UTI in the community include *E. coli* derived from the gastrointestinal tract (about 75% of infections), *Proteus* spp., *Pseudomonas* spp., streptococci and *Staphylococcus epidermidis*. In hospital, *E. coli* still predominates but *Klebsiella* and streptococci are becoming more common. Certain strains of *E. coli* have a particular propensity to invade the urinary tract.

Investigations to detect underlying predisposing factors for UTI are used selectively, most commonly in children, men or patients with recurrent infections (see Box 15.45).

Management

Antibiotics are recommended in all cases of proven UTI (Box 15.47). If urine culture has been performed, treatment may be started while awaiting the result. For infection of the lower urinary tract, treatment for 3 days is the norm and is less likely to induce significant alterations in bowel flora than more prolonged therapy. Trimethoprim or nitrofurantoin is the usual first choice of drug for initial treatment; however, between 10% and 40% of organisms causing UTI are resistant to trimethoprim, the lower rates being seen in community-based practice. Trimethoprim and nitrofurantoin are not recommended if eGFR is <30 mL/min/1.73m^2 due to reduced efficacy/increased risk of toxicity. In addition, trimethoprim may increase serum potassium and creatinine levels and lead to artefactual reductions in eGFR, which resolve once the drug is discontinued. Quinolone antibiotics such as ciprofloxacin and norfloxacin, and cefalexin are also generally effective. Co-amoxiclav and amoxicillin are no longer recommended as blind therapy, as up to 30% of organisms are resistant. They may be used once cultures confirm that the organism is sensitive. Penicillins and cephalosporins are safe to use in pregnancy but trimethoprim, sulphonamides, quinolones and tetracyclines should be avoided.

15.47 Antibiotic regimens for urinary tract infection in adults

Scenario	Drug	Regimen	Duration	Comment
Cystitis				
First choices	Trimethoprim	200 mg twice daily	3 days	7–10 days in men
	Nitrofurantoin	50 mg 4 times daily		
Second choices[1]	Cefalexin	250 mg 4 times daily		
	Ciprofloxacin	250 mg twice daily		
	Pivmecillinam	400 mg 3 times daily		
In pregnancy	Nitrofurantoin	50 mg 4 times daily	7 days	Avoid trimethoprim and quinolones during pregnancy; avoid nitrofurantoin at term
	Cefalexin	250 mg 4 times daily		
Prophylactic therapy				
First choice	Trimethoprim	100 mg at night	Continuous	
Second choice[1]	Nitrofurantoin	50 mg at night		
Pyelonephritis				
First choice	Cefalexin	1 g 4 times daily	14 days	Admit to hospital if no response within 24 hrs
	Ciprofloxacin	500 mg twice daily	7 days	
Second choice	Gentamicin[2]	Adjust dose according to renal function and serum levels	14 days	Switch to appropriate oral agent as soon as possible
	Cefuroxime	750–1500 mg 3 times daily		
Epididymo-orchitis				
First choice	Ciprofloxacin	500 mg twice daily	14 days	Refer young men to genito-urinary department to check for *Neisseria gonorrhoeae*, which requires addition of a single dose of ceftriaxone 500 mg IM
Young men	Doxycycline	100 mg twice daily		
Older men	Ciprofloxacin	500 mg twice daily		
Acute prostatitis				
First choice	Trimethoprim	200 mg twice daily	28 days	
Second choice	Ciprofloxacin	500 mg twice daily		

[1]In all cases, the choice of drug should take locally determined antibiotic resistance patterns into account. [2]See Hartford nomogram (Fig. 6.18, p. 122).
(IM = intramuscular)

In more severe infection, antibiotics should be continued for 7–14 days. Seriously ill patients may require intravenous therapy with gentamicin for a few days (Box 15.47), later switching to an oral agent.

A fluid intake of at least 2 L/day is usually recommended, although this is not based on evidence and may make symptoms of dysuria worse.

Persistent or recurrent UTI

If the causative organism persists on repeat culture despite treatment, or if there is reinfection with any organism after an interval, then an underlying cause is more likely to be present (see Box 15.44) and more detailed investigation is justified (see Box 15.45). In women, recurrent infections are common and investigation is justified only if infections are frequent (three or more per year) or unusually severe. Recurrent UTI, particularly in the presence of an underlying cause, may result in permanent renal damage, whereas uncomplicated infections rarely (if ever) do so (see chronic reflux nephropathy, p. 430).

If an underlying cause cannot be treated, suppressive antibiotic therapy (see Box 15.47) can be used to prevent recurrence and reduce the risk of sepsis and renal damage. Urine should be cultured at regular intervals; a regimen of two or three antibiotics in sequence, rotating every 6 months, is often used in an attempt to reduce the emergence of resistant organisms. Other simple measures may help to prevent recurrence (Box 15.48). Trimethoprim or nitrofurantion is recommended for prophylaxis. Alternative antibiotics include cefalexin, co-amoxiclav and ciprofloxacin, but these should be avoided if possible because of adverse effects and the generation of resistance.

15.48 Prophylactic measures to be adopted by women with recurrent urinary infections

- Fluid intake of at least 2 L/day
- Regular complete emptying of bladder
- Good personal hygiene
- Emptying of bladder before and after sexual intercourse
- Cranberry juice/tablets may be effective

Asymptomatic bacteriuria
